where Z is the atomic number of the atom, r and θ are the coordinates of the separated electron, and $\mathbf{r}_j$ represents the position of the jth atomic electron. The absence of an $L=0$ term results from the assumed neutrality of the atom. From this, the limiting form Eq. (1.1) of the effective potential seen by the scattered electron has been derived by a number of authors.[13]

The simplest way to derive an effective potential is to treat the asymptotic potential (4.1) as a perturbation of the atomic ground state and to find its expectation value in first- and second-order perturbation theory,[14] treating r as a (large) parameter. If we assume the atom to be and to remain in a particular state of magnetic quantum number M, the first-order result is

$$V_{00} \sim -\frac{e}{2}\sum_{L=1}^{\infty} \frac{Q_L(M)P_L(\cos\theta)}{r^{L+1}}, \quad (4.2)$$

where the $Q_L(M)$ are the permanent electric multipole moments of the atom in its ground state with quantum numbers J and M. Only those moments will exist for which $L \leq 2J$, so that for example a spherically symmetric atom will have no permanent moments. Further, since all atoms in their ground states have a well-defined parity,[15] all the odd moments vanish so that the leading term in (4.2) is that for $L=2$, the quadrupole term. This immediately gives us the first term of Eq. (1.1). The M dependence of the quadrupole

moment is given by[16]

$$Q(M)=\frac{3M^2-J(J+1)}{J(2J-1)}Q, \tag{4.3}$$

where the number Q is defined[17] as the expectation value of the quadrupole operator for the state $M=J$,

$$\tfrac{1}{2}Q=e\int d\tau \sum_{j=1}^{Z} r_j^2 P_2(\cos\theta_j)\,|\psi_0|^2_{M=J} \tag{4.4}$$

with the integral extending over all the coordinates of the atom (a sum over spins is implied). Equation (4.3) has as a consequence that the average of $Q(M)$ over M vanishes

$$Q_{\rm av}=0. \tag{4.5}$$

Unfortunately the physical situation is somewhat more complicated. Due to the degeneracy of states with the same magnetic quantum number M, *transitions* between these states may be caused by electrons with vanishingly small energy, so that the first-order potential should really be written as a matrix of dimension $2J+1$. What has been done in (4.2) is to neglect all but "elastic" collisions, i.e., those in which M remains constant. This neglect is not justified, and an attempt is made below to remedy it.

Returning to Eq. (4.1) and evaluating it now in second-order perturbation theory gives

$$V^{(2)}\sim -e^2/(2r^4)[\alpha+\alpha'(M)P_2(\cos\theta)]+O(r^{-6}), \tag{4.6}$$

where α is the (average) electric polarizability of the atom and α' (which exists only for nonsymmetric atoms) has the property that, like the quadrupole moment, its average over M vanishes. In evaluating this result, the variable r is treated as a constant parameter. This is known as the adiabatic approximation. However, it has been shown[18] that the result gives the correct asymptotic behavior of the effective potential, in other words that the adiabatic approximation is correct asymptotically. This gives rise to the second term in Eq. (1.1).

A more consistent and satisfying way of arriving at the long-range electron-atom potential is to start from the exact one-body optical potential equation[19] for an electron scattered from an atom in its ground state

$$[\nabla^2+k^2-(2m/\hbar^2)V_{\rm opt}]u(\mathbf{r})=0, \tag{4.7}$$

where

$$V_{\rm opt}(\mathbf{r})=V_{00}+\mathbf{V}(E-\mathbf{H})^{-1}\mathbf{V}^{+}. \tag{4.8}$$

V_{00} is the expectation value of the full electron-atom potential averaged over the target ground state. It corresponds exactly with the first-order perturbation theory result whose asymptotic form is given in Eq. (4.2) and the same comments made there again apply. In the second term, the vector $\mathbf{V}$ has as its components the matrix elements V_{0i} connecting the target ground state with each of its excited states. Similarly the matrix $\mathbf{H}$ has components H_{ij} connecting any 2 excited states of the atom (but with no ground-state components). The Pauli principle may be considered to be implicit in (4.8) or else exchange terms may be added explicitly. In either case it may easily be shown[20] that its effects fall off exponentially as $r\to\infty$ and so will not affect the asymptotic behavior of $V_{\rm opt}$.

Now if one lets $r\to\infty$ in Eq. (4.8) using (4.1) for the potential one obtains in a straight forward manner Eq. (4.6) as the limiting form for the second term but with error this time[20] of $O(r^{-5}d/dr)$. And so the asymptotic form of the optical potential (with the restriction mentioned below to "elastic," i.e., M conserving, collisions) is

$$\frac{2m}{\hbar^2}V_{\rm opt}\sim\frac{Q(M)}{ea_0}\frac{P_2(\cos\theta)}{r^3}-\frac{1}{a_0r^4}[\alpha+\alpha'(M)P_2(\cos\theta)]+O\left(\frac{1}{r^5}\right), \tag{4.9}$$

where $a_0=\hbar^2/me^2$ is the electron Bohr radius. Comparing Eq. (4.9) with Eq. (1.1) we see that in applying the formulas of Sec. 3 to this case we should set

$$q=Q(M)/ea_0, \quad p=\alpha/a_0, \quad p'=\alpha'(M)/a_0. \tag{4.10}$$

The foregoing, however is not really adequate to describe the scattering of electrons by atoms, since transitions of the atom from one magnetic state to another have not been taken into account.

Allowance for Transitions Between Magnetic States

If the target atom is initially in a magnetic state M relative to some z axis, and an electron beam is incident with momentum $\mathbf{k}_i$, the asymptotic form of the wave function may be written

$$\psi\sim\psi_M(\mathbf{r}_j)e^{i\mathbf{k}_i\cdot\mathbf{r}}+\sum_{M'=-J}^{J} f_{M,M'}(\theta,\phi)\psi_{M'}(\mathbf{r}_j)e^{ikr}/r, \tag{4.11}$$

where $\psi_{M'}(\mathbf{r}_j)$ are the ground-state wave functions for

Digitized by Arya Samaj Foundation Chennai and eGangotri

the atom in the magnetic state M'. The amplitude $f(\theta,\phi)$ is now a matrix of dimension $2J+1$, connecting these states. Correspondingly the potential V_{00} of Eq. (4.8) is likewise a matrix, as mentioned earlier. If the matrix elements of the potential V_{00} connecting the states M and M' are labeled $V_{00}(M,M')$, where V is still given by Eq. (4.1) the asymptotic form of the potential matrix elements is given by

$$(2m/\hbar^2)V_{00}(M,M')\sim r^{-3}(4\pi/5)^{1/2}Y_{2,M-M'}(\theta,\phi)\times(Q_{M,M'}/ea_0)+O(r^{-5}), \quad (4.12)$$

where

$$\tfrac{1}{2}Q_{M,M'}=e(4\pi/5)^{1/2}\int d\tau\psi_{M'}{}^*\times\sum_{j=1}^{Z} r_j^2 Y_{2,M-M'}{}^*(\theta_j,\phi_j)\psi_M. \quad (4.13)$$

The $Q_{M,M'}$ are related to the ordinary quadrupole moment, $Q=Q_{J,J}$ by the relation

$$Q_{M,M'}=\left[\frac{(J+1)(2J+3)}{J(2J-1)}\right]^{1/2}\times C(J,2,J;M',M-M')Q, \quad (4.14)$$

where Q is the quadrupole moment defined by Eq. (4.4), and C is the Clebsch Gordon coefficient.[21] The $Q(M)$ defined before are simply the diagonal elements, Q_{MM}.

The second term of the optical potential, Eq. (4.8), is still $O(r^{-4})$, so that Eq. (4.12) represents the leading term in the optical potential matrix as $r\to\infty$. If the amplitudes $f_{M,M'}$ are now written as functions of r as was done in Sec. 3 for f, they satisfy coupled equations. These equations may be derived from the coupled optical potential equations for the coefficients of the various ψ_M, whose asymptotic forms appear in Eq. (4.11), exactly as was done for the amplitude f in Ref. 8. The equations are

$$f_{M,M';r}(\mathbf{k}_i\to\mathbf{k}_f)=-(1/4\pi)\int_0^r r'^2dr'\int d\Omega'\times\sum_{M''}\sum_{M'''}\psi_{M''}{}^{M}(\mathbf{r}';\mathbf{k}_i\to\mathbf{k}')U_{M'',M'''}(\mathbf{r}')\times\psi_{M'''}{}^{M'}(\mathbf{r}';-\mathbf{k}_f\to\mathbf{k}'),$$

where

$$\psi_{M''}{}^{M}(\mathbf{r}';\mathbf{k}_j\to\mathbf{k}')=\delta_{M,M''}e^{i\mathbf{k}_j\cdot\mathbf{r}'}+f_{M,M'';r'}(\mathbf{k}_j\to\mathbf{k}')e^{ikr'}/r'.$$

The vector $\mathbf{k}'$ again has the angles Ω' of integration. The sums are over all magnetic substates, and the asymptotic form of the $U_{M'',M'''}$ are given by Eq. (4.12) plus terms of $O(r^{-4})$. If we are satisfied with terms in the amplitude of $O(1)$, we see that these were given in Sec. 3 by the Born term in Eq. (3.3), together with the r^{-3} term in the potential, apart from contributions from the short-range part of the potential. The same will be true in the present case. The Born term for the $f_{M,M'}$, with the potential given by Eq. (4.12), is

$$f_{M,M'}(\mathbf{k}_i\to\mathbf{k}_f)=f_{M,M';R}-\frac{1}{4\pi}\int_R^\infty r^2dr\int d\Omega e^{i\mathbf{K}\cdot\mathbf{r}}\times\frac{1}{r^3}\left(\frac{4\pi}{5}\right)^{1/2}Y_{2,M-M'}(\theta,\phi)\times\frac{Q_{M,M'}}{ea_0}+O(k)$$

$$=-A\delta_{M,M'}+\frac{1}{3}\frac{Q_{M,M'}}{ea_0}\left(\frac{4\pi}{5}\right)^{1/2}\times Y_{2,M-M'}(\theta_K,\phi_K)+O(k). \quad (4.15)$$

$\mathbf{K}$ is again the momentum transfer vector $\mathbf{k}_i-\mathbf{k}_f$, A has the same meaning as in Sec. 3, and the substitution of A for $A(R)$ has again been made as in Secs. 2 and 3. The relation of θ_K to the angles of $\mathbf{k}_i$ and $\mathbf{k}_f$ was given by Eq. (3.15). Similarly $\tan\phi_K=K_x/K_y$ and this is equal to

$$\tan\phi_K=\frac{\sin\theta_i\sin\phi_i-\sin\theta_f\sin\phi_f}{\sin\theta_i\cos\phi_i-\sin\theta_f\cos\phi_f}. \quad (4.16)$$

The delta function arises from the fact that the (scattering length) equation which determines the leading term of f_R contains only the angular average of the potential and so does not connect states of different M.

Equation (4.15) represents the final result of this section, the scattering amplitude to lowest order in k for collisions of very slow electrons with a nonsymmetric atom initially in magnetic state M. We shall now mention two obvious applications of this formula. The first is the scattering of slow electrons from unoriented atoms. For this case one should construct the cross sections and then average over initial states M and sum over final states M'. Using Eq. (4.14) for $Q_{M,M'}$ we find

$$\sigma(\theta)_{\rm av}=\frac{1}{2J+1}\sum_M\sum_{M'}|f_{M,M'}|^2=A^2+\frac{1}{9}\left(\frac{Q}{ea_0}\right)^2\times\frac{(J+1)(2J+3)}{5J(2J-1)}+O(k), \quad (4.17)$$

where J is the total angular momentum of the atom.[22]

[21] M. E. Rose, *Elementary Theory of Angular Momentum* (John Wiley & Sons, Inc., New York, 1957), p. 33 ff.; E. U. Condon and G. H. Shortley, *The Theory of Atomic Spectra* (The University Press, Cambridge, 1951), p. 76 ff.

[22] It is interesting to compare the above result with those of Gerjuoy and Stein, Ref. 13, although they were not concerned with elastic scattering. If one nevertheless sets $J_b=J_a$ in their results and $k_b=k_a$ and uses the relation between the quadrupole moments mentioned in Ref. 17, one reproduces the second term of Eq. (4.17). (There is of course no A^2 term in these results since they did not consider elastic scattering.)

We have used the sum rules for spherical harmonics and for Clebsch Gordan coefficients[23] together with Eq. (4.5). It should be noted that the differential cross section given by Eq. (4.17) is spherically symmetric.

If the target atoms have been *oriented* so that they are initially in magnetic state M, then Eq. (4.15) may be used directly to determine the differential cross section for transitions to any other state M' caused by collisions with very slow electrons. In this case, changes of M by 0, 1, and 2 units are allowed. To find the total cross sections for these transitions, the integrals over ϕ_f and θ_f may be done, after substituting Eq. (3.15) for θ_K, giving

$$\sigma_{M,M}=4\pi A^2-(2/3)\pi A\frac{Q_{M,M}}{ea_0}P_2(\cos\theta_i)+(1/9)\pi\left(\frac{Q_{MM}}{ea_0}\right)^2[1-(3/8)(\sin\theta_i)^4]+O(k),$$

$$\sigma_{M,M\pm1}=(1/12)\pi\left(\frac{Q_{M,M\pm1}}{ea_0}\right)^2[1+(1/3)(\cos\theta_i)^4]+O(k), \quad (4.18)$$

$$\sigma_{M,M\pm2}=(5/48)\pi\left(\frac{Q_{M,M\pm2}}{ea_0}\right)^2[1-(2/5)(\cos\theta_i)^2-(1/15)(\cos\theta_i)^4]+O(k).$$

These total cross sections still depend on the angle θ_i between the direction of the incident electron and the z axis along which the atoms have been oriented.

Finally with regard to the energy range of validity of Eq. (4.15) and the results of Sec. 3, as in previous work[4] necessary conditions can be found for the energy. In the iteration process begun in Sec. 3 and implied in the work of the present section, the iterated quantities consisted of the terms qk and pk^2 each multiplied by a factor of order unity. Necessary conditions then on the applicability of the preceding results is that dimensionless quantities kQ/ea_0 and $k^2\alpha/a_0$ be small compared to unity. The latter condition is that already found for the polarization potential.

Lifetime of the First $^1P_1$ State of Zinc, Calcium, and Strontium*

ALLEN LURIO

AND

R. L. DEZAFRA† AND ROBERT J. GOSHEN
Columbia Radiation Laboratory, Columbia University, New York, New York

(Received 9 January 1964)

The lifetime of the first excited $^1P_1$ state of zinc, calcium, and strontium has been measured by the zero-field level-crossing technique. The results are: zinc $\tau(^1P_1)=1.41\pm0.04\times10^{-9}$ sec, calcium $\tau(^1P_1)=4.48\pm0.15\times10^{-9}$ sec, and strontium $\tau(^1P_1)=4.97\pm0.15\times10^{-9}$ sec. The results are compared to earlier experimental results and also to theoretical predictions. It is found that our results are in excellent agreement with the Bates and Damgaard Coulomb approximation method for estimating the oscillator strengths.

I. INTRODUCTION

THE problem of determining atomic transition probabilities and excited-state lifetimes is an old one in physics, although it has received relatively little experimental attention in recent years. At the same time, advances in photoelectric recording and optical techniques make many early methods well worth reviewing and revising. Surveys of existing literature show a few advances in techniques since the early 1930's, while revealing upon occasion a rather considerable state of disagreement—not uncommonly by an order of magnitude or more—in many "absolute" measurements. Several excellent compilations of previous literature, tables of numerical values, and review articles exist. The best reference for all of these as well as individual articles, up to 1962, is the National Bureau of Standards monograph by Glennon and Wiese.[1]

Most absolute experimental determinations of oscillator strengths or transition probabilities of spectral lines have used the "hook" method developed by Rozhdestvenski and co-workers at Leningrad over the years from 1912 to the present.[2] This method and the various line absorption methods of measuring absolute oscillator strengths all require a knowledge of the density of the scattering atoms.[3] It is this requirement that presents a limitation to the precision of these methods. (For the measurement of *relative* oscillator strengths, however, the "hook" method seems to be excellent.) The zero-field level crossing or Hanle effect,[4] on the other hand, does not suffer from this requirement in the limit of low vapor densities, and should therefore be much more reliable. The level-crossing technique does require the production of strong unself-reversed resonance lines and consequently is limited to measurements of the oscillator strengths of the first few resonance lines of an element. In this respect the "hook" method would seem superior since it does not require resonance lines.

In a previous paper[5] the measurement of the lifetime of the first excited $^1P_1$ state of Cd by the zero-field level-crossing technique is reported. In the present paper we report on the lifetime of the first excited $^1P_1$ state of Ca, Sr, and Zn. In these experiments the resonance radiation is scattered from an atomic beam so that the difficulty of finding a transparent cell which is not attacked by Ca or Sr vapor is avoided. Our results are compared to previous measurements and to theoretical calculations for the oscillator strengths and are found to agree surprisingly well with the Bates and Damgaard approximation.[6]

II. THEORY

We first present a simple and somewhat restricted theory derived on strictly classical grounds, to give as directly as possible a physical picture of the Hanle or zero-field level-crossing effect. Later, a more generalized quantum-mechanical treatment is given leading to the same conclusions.

More than one geometrical arrangement is possible, and polarized light need not be used, but the simplest arrangement conceptually is probably the following. Consider a vapor of the atoms to be investigated—either in the form of a free atomic beam, or in a closed evacuated container—with the scattering region at the coordinate origin (see Fig. 1). A beam of resonance radiation with the **E** field polarized in the Y direction is sent in along the X axis. Absorption of the resonant light by the vapor raises the atoms to the excited state whose lifetime is to be measured. Classically one may consider the resonance light to excite electric dipoles

oscillating along the direction of the Y axis.[7] These dipoles then re-radiate energy with the usual dipole radiation pattern, producing maximum intensity perpendicular to, and zero intensity along, the Y axis. However, if a magnetic field is present, aligned with the Z axis, the dipoles will precess about this field at their Larmor frequency ω until they re-radiate. ω depends on the field strength H via the Larmor relation $\omega=\gamma H$ where γ is the gyromagnetic ratio: in this case

$$\gamma=\omega/H=g_J\mu_0/\hbar, \qquad (1)$$

with g_J = the electronic g factor and μ_0 = the Bohr magneton. The angle of rotation through which a given dipole precesses before re-radiating is thus dependent on H. Multiplying the $\sin^2$ dipole-radiation pattern by an exponential damping factor to account for the random finite excited-state lifetimes over a large continuously excited collection of atoms, and integrating over all times, yields the following results for the observed intensity of scattered resonant radiation along the Y axis (at 90° to the incident beam) as a function of the magnetic field strength H:

$$I=C\int_0^\infty e^{-\Gamma t}\sin^2\omega t dt=\frac{C}{2}\left[1-\frac{\Gamma^2}{\Gamma^2+4\gamma^2H^2}\right], \qquad (2)$$

where Γ is the reciprocal of the mean life of the excited state and C is an arbitrary constant relating to the incident light intensity, the experimental geometry, and the number of scatterers. The result is just an inverted Lorentzian line shape as a function of H, with a full width at half-maximum equal to Γ. The half-maximum is seen to occur at a field value $H_{1/2}$ for which $4\gamma^2H^2_{1/2}=\Gamma^2$, or using Eq. 1, when

$$\Gamma=(2g_J\mu_0H_{1/2}/\hbar)\ \text{sec}^{-1}. \qquad (3)$$

Thus, a simple determination of the value of the magnetic field required to produce the half-maximum level in the Lorentzian line shape serves in principle to determine the mean life $\tau=1/\Gamma$, since g_J is generally well known. In practice fairly detailed profiles of the scattered intensity were taken as a function of H, as described in the next section, in order to carefully analyze and verify the Lorentzian shape. If the incident light along the X axis is unpolarized, one may carry out the theoretical analysis by resolving this light into two orthogonal polarizations. For the component polarized parallel to the Y axis the treatment is the same as given above. For the component polarized parallel to the Z axis, the scattered light is independent of the applied magnetic field since a dipole oscillating parallel to H does not precess. In practice one polarizes the incident light parallel to the Y axis in order to eliminate this constant background.

[7] The classical treatment gives the correct results for the simple case of the excitation from a $J=0$ ground state to a $J=1$ excited state. We have not examined the classical treatment in more complicated cases.

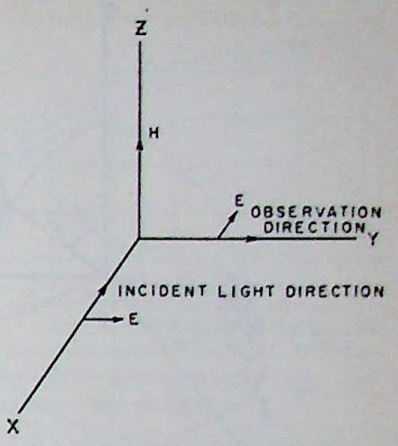

FIG. 1. Geometry used in Hanle effect experiment.

In odd A isotopes the presence of hyperfine structure may alter the Lorentzian profile in particular cases. This occurs since the g_F value of the odd isotopes will differ from the g_J value for the even isotopes. Moreover, the Hanle effect is only a special case at zero field of the more general "level-crossing" phenomenon discovered by Franken and co-workers[8] and the observational technique used here will also detect these nonzero-field crossings. This may then introduce distortions in the wings of the Lorentzian profile if fields large enough to reach nonzero-field level crossings are used, which may be the case with comparatively small hyperfine intervals and short lifetimes (e.g., $\tau\lesssim10^{-9}$ sec). This was not of importance for the elements studied here since the naturally occuring group II elements contain at most small amounts of odd A isotopes and those odd A isotopes which do occur all have $I\geq\frac{5}{2}$. Thus for these isotopes the level-crossing signals are a very small fraction of the scattered resonance radiation because of the large number of Zeeman levels.

We shall now give a quantum-mechanical derivation for the intensity of the scattered resonance radiation from a collection of identical atoms with $I=0$, excited from the $^1S_0$ ground state to the $^1P_1$ state and decaying back to the $^1S_0$ state. We will take the externally applied static magnetic field to be along the Z axis but will allow for arbitrary incident light and observing directions (see Fig. 2). The general expression for the rate of scattering of resonance radiation has been given by Breit[9] and Franken[8] and is

$$R(f,g)\propto N\sum_{\substack{\mu\mu'\\ mm'}}\frac{f_{\mu m}f_{m\mu'}g_{\mu' m'}g_{m'\mu}}{\Gamma-i[(E_\mu-E_{\mu'})/\hbar]}, \qquad (4)$$

where $f_{\mu m}=(\mu|\hat{e}\cdot\mathbf{r}|m)$, $g_{\mu m}=(\mu|\hat{e}'\cdot\mathbf{r}'|m)$, μ and μ' refer to the excited state magnetic sublevels, m and m' refer to the ground-state sublevels, and E_μ is the energy of the μth excited state. Figure 2 shows the spherical

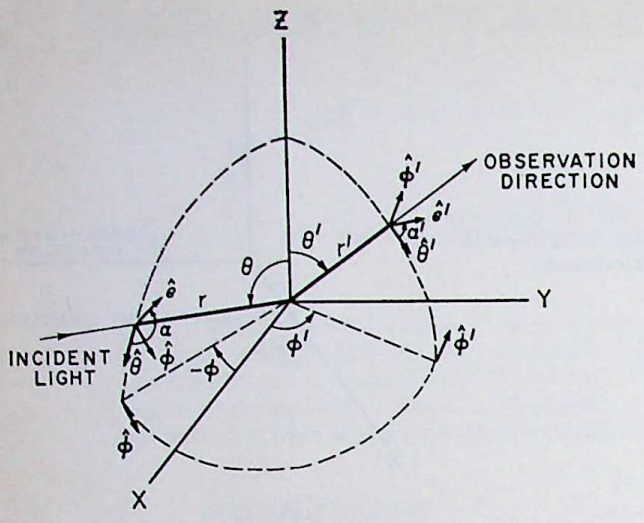

FIG. 2. Coordinate and polarization system used in quantum mechanical calculation of zero-field level-crossing signal.

coordinate system used to evaluate R. The incident light is directed toward the origin at coordinate angles θ and φ and the light polarization vector $\hat{e}$ makes an angle α with respect to $\boldsymbol{\theta}$ and lies in a plane normal to $\mathbf{r}$. $\hat{e}'$ and $\mathbf{r}'$ refer to the scattered light. With this coordinate system we have

$$\hat{e}=\hat{\imath}(\cos\theta\cos\varphi\cos\alpha-\sin\varphi\sin\alpha)+\hat{\jmath}(\cos\theta\sin\varphi\cos\alpha+\cos\varphi\sin\alpha)-\hat{k}(\sin\theta\cos\alpha). \quad (5)$$

We may define a new set of complex vectors which will prove useful by the relations

$$\begin{aligned} e_{\pm}&=e_x\pm ie_y=(\cos\theta\cos\alpha\pm i\sin\alpha)e^{\pm i\varphi},\\ e_z&=-\sin\theta\cos\alpha,\\ r_{\pm}&=r_x\pm ir_y, \end{aligned} \quad (6)$$

so that $\hat{e}\cdot\mathbf{r}=\frac{1}{2}(e_+r_-+e_-r_+)+e_zr_z$. In order to evaluate $f_{m\mu}$ and $g_{m\mu}$ we need the matrix elements[10]

$$\begin{aligned} \langle\gamma,0,0|e_{\pm}r_{\mp}|\gamma',1,\pm1\rangle&=\mp\sqrt{2}e_{\pm}\langle r\rangle,\\ \langle\gamma,0,0|e_zr_z|\gamma',1,0\rangle&=e_z\langle r\rangle, \end{aligned} \quad (7)$$

where $\langle r\rangle$ is the reduced matrix element of $\mathbf{r}$. Let us now define the excitation matrix $F_{\mu\mu'}=\sum_m f_{\mu m}f_{m\mu'}$ or more explicitly

$$F_{\mu\mu'}=\begin{vmatrix} \frac{1}{2}(e_+e_-) & -e_-e_z/\sqrt{2} & -\frac{1}{2}e_-^2\\ -e_+e_z/\sqrt{2} & e_z^2 & e_ze_-/\sqrt{2}\\ -\frac{1}{2}e_+^2 & e_ze_+/\sqrt{2} & \frac{1}{2}e_+e_- \end{vmatrix}|\langle r\rangle|^2. \quad (8)$$

For our simple case the re-radiation matrix $G_{\mu'\mu}=\sum_{m'}g_{\mu'm'}g_{m'\mu}$ is the same matrix as $F_{\mu\mu'}$ except that all quantities are primed since they refer to the scattered light.

It is convenient for understanding the coherent scattering process to break R up into different $\Delta\mu$ components where $\Delta\mu=|\mu-\mu'|$. Then

$$R(f,g)=R(\Delta\mu=0)+R(\Delta\mu=1)+R(\Delta\mu=2), \quad (9)$$

and

$$R(\Delta\mu=0)=\sum_{\substack{\mu,\mu'\\ \mu=\mu'}}\frac{F_{\mu\mu'}G_{\mu'\mu}}{\Gamma-(i/\hbar)(E_\mu-E_{\mu'})}=\frac{1}{2\Gamma}(1-e_z^2-e_z'^2+3e_z^2e_z'^2), \quad (10)$$

$$R(\Delta\mu=1)=\sum_{\substack{\mu,\mu'\\ |\mu-\mu'|=1}}\frac{F_{\mu\mu'}G_{\mu'\mu}}{\Gamma-(i/\hbar)(E_\mu-E_{\mu'})}=\frac{\frac{1}{2}e_ze_z'}{\Gamma^2+(E_{1,1}-E_{1,0})^2/\hbar}\left[\Gamma(e_-e_+'+e_+e_-')+\frac{i(E_{1,1}-E_{1,0})}{\hbar}(e_-e_+'-e_+e_-')\right]$$
$$+\frac{\frac{1}{2}e_ze_z'}{\Gamma^2+(E_{1,0}-E_{1,1})^2/\hbar}\left[\Gamma(e_-e_+'+e_+e_-')+\frac{i(E_{1,0}-E_{1,-1})}{\hbar}(e_-e_+'-e_+e_-')\right], \quad (11)$$

$$R(\Delta\mu=2)=\sum_{\substack{\mu,\mu'\\ |\mu-\mu'|=2}}\frac{F_{\mu\mu'}G_{\mu'\mu}}{\Gamma-(i/\hbar)(E_\mu-E_{\mu'})}=\frac{1}{4[\Gamma^2+(E_{1,1}-E_{1,-1})^2/\hbar]}$$
$$\times\left[\Gamma(e_-^2e_+'^2+e_+^2e_-'^2)+\frac{i(E_{1,1}-E_{1,-1})}{\hbar}(e_+^2e_-'^2-e_-^2e_+'^2)\right]. \quad (12)$$

For our experimental arrangement $\theta=\theta'=\frac{1}{2}\pi$, $\varphi=0$, $\varphi'=\frac{1}{2}\pi$. Also $E_{1,1}=-E_{1,-1}=g_J\mu_0H$ and $E_{1,0}=0$ so that we may simplify the above equations to

$$R(\Delta\mu=0)=(1/\Gamma)(\tfrac{1}{2}\sin^2\alpha\sin^2\alpha'+\cos^2\alpha\cos^2\alpha'), \quad (13)$$

$$R(\Delta\mu=1)=-\frac{1}{2}\frac{g_J\mu_0H\sin2\alpha\sin2\alpha'}{\Gamma^2+(g_J\mu_0H/\hbar)^2}, \quad (14)$$

$$R(\Delta\mu=2)=-\frac{\Gamma/2\sin^2\alpha\sin^2\alpha'}{\Gamma^2+(2g_J\mu_0H/\hbar)^2}. \quad (15)$$

If the incident light is polarized with $\alpha=\frac{1}{2}\pi$ (i.e., parallel to the Y axis) and the outgoing intensity is

[10] E. U. Condon and G. H. Shortley, *The Theory of Atomic Spectra* (Cambridge University Press, Cambridge, 1935), Chap. III.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

measured without polarizers then

$$R(f,g)=\frac{1}{2}\left[\frac{1}{\Gamma}-\frac{\Gamma}{\Gamma^2+(2g_J\mu_0 H/\hbar)^2}\right]. \quad (16)$$

To obtain Eq. (16), the result for the intensity of the scattered light, we have summed Eq. (9) for α' and for $\alpha'+\pi/2$ since this takes account of both orthogonal components of the outgoing beam.

Experimental Details and Results

In Fig. 3 is shown a schematic diagram of the apparatus. The beam source is a stainless-steel oven positioned about 4 in. below the scattering region. The beam effuses through a $\frac{1}{4}$-in.-diam crinkle foil aperture at the top of the oven and is further collimated into a $\frac{1}{2}$-in.-diam region as it passes vertically through the scattering chamber. The beam is then collected on a liquid N_2 trap. A beam flag is provided to determine the degree of instrumental scattering in the absence of the beam and to aid in aligning the optics. Under actual conditions of operation the instrumental scattering can be reduced to several times the dark current of the photomultiplier while the resonance radiation scattered from the beam can easily be made 30 times the dark current. In this arrangement the dc scattered resonance radiation signal is collected by an aluminized light pipe, passed through a narrow-band interference filter for the $^1S_0$–$^1P_1$ resonance line in order to reduce the scattered-light background, and detected by a Dumont 7664 photomultiplier. The photomultiplier output is further amplified by a Hewlett Packard 412A vacuum-tube voltmeter and displayed on a servo recorder.

The externally applied vertical magnetic field at the scattering region was calibrated by proton resonance and found to be 7.51±0.02 G/A. The principal component of the stray magnetic field at the scattering region was 0.35 G in the vertical direction. This field was not compensated but was taken into account in evaluating

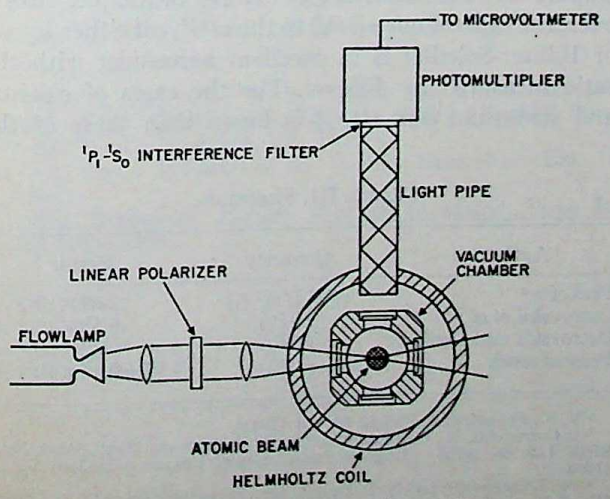

FIG. 3. Schematic diagram of apparatus.

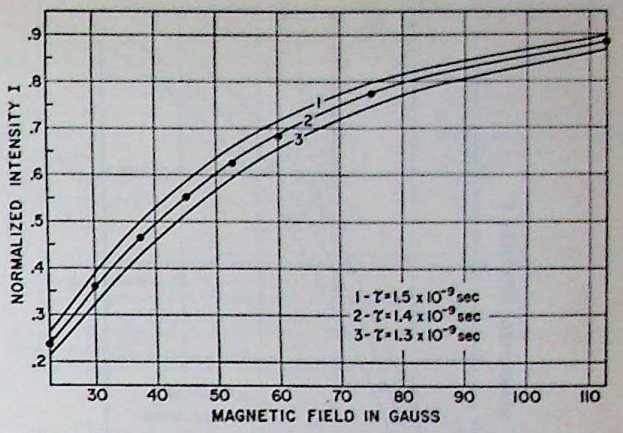

FIG. 4. Normalized plot of level-crossing signal versus magnetic field for zinc. 1, 2 and 3 are theoretical curves. Only the portion of the curve near the half-width is shown.

the data. Most of the measurements were made with the incident light polarized with the electric vector in the direction of observation. Measurements were also made with unpolarized incident light and gave the same results.

The data was taken in the following manner. By means of a reversing switch, the intensity I of the scattered light was recorded successively with the magnetic field in the "up" and then in the "down" direction. A series of about ten such determinations for values of H between 0 and 200 G comprised a run. A plot of I versus H with the zero-field scattered-light intensity subtracted should be an inverted Lorentzian curve. From an approximate value of τ and the value of I at the larger magnetic-field values we may obtain the constant C in Eq. 2. For each run, after C has been determined, the experimental curve is normalized to unity amplitude and plotted together with a family of theoretical Lorentzian curves with different values of τ. In this way τ and an estimate of the uncertainty in τ can be obtained. Between 10 and 15 runs were taken for each element and the values for τ quoted below are the average values derived from these independent runs. Figures 4 and 5 show typical data for zinc and calcium. The slight asymmetry between the field up and the field down points for calcium is due to the incident and observing directions not being exactly perpendicular. Careful arrangement of the optics can eliminate this asymmetry. We find for the lifetime of the $^1P_1$ states the following values: $\tau(\mathrm{Zn})=1.41\pm0.04\times10^{-9}$ sec, $\tau(\mathrm{Ca})=4.48\pm0.15\times10^{-9}$ sec, and $\tau(\mathrm{Sr})=4.97\pm0.15\times10^{-9}$ sec. The quoted errors are twice the standard deviations for the different runs and represent a conservative estimate of the accumulated uncertainty arising from possible instrumental inaccuracies. We have taken $g_J=1.00$ in obtaining τ from the measured linewidths.

The beam density was varied over a factor of about 20 during these measurements in order to detect and correct for coherence narrowing. At the highest beam

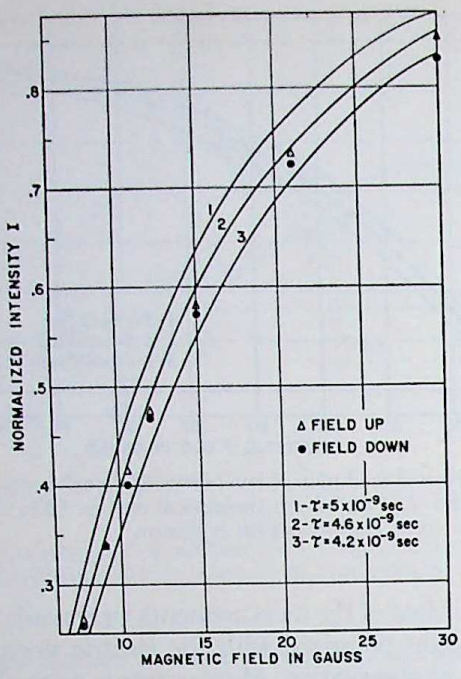

FIG. 5. Normalized plot of level-crossing signal versus magnetic field for calcium. 1, 2, and 3 are theoretical curves.

densities a narrowing of a few percent was obtained. For this reason the results quoted are from those runs taken at low-beam densities.

The possibility exists that self-reversal in the lamp might affect the results. One would expect this effect to distort the Lorentzian line shape. This would occur because as the magnetic field is increased at the scattering atoms, the $\Delta m=\pm 1$ Zeeman levels of the atom would scan a higher intensity part of the lamp profile, and consequently the scattered light would increase faster than it would for a flat profile. No such distortion of the measured Lorentzian shaped lines occurred to within the accuracy of the experiment.

Finally, we wish to mention that originally data for all three elements, with standard deviations of 3–6%, were taken with a somewhat cruder version of the present apparatus. The data presented here were obtained in a physically different location, with entirely different hardware, including different recording instruments and calibrating standards. The results presented here fall within the standard deviations of the preliminary results. This degree of care was taken in part because of disagreement between the preliminary data and previous values in the literature.

Discussion of Results

Tables I, II, and III list the present and previous results for the lifetime of the first excited $^1P_1$ and $^3P_1$ states of zinc, calcium, and strontium. These lifetimes have been calculated from the quoted f values by use of the relation[3]

$$f\tau=\frac{mc}{8\pi^2e^2}\frac{g_2}{g_1}\lambda^2=1.499\frac{g_2}{g_1}\lambda^2.$$

In the case of zinc, one has excellent agreement between the present results and those of Landman although it should be observed that both of these experiments employ the zero-field level-crossing technique. Moreover, the ratio of our $\tau(^1P_1)$ to the $\tau(^3P_1)$ of either Byron or Billiter-Soleillet is in excellent agreement with the ratio measured by Filipov. For the cases of calcium and strontium our $\tau(^1P_1)$ is lower than those of the

TABLE IV. Intermediate coupling coefficients.

		Wolfe method	Lifetime ratio method
Zn	c_1	0.5656	0.5657
	c_2	0.8247	0.8246
Sr[a]	c_1	0.5519	0.5526
	c_2	0.8339	0.8334
Ca[a]	c_1	0.5709	0.5717
	c_2	0.8210	0.8204

[a] We use the Prokofev lifetime ratio in the case of Ca and Sr since no direct measurement of $\tau(^3P_1)$ is available for these elements.

Russian measurements, however, we note that their most recent results are in better agreement with ours. We do not know the source of these discrepancies but we should point out the following fact: The recent ingenious improvement in the hook method[11] utilizes total absorption to measure $Nf\Gamma$. The use of this method requires that the absorption follow a Lorentzian law at about three Doppler widths from the line center or typically about 200 times the natural linewidth from the line center. It is important to note that this has never been checked experimentally and any deviation from a Lorentzian line shape well out in the wings of the line could lead to erroneous results.

The excellent agreement in the case of Cd and Zn between the hook measurement of $\tau(^1P_1)/\tau(^3P_1)$ and the recent measurements of $\tau(^1P_1)$ and $\tau(^3P_1)$ for these states indicates that one may get good estimates of $\tau(^3P_1)$ by using our $\tau(^1P_1)$ and the ratio obtained from the hook measurements.

It is also of interest to compare the intermediate coupling coefficients[12] c_1 and c_2 for the $^1P_1$ and $^3P_1$ states as derived from lifetime measurements with those derived from Wolfe's[12,13] theory which makes use of the deviation of the fine structure from an interval rule. This theory takes account of spin-orbit and spin-other-orbit interactions but does not allow for spin-spin interactions or the fact that the $^1P_1$ and $^3P_1$ states can have slightly different radial wave functions. The values of c_1 and c_2 calculated by the two different methods are given in Table IV and are in very good agreement.

TABLE V. Comparison of theoretical and experimental values of the oscillator strengths.

	Ca	Sr	Zn
$\lambda(^1S_0-^1P_1)$	4227 Å	4608 Å	2139 Å
f (exp)[a]	1.80	1.92	1.46
f (B & D)[b]	1.83	1.90	1.49
f (Vainshtein)[c]	2.32		
f (Trefftz)[d]	1.737–1.223		

[a] Present work only.
[b] D. R. Bates and A. Damgaard, Phil. Trans. **242**, 101 (1949).
[c] L. A. Vainshtein, Transactions of the P. N. Lebedev Institute, Vol. XV. (English translation available from Consultants Bureau Enterprises, Inc., New York, 1962.)
[d] E. Trefftz, Z. Astrophys. **29**, 287 (1951).

As pointed out in the introduction, the lifetime of the $^1P_1$ state provides a test of approximate methods used to calculate the oscillator strength of the $^1P_1$ to $^1S_0$ transition. The prediction of the Coulomb approximation method of Bates and Damgaard[6] can be obtained by making use of the formula of Garstang.[14]

$$(^1S_0\|P\|^1P_1)=-\sqrt{2}(c_1+\sqrt{2}c_2)\sigma\cong-\sqrt{6}\sigma,$$

and

$$S(J,J^1)=|-\sqrt{2}(c_1+\sqrt{2}c_2)\sigma|^2\cong 6\sigma^2,$$

where σ^2 is obtained for the p electron from the tables given in the Bates and Damgaard paper. The estimate of the oscillator strengths f from this calculation is shown in Table V. Also included in Table V are other estimates for f using explicit forms for the wave functions of the two states. The surprising conclusion to be drawn from Table V is that the Coulomb approximation is in very good agreement with the experimental results.

Note added in proof. After this article was submitted for publication a paper with the following reference appeared: E. Hulpke, E. Paul, and W. Paul, Z. Physik **177**, 257 (1964). In this paper the following results are given: $\tau(\text{Ca})=4.67\pm0.11\times10^{-9}$ sec and $\tau(\text{Sr})=4.56\pm0.21\times10^{-9}$ sec, which are in excellent agreement with ours. As in their paper we have also considered the transitions from the $^1P_1$ to the $^1D_2$ state to be negligible compared to the decay to the ground state.

ACKNOWLEDGMENTS

We would like to thank Robert Holohan for his help in assembling the apparatus and in taking much of the final data. We also appreciate several helpful discussions with Professor R. Novick and A. Gallagher.

g_J of the $(5s5p)\,^3P_1$ Level of Cd and the $(6s6p)\,^3P_1$ Level of Hg by High-Field Double Resonance*

R. KOHLER

Columbia Radiation Laboratory, Columbia University, New York, New York and Physics Department, New York University, University Heights, New York, New York,

AND

P. THADDEUS

Goddard Institute for Space Studies, National Aeronautics and Space Administration, New York, New York

(Received 20 January 1964)

An optical double resonance experiment at high magnetic fields has determined g_J for the $(5s5p)\,^3P_1$ level of the even cadmium isotopes to be 1.499846(13), and g_J for the $(6s6p)\,^3P_1$ level of the even mercury isotopes to be 1.486094(8). Resonance was observed in all cases at a frequency of exactly 24 Gc/sec, and magnetic fields near 11 430 G. At these high fields the Zeeman energy is of the order of 10^{-3} of the fine structure separations of the triplet terms of the $(nsnp)$ configuration, and the $\Delta m = \pm 1$ transitions are split by 9.51(7) G for Cd, and by 2.99(7) G for Hg. This splitting represents several linewidths in the case of Hg, and many linewidths in that of Cd. The average field of the two $\Delta m = \pm 1$ transitions, however, determines g_J to high precision independent of second-order corrections.

I. INTRODUCTION

THE double resonance[1,2] and level crossing techniques[3,4] have been used in extensive studies of hyperfine structure (hfs) in the lowest lying $(nsnp)\,^3P_1$ level of mercury,[5–11] cadmium,[12–17] and zinc.[18–20] Sufficient sensitivity has been obtained to allow the determination of the hfs, and consequently the nuclear moments, of radioactive isotopes with half-lives as short as a few hours.[15,16]

While the level crossing method has the great advantage in practice of doing away with all radio-frequency and microwave apparatus, aside from nuclear magnetic-resonance (NMR) magnetometers, it allows a determination of only the ratio of the hyperfine interaction constants to g_J, and an independent measurement of g_J must therefore be made to determine these constants to high precision.[16] While g_J can of course be measured by double resonance in the odd isotopes at various fields, or by observing both double resonance and level crossings,[9,13] it is most directly found from double resonance in the even isotopes of the element.

In principle, the higher the frequency and the greater the magnetic field, the more accurate the determination of g_J. In a series of experiments designed to measure g_J of the lowest lying $^3P_1$ level of zinc, cadmium, and

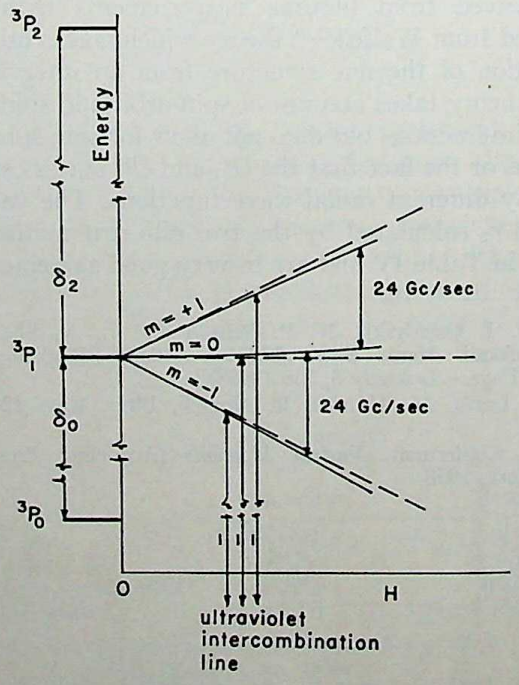

FIG. 1. Zeeman effect of the $^3P_1$ state of the even isotopes of zinc, cadmium and mercury, showing the effect of second-order interaction with the other fine structure levels of the configuration.

mercury to high precision (it is $\frac{3}{2}$ on the basis of LS coupling), we therefore chose to work at a frequency of 24 Gc/sec, and a field near 11 400 G—approaching the limit attainable with the available 12-in. electromagnet when operating with a gap of 2 in.

The $\Delta m=\pm1$ transitions for these states coincide at low magnetic fields, but at high fields interaction with the neighboring fine structure terms of the configuration (and to a negligible degree with levels of other configurations) splits the resonances into two well-resolved components, as shown in Fig. 1. Precise measurement of the splitting of the two resonances therefore serves also as a check on the theory of the second-order fine structure interactions.

II. THEORY

Signal Strengths

It is well known that double resonance can be observed between hyperfine or Zeeman states excited by resonance radiation in a variety of ways. Population differences can be produced by resonance radiation that is polarized, nonisotropic, or confined to a narrow wavelength interval, and all of these methods have been put to practical use.[1,2,6]

To dispense with ultraviolet polarizers, we relied on the latter two effects and used the experimental geometry shown in Fig. 2. Only lamps containing the natural metal were used. In the case of cadmium, the Zeeman shift of the $m=\pm1$ states at 11 400 G is somewhat greater than the isotope shifts and the hyperfine splittings of the natural cadmium isotopes (and the optical Doppler width),[14] and only the $m=0$ state is therefore illuminated. It is then readily calculated in terms of the transition probabilities that at double resonance the resonance fluorescence at 90° is reduced by a factor of $\frac{1}{4}$.

For mercury, on the other hand, the isotope shifts and hyperfine splittings are comparable to the Zeeman shift of the $\Delta m=\pm1$ states,[21] and we must rely mainly on the nonisotropic nature of the resonance radiation. In the least favorable case, on the assumption that all three states are equally illuminated, it is calculated that the resonance fluorescence at 90° is reduced by a factor of $\frac{1}{12}$ at double resonance.

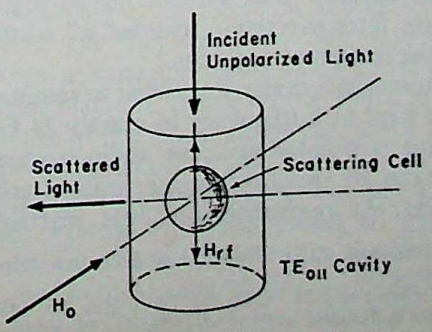

FIG. 2. Geometry of the experiment.

Linewidths

Several effects determine the linewidth and shape of the double resonance effect, and have all been considered in detail elsewhere. Most fundamentally, the natural lifetime τ of the state gives a Lorentzian line shape with full width at half-maximum of $g_J\mu_0\Delta H_n=\Delta\nu_n=1/\pi\tau$.[1,6] The natural linewidths for zinc, cadmium, and mercury calculated from the lifetimes in Table I are listed in Table II.

If the rf magnetic field is strong enough to induce many transitions during the lifetime τ, the resonance will be power broadened.[1,6] In practice the rf power is always attenuated to the point where this effect is small, and it will therefore not be considered further.

Double resonance owes its high resolution to the fact that Doppler broadening is determined by the radio rather than by the optical frequency. At microwave frequencies, however, the Doppler linewidth $\Delta\nu_d=(\nu/c)\times(8NkT\ln2/M)^{1/2}$, where N is Avogadro's number and

TABLE II. Theoretical and observed linewidths in milligauss. ΔH_{calc} is taken as the sum of the natural, Doppler, magnetic field, and wall collision widths.

Atom	ΔH_n	ΔH_d	ΔH_m	ΔH_w	ΔH_{calc}	ΔH_{obs}
Zn	8	29	50	37	124	...
Cd	68	18	50	26	162	175
Hg	1295	10	50	15	1370	1300

M is the molecular weight, may not be altogether negligible, as is shown in Table II.

Inhomogeneity of the magnetic field over the scattering sample contributes a linewidth ΔH_m that can often be reduced by careful alignment of the pole pieces. We found, however, that as our magnetic field approached 11 400 G, its homogeneity fell off rapidly due presumably to uneven saturation. We estimate that $\Delta H_m = 50$ mG over a 5-mm sample.

Collisions with the walls of the scattering cell effectively shorten the lifetime of the excited state, and contribute a wall-quenching linewidth $\Delta\nu_w$ which depends mainly on the size of the cell. We have made estimates of $\Delta\nu_w$ in Table II on the assumption that $\Delta\nu_w = 1/\pi\tau_w = (3NkT/M)^{1/2}/\pi a$, where τ_w is the time for an atom at the temperature of the optimum vapor pressure to travel the radius a of the scattering cell.

Collisions between the scattering atoms will broaden the resonance at high vapor densities, while multiple scattering of the optical photons may actually decrease the linewidth (coherence narrowing).[22,23] Both of these effects may be avoided by working at low enough temperatures.

Quenching by atomic or molecular contaminants in the scattering cell, on the other hand, may contribute a linewidth $\Delta\nu_c$ which cannot be easily estimated in advance, and cannot be reduced once the cell is made. We shall see that possibly except for zinc we found no evidence of quenching of this kind.

Zeeman Effect

Interaction with the two neighboring triplet levels of the ($nsnp$) configuration contributes a term which is of the order of the (Zeeman energy)^2/(fine structure energy) $\approx 10^{-3} \times$ (Zeeman energy) to the energy of the $m = \pm 1$, 0 states. More precisely, from perturbation theory,[24]

$$W_{+1} = g_J\mu_0 H - \frac{\alpha^2(g_S - g_L)^2\mu_0^2 H^2}{4\delta_2}, \tag{1a}$$

$$W_0 = \alpha^2(g_S - g_L)^2\mu_0^2 H^2\left(\frac{2}{3\delta_0} - \frac{1}{3\delta_2}\right), \tag{1b}$$

$$W_{-1} = -g_J\mu_0 H - \frac{\alpha^2(g_S - g_L)^2\mu_0^2 H^2}{4\delta_2}, \tag{1c}$$

where μ_0 is the Bohr magneton, α is the mixing coefficient which indicates the departure from Russell-Saunders coupling, and δ_0 and δ_2 are the magnitude of the fine structure separations. We adopt the convention that g_J is positive. Interaction with the singlet term of the configuration, and with terms of other configurations, contributes less than one part in 10^6 to the energy, and third-order terms vanish.

For double resonance at a fixed frequency ν_{dr}, the field H^+, for which $m = 0 \rightarrow +1$, is greater than H^-, for which $m = 0 \rightarrow -1$. To within one part in 10^6 we find from Eq. (1) that in terms of the average field $\bar{H} = (H^+ + H^-)/2$

$$g_J = h\nu_{dr}/\mu_0\bar{H}. \tag{2a}$$

This becomes

$$g_J = g_p(\nu_{dr}/\bar{\nu}_p), \tag{2b}$$

if the field is measured in terms of the NMR frequency ν_p of protons. g_p is defined such that the proton magnetic dipole-moment operator is $\boldsymbol{\mu}_p = g_p\mu_0\mathbf{I}_p$. For protons in mineral oil we will take $g_p = 3.041978(3) \times 10^{-3}$, from the average of the measurements of g_s/g_p for protons in mineral oil of Koenig, Prodell, and Kusch,[25] and Beringer and Heald,[26] and the recent measurement of g_s of Wilkinson and Crane.[27]

For the separation of the two resonances we find that

$$\Delta H = H^+ - H^- = \frac{\alpha^2(g_S - g_L)^2\mu_0\bar{H}^2}{g_J}\left(\frac{4}{3\delta_0} - \frac{1}{6\delta_2}\right), \tag{3a}$$

where δ_0 and δ_2 are in ergs. When the field is measured in terms of the proton frequency,

$$\Delta\nu_p = \frac{\alpha^2(g_S - g_L)^2\bar{\nu}_p^2}{cg_pg_J}\left(\frac{4}{3\delta_0} - \frac{1}{6\delta_2}\right), \tag{3b}$$

where δ_0 and δ_2 are in cm^{-1}.

III. EXPERIMENT

A schematic illustration of the experiment is shown in Fig. 3. Resonance radiation from an rf lamp was focused with a quartz condensing lens onto a small cell containing cadmium or mercury vapor. The cell was located within a microwave cavity between the poles of a 12-in. electromagnet. This cavity in the case of cadmium also served as an oven to control the vapor density in the scattering cell.

Resonance fluorescence of the atomic vapor was observed with a photomultiplier at an angle of 90°. A light pipe allowed the photomultiplier to be removed from the magnetic field without loss of solid angle. A glass color filter effectively removed all scattered light except the resonance radiation.

The microwave cavity was tuned to resonance with a klystron kept at a frequency of exactly 24 Gc/sec, the field being modulated at a low audio frequency, typically 37 cps, by small rectangular coils attached to the pole faces. At resonance, the light scattered at 90°

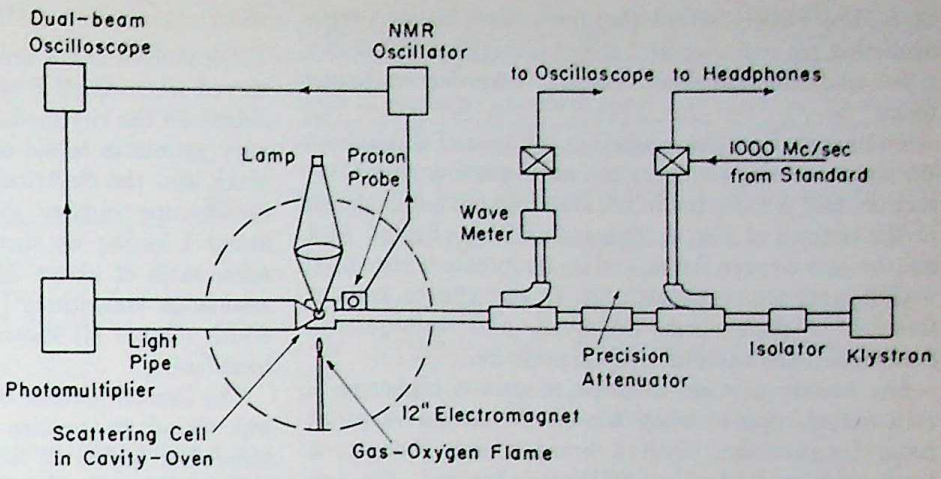

FIG. 3. Schematic diagram of the experiment.

changed in intensity, and the signal from the photomultiplier was displayed on an oscilloscope.

Field measurements were made with an NMR magnetometer, whose small mineral-oil probe was located as close to the scattering cell as possible. The offset correction was measured with a second probe and oscillator.

Optics

The cadmium lamp used consisted of a small quartz cylinder, 1.5 cm in diameter and 2.5 cm long, carefully baked out, purged with an rf discharge in argon and then filled with a small amount of distilled natural cadmium and about 1 torr of spectroscopically pure argon. It was identical to the lamps previously used in this laboratory for several level crossing and double resonance experiments.[13,14] It was excited by being placed, without cooling, in the tank coil of a Hartley oscillator operating in the vicinity of 30 Mc/sec. Experience has shown that these lamps furnish about 1 W (total output over 4π solid angle) in the 3261-Å intercombination line.

For mercury an Osram lamp was used that had the outer jacket removed, and was cooled with a gentle air stream to eliminate self-reversal. It too was excited with a radiofrequency oscillator operating near 30 Mc/sec and was run at the same current specified by the manufacturer for operation at 60 cps.

The scattering cells were designed to have as small an effect as possible on the electrical properties of the microwave cavity. They were very thin walled quartz bubbles, 5 mm in diameter, blown at the end of a length of 2 mm outer diameter quartz tubing, which, when cut off at a length of 5 cm, served as the tail of the cell. These cells were baked out at 1000°C for a day or longer, purged with a Tessla coil for several minutes, and filled with a small quantity of distilled metal, all under very high vacuum (less than 10^{-8} Torr for the last stage). The light pipe used to remove the RCA-1P28 photomultiplier from the vicinity of the magnet was a glass tube aluminized on the inside, 1 in. in diameter, and about $2\frac{1}{2}$ ft long. To pass the 3261-Å line of cadmium, or the 2537-Å line of mercury, and exclude other scattered light, a Schott UG-11 or UG-5 colored glass filter was cemented to the end of the light pipe.

Microwave Cavity and Oven

The TE_{011} cylindrical aluminum cavity oven used for cadmium is shown in Fig. 4. It had an internal diameter of 1.4 cm, a Q of about 4000 when loaded with the cell, and was coupled about 50% to the microwave line. A hole 6 mm in diameter at the top of the cavity, below cutoff at 24 Gc/sec, allowed illumination of the scattering cell. Small slits in the side of the cavity, also below cutoff, allowed the light scattered at 90° to be observed.

The waveguide connecting the cavity to the microwave line was thinned to provide thermal insulation. The cavity was heated with a small gas-oxygen flame, the temperature being monitored by a small copper-constantin thermocouple. Thermal regulation was provided

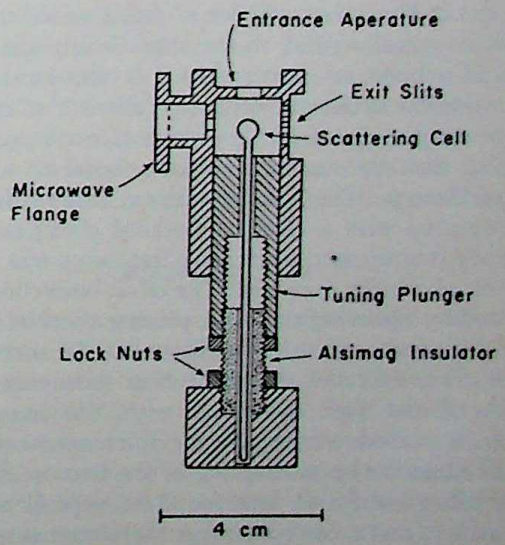

FIG. 4. The cavity oven used for cadmium.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

by a Honeywell R7086A thermocouple-activated regulator that played a stream of cool air against the cavity when the thermocouple voltage exceeded a preset figure.

The long tail of the scattering cell passed through an aluminum tuning plunger, and an insulating refractory section, and terminated in the aluminum cylinder shown in the bottom of Fig. 4. This cylinder was heated with another gas-oxygen flame, and its temperature regulated with a separate regulator unit. It was always kept at least 40°C cooler than the oven, and consequently determined the cadmium vapor pressure.

For mercury, in an attempt to gain a higher Q, a thin-walled copper cavity was used that was kept at room temperature. With a brass tuning plunger, a loaded cavity Q of about 8000 was obtained. The tail of the cell was usually kept at room temperature, but could also be cooled in an ice bath.

Microwave Measurements

The Varian VA-98E klystron used in this experiment is an extremely stable tube that oscillates only over the region from 23.6 to 24.4 Gc/sec, with an average output of about 30 mW. To achieve maximum stability, we used batteries for both the heater and repeller voltages, and a well-regulated power supply for the beam voltage. No electronic stabilization of the tube was employed. During a run it was kept manually to within an audio-beat note of the 24th harmonic of the 1000 Mc/sec output of the laboratory's frequency standard. This represents a stability of about one part in 10^6, and is therefore quite adequate for the purpose of this experiment.

Field Measurements

The proton probe of the NMR magnetometer used for field measurements consisted of a small spherical cavity filled with mineral oil drilled in the center of a teflon spool. The inductance for a transistorized marginal oscillator was wound on the spool which was then placed in a brass or copper shield. It was located as close as possible to the scattering cell (about 4 cm away), and the output signal of the marginal oscillator was displayed with the double resonance signal on a dual beam oscilloscope. The NMR frequency, near 48 Mc/sec, was measured with a Hewlett-Packard direct reading frequency counter whose reference frequency was taken from the laboratory standard. The offset correction was measured by removing the oven, placing a second probe driven by another identical oscillator at the scattering cell location, and measuring the beat frequency ($\approx$4 kc/sec) of the two oscillators with the frequency counter. A pentode mixer gave the difference frequency without excessive cross coupling of the two oscillators.

The offset correction was found to depend on the field history, and a correction was therefore made after each field measurement.

IV. RESULTS

For cadmium the onset of power broadening was observed when about 5 mW of microwave power were incident on the cavity, in rough accord with our preliminary estimates based on the lifetime of the $(5s5p)\ ^3P_1$ level, and the electrical properties of the cavity. With oscilloscope display giving a detector bandwidth of about 1 kc/sec we succeeded in obtaining a signal-to-noise ratio of about 30 for both the $\Delta m=\pm 1$ double resonance transitions [Fig. 5(a)]. The observed linewidth (Table II) shows no evidence of contamination broadening.

The shorter lifetime of the $(6s6p)\ ^3P_1$ level of mercury was found to require for maximum signal strength somewhat higher rf fields than the VA-98E klystron and aluminum cavity could provide. A higher Q copper cavity subsequently used for mercury just allowed the level of power broadening to be reached. The observed resonances [Fig. 5(b)] had a signal-to-noise ratio of about 5. It should be recalled that because of the illumination of the $m=\pm 1$ states the mercury signals are expected to be about 3 times weaker than those of cadmium. The additional discrepancy in signal strength can be attributed to the somewhat weaker output of the mercury lamp. The linewidth was in agreement with expectations (Table II).

We had originally hoped to extend our measurements to the $(4s4p)\ ^3P_1$ level of the even zinc isotopes, although we were aware that the long lifetime of this level would produce serious quenching of the excited state atoms against the wall of the scattering cell. We, in fact, made several runs using narrow-band phase-sensitive detection with time constants as long as 5 sec, but failed to detect either double resonance or fluorescence. Beyond the quenching and broadening mechanisms listed in Table II, we are inclined to attribute this to contaminants produced by the high cell temperature required for zinc.

The magnetic fields at which double resonance was observed for cadmium and mercury are listed in Table III. From Eq. (2) we then find for the $(5s5p)\ ^3P_1$ level of cadmium that

$$g_J=1.499846(13)=\tfrac{3}{2}-154(13)\times 10^{-6},$$

in good agreement with the values $g_J^{111}=\frac{3}{2}-171(9)\times 10^{-6}$ and $g_J^{113}=\frac{3}{2}-157(9)\times 10^{-6}$ found for the odd isotopes from level crossings[13] and zero-field double resonance[12] (we have here recalculated g_J^{111} and g_J^{113} taking $g_p=3.041978\times 10^{-3}$).

Likewise, we find for the $(6s6p)\ ^3P_1$ level of mercury that

$$g_J=1.486094(8)=\tfrac{3}{2}-13\,906(8)\times 10^{-6}.$$

This is in reasonably good agreement with a recent preliminary value of $g_J^{199}=1.486118(16)$ found by Smith,[28] who considered both his own level-crossing

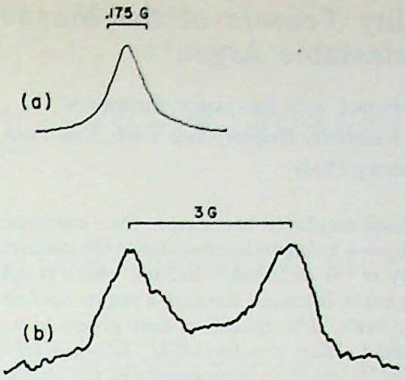

FIG. 5. Oscilloscope traces of the double resonance signals: (a) is one of the $\Delta m = \pm 1$ cadmium transitions, (b) is the sum of these two transitions for mercury, split by the second-order interactions.

study of Hg^{199}, and the results of low-field double resonance.[11] It is also in agreement with the less precise value 1.486350(300) found by Dodd[29] from double resonance in the even isotopes. It is in disagreement, however, with the self-consistent values $g_J^{199} = 1.486147(10)$ and $g_J^{201} = 1.486156(18)$ calculated by Kaul in his thesis[9] from his study of level crossings, and the low-field double resonance results.[6,11]

For cadmium the known lifetimes of the $^3P_1$ and $^1P_1$ levels allow α to be calculated directly from the relation

$$\frac{\beta^2}{\alpha^2} = \frac{\tau(^1P_1)\lambda^3(^3P_1)}{\tau(^3P_1)\lambda^3(^1P_1)}, \tag{4}$$

and the normalization condition $\alpha^2+\beta^2=1$. Using the lifetimes and wavelengths of Table I we find that $\alpha = 0.99900(5)$ and $\beta = -0.0448(11)$. The phase convention of Condon and Shortley is used to determine the sign of β.[24] From Eq. (3) the splitting of the resonances is then calculated to be $\Delta\nu_p = 40.245(4)$ kc/sec, or $\Delta H = 9.452(1)$ G. This is seen from Table III to be 0.255 kc/sec lower than the experimental value, but just within the experimental uncertainty.

Knowing α and β independently from the lifetimes, we are in a position to determine the sum of the relativistic and diamagnetic corrections to g_J. Theoretically

$$g_J = \tfrac{1}{2}\alpha^2(g_L+g_S)+\beta^2 g_L+\Delta g_{\rm rel}+\Delta g_{\rm diam}. \tag{5}$$

Taking $g_L = 1$,[30] and $g_S = 2.002319$,[27] we find that[31]

$$\Delta g_{\rm rel}+\Delta g_{\rm diam} = -318(40)\times 10^{-6}.$$

Since for mercury the lifetime of the $^1P_1$ level is poorly known, the sum of the relativistic and diamagnetic corrections cannot be found. Instead, however, we may use Eq. (5) neglecting these corrections to obtain $\alpha = 0.9849(4)$ and $\beta = -0.1733(24)$. We then calculate from Eq. (3) the splitting of the mercury resonances to be $\Delta\nu_p = 12.468(8)$ kc/sec or $\Delta H = 2.928(2)$ G. It is interesting to note that this is lower than the experimental value by 0.252 kc/sec, nearly the same as in the case of cadmium. Since the measurement of the splitting ΔH is not susceptible to the same systematic errors as the absolute field measurements, the uncertainties in ΔH given in Table III must be considered quite conservative, and this discrepancy may be significant.

TABLE III. Measured fields for double resonance in cadmium and mercury, in terms of the NMR frequency of protons in mineral oil, and in G, taking for $1/2\pi\times$ the gyromagnetic ratio 4.25760(4) kc/sec-G.[a] A series of runs were made for each atom, care being taken to randomize systematic errors from run to run by slightly relocating the cell and probe within the field, reversing the polarity of the magnet, varying the modulation frequency, changing the vapor pressure, reassembling the optics, etc. The uncertainties quoted are 3 times the standard deviation of the means of the individual runs.

Atom	H^+	H^-	ΔH
Cd	48 696.91(66) kc/sec	48 656.40(45) kc/sec	40.50(28) kc/sec
	11 437.64(19) G	11 428.13(15) G	9.51(7) G
Hg	49 133.45(35) kc/sec	49 120.73(38) kc/sec	12.72(26) kc/sec
	11 540.17(14) G	11 537.19(14) G	2.99(7) G

[a] R. L. Driscoll and P. L. Bender, Phys. Rev. Letters 1, 413 (1958).

V. DISCUSSION

While an accuracy of about one part in 10^5 has been attained in the field measurements reported in this experiment, for cadmium this represents an uncertainty of one linewidth, and can certainly be improved upon. In retrospect we believe that higher precision could have been realized at somewhat lower frequencies and fields. Most of our uncertainty can be ascribed to the inhomogeneities which crept in as the field approached 11 400 G. Had we worked at half the present field and frequency, for example, the field would have been considerably more uniform, the scattering cell would have been twice as large (and easier to construct and more durable), the Doppler and wall collision linewidths halved, and the exit and entrance apertures increased in area by four. It is probable that under these circumstances we would have had sufficient signal strength to observe double resonance in zinc, and that the cadmium resonance could have been measured to a small fraction of its width.

ACKNOWLEDGMENTS

We wish to express our thanks to the staff of the Columbia Radiation Laboratory for their invaluable assistance, and to Professor R. Novick for his advice and support. We would like especially to acknowledge the assistance of H. Feldman, who collaborated with us during a part of the cadmium experiment. Finally, Raymond Eisenstark assisted us liberally during all phases of this work as data taker and calculator, and T. Psaropulos kindly prepared the drawings.

[29] J. N. Dodd, Proc. Phys. Soc. (London) 78, 65 (1961).

[30] This neglects effects due to nuclear motion, which are expected to contribute a correction to g_L of the order of a few ppm. See A. Abragam and J. H. Van Vleck, Phys. Rev. 92, 1448 (1953).

[31] The theoretical values of $g_J = \frac{3}{2} - 18(80)\times 10^{-6}$ and $\Delta g_{\rm rel} + \Delta g_{\rm diam} = -135(81)\times 10^{-6}$ given in Ref. 13 are in error. These values were calculated from Eq. (13), Ref. 13 on the basis of outdated lifetimes—not those given in Table I, Ref. 13. To the best of our knowledge, the remaining results in that work are self-consistent.

Determination of the Polarizability Tensors of the Magnetic Substates of $^3P_2$ Metastable Argon*†

EDWARD POLLACK,‡ EDWARD J. ROBINSON,§ AND BENJAMIN BEDERSON
Department of Physics, New York University, University Heights, New York, New York

(Received 8 January 1964)

The atomic beam E-H gradient-balance method has been employed to measure the z-component $\alpha_z(m_J)$ of the electric polarizability tensors of the $m_J=+2$ and $m_J=+1$ magnetic substates of $^3P_2$ metastable argon. The measurements were normalized to the polarizability of $^3S_1$ metastable helium, which is calculable to within an accuracy of 1%. In this method, a metastable beam is passed through a region containing transverse, congruent, inhomogeneous electric and magnetic fields. The condition that atoms in a particular magnetic substate experience no deflection in such a field region is $\alpha_z(m_J)E(\delta E/\delta z)=\mu_{\rm eff}(\delta H/\delta z)$, where $\mu_{\rm eff}$ is the magnetic moment in the field H, and $\delta E/\delta z$, $\delta H/\delta z$ are the z components of the gradients of the magnitudes of the electric and magnetic fields, respectively. Because of the congruency of the E and H fields $(\delta E/\delta z)/E=(\delta H/\delta z)/H$, and therefore $\alpha_z(m_J)=\mu_{\rm eff}H/E^2$. Because of the normalization, it was unnecessary to find either E or H. The results, in units of 10^{-24} cm^3, are $\alpha_z(\pm1)=50.4\pm3.5$ and $\alpha_z(\pm2)=44.5\pm3.1$. The measured values of $\alpha_z(+1)$ and $\alpha_z(+2)$ can be used to determine the polarizability tensors of each of the magnetic substates. The other components of the diagonalized tensors, with $\alpha_x(m_J)=\alpha_y(m_J)$, in units of 10^{-24}cm^3 are $\alpha_x(0)=46.4\pm2.4$, $\alpha_x(\pm1)=47.2\pm2.3$, $\alpha_x(\pm2)=50.4\pm3.5$, and $\alpha_z(0)=52.4\pm4.8$.

INTRODUCTION

RECENTLY an atomic beam method has been developed to measure the electric polarizabilities of atoms.[1–3] Using this technique, called the "E-H gradient balance method," polarizability determinations are independent of the atomic-beam velocity distribution and specific values of the field gradients and apparatus geometry except where employed in the calculation of the electric field at the beam position from knowledge of the applied voltage and pole-face contour. Salop, Pollack, and Bederson[2,3] used this method to measure the polarizabilities of the alkalis, and the results of this work, as well as those of Chamberlain and Zorn,[4] are in agreement with recent theoretical determinations, to within experimental error.[5,6] For all these systems, the ground states are S states and the polarizability is therefore scalar.

We will here briefly review our basic technique, applied to an atom possessing a tensor polarizability. Consider an atom traversing a region of space containing both an inhomogeneous transverse electric field and an inhomogeneous transverse magnetic field, with both fields possessing large transverse gradients. We assume that these fields are congruent, that is, the electric and magnetic fields as well as their gradients are proportional and in the same direction throughout the interaction region. The atom experiences a transverse force due to its magnetic moment given by

$$F_m=\mu_{\rm eff}(m_J)(\delta H/\delta z)\,, \tag{1}$$

where $\mu_{\rm eff}(m_J)$ is the effective atomic magnetic moment of the magnetic substate m_J and $\delta H/\delta z$ is the transverse component of the gradient of the magnitude of the magnetic field.

For an atomic system possessing a tensor polarizability the electric dipole moment $\boldsymbol{\mu}_e$ induced in the atom by the electric field $\mathbf{E}$ is generally not along the field direction. For the case where the polarizability tensor is in diagonal form, $\boldsymbol{\mu}_e$ is given by

$$\boldsymbol{\mu}_e=\hat{\imath}\alpha_xE_x+\hat{\jmath}\alpha_yE_y+\hat{k}\alpha_zE_z\,,$$

where α_x is the xx component of the polarizability tensor α, etc. For S-state atoms, $\alpha_x=\alpha_y=\alpha_z=\alpha$, i.e., the polarizability is a scalar. For the magnetic substates of P-state atoms, this is in general not the case and the polarizability of each of the substates is a tensor. In the present work, the electric and magnetic fields, which are in the z direction, establish the z axis as a symmetry axis in the atom. Thus, α is in diagonal form, with the x and y components being equal. In terms of matrix elements, the polarizability components may be

written (in atomic units) as follows[7]:

$$\alpha_x(m_J)=\alpha_y(m_J)=\sum_{k\neq 0}\left[(J^2+J-m_J^2)\delta_{JJ'}+(J^2+m_J^2+3J+2)\delta_{J+1,J'}+(J^2+m_J^2-J)\delta_{J-1,J'}\right]\frac{|\langle 0|\sum_{i=1}^{N} r_i|k\rangle|^2}{E_k-E_0}, \quad (2a)$$

$$\alpha_z(m_J)=2\sum_{k\neq 0}\left[m_J^2\delta_{JJ'}+\{(J+1)^2-m_J^2\}\delta_{J+1,J'}+(J^2-m_J^2)\delta_{J-1,J'}\right]\frac{|\langle 0|\sum_{i=1}^{N} r_i|k\rangle|^2}{E_k-E_0}, \quad (2b)$$

where J and m_J are the total angular momentum and magnetic quantum numbers of the unperturbed state $|0\rangle$, J' is the total angular momentum quantum number of the state $|k\rangle$, (E_k-E_0) the difference in energy between $|k\rangle$ and $|0\rangle$, r_i the radial coordinate of the ith electron, and N the number of electrons. Since the electric field is parallel to the z axis, the induced dipole is

$$\mathfrak{y}_e=\hat{k}\alpha_z E_z.$$

The resulting force is also in the z direction, and is given by

$$F_e=\alpha_z(m_J)E(\delta E/\delta z), \quad (3)$$

where $\alpha_z(m_J)$ is the "effective" polarizability of the atom in the substate m_J and $\delta E/\delta z$ is the transverse component of the gradient of the magnitude of the electric field. (It is assumed throughout that the nuclear spin is zero.) For substates possessing negative atomic moments, the fields can be adjusted so that the electric and magnetic forces given by Eqs. (1) and (3) are equal and opposite. (In the present experiment these are the positive m_J states.) When this is the case, it follows that

$$\mu_{\rm eff}(m_J)(\delta H/\delta z)=\alpha_z(m_J)E(\delta E/\delta z). \quad (4)$$

Should Eq. (4) apply for several magnetic substates, $\alpha_z(m_J)$ for each substate can be determined separately.

It can readily be shown that the polarizability tensors of all the substates can be uniquely expressed in terms of the effective polarizabilities of the $m_J=+1$ and $m_J=+2$ substates. Thus,

$$\begin{aligned}\alpha_z(0)&=\tfrac{1}{3}[4\alpha_z(+1)-\alpha_z(+2)],\\ \alpha_x(0)&=\tfrac{1}{3}[\alpha_z(+1)+2\alpha_z(+2)],\\ \alpha_x(\pm 1)&=\tfrac{1}{2}[\alpha_z(+1)+\alpha_z(+2)],\\ \alpha_z(\pm 2)&=\alpha_z(+1),\\ \alpha_z(m_J)&=\alpha_y(m_J).\end{aligned} \quad (5)$$

Note that $\bar{\alpha}_x=\bar{\alpha}_y=\bar{\alpha}_z$, where $\bar{\alpha}_x$ is the x component of the polarizability tensor averaged over the five magnetic substates, etc.

[7] E. U. Condon and G. H. Shortley, *The Theory of Atomic Spectra* (Cambridge University Press, Cambridge, England, 1951). The tensor polarizability is defined on p. 106. Eqs. (2a) and (2b) are obtained by using the T-operator properties tabulated in Eq. (11), p. 63.

Because of the assumed congruency of the electric and magnetic fields, we may write $\delta H/\delta z=kH$ and $\delta E/\delta z=kE$, where k is a geometry factor. Substituting for the gradients in terms of the fields, the balance condition, Eq. (4), can be rewritten as

$$\alpha_z(m_J)=\mu_{\rm eff}(m_J)H/E^2. \quad (6)$$

The measurement of $\alpha_z(m_J)$ is therefore independent of velocity, and specific values of the field gradients and geometry, except in the determination of E from the applied voltage. H can be accurately determined by means of a "zero-moment" experiment,[8] and $\mu_{\rm eff}(H)$ is an accurately known function of H.

Relative measurements, using a normalizing element whose polarizability is known, can also be performed. In the present work, $\alpha_z(1)$ and $\alpha_z(2)$ of metastable $^3P_2$ argon were measured in terms of the polarizability of metastable $^3S_1$ helium, which has been calculated[9] (46.6×10^{-24} cm^3) to an accuracy of about 1%. Substituting for the magnetic field in terms of α(He) in Eq. (6) we obtain

$$\alpha_z(m_J)=\mu_{\rm eff}(m_J)/2\mu_0(V_{\rm He}/V)^2\alpha({\rm He}), \quad (7)$$

where μ_0 is the Bohr magneton, $V_{\rm He}$ is the voltage at balance for metastable helium and V is the voltage balance for the argon substate.

Although the balance condition is valid for beams of infinitesimal width, Salop *et al.*[3] have shown that it is a good approximation for the narrow beams used in the present experiment.

APPARATUS

Figure 1 is a schematic diagram of the apparatus. The metastable beam is formed by effusion of argon into a region where it is cross fired by an electron beam. It then passes through a narrow collimator into the $E-H$ field region, and is finally incident upon a tungsten surface which serves as the cathode of a Bendix electron multiplier. The metastable $^3P_2$ and $^3P_0$ atoms are capable of ejecting electrons from the tungsten cathode, and these electrons are multiplied

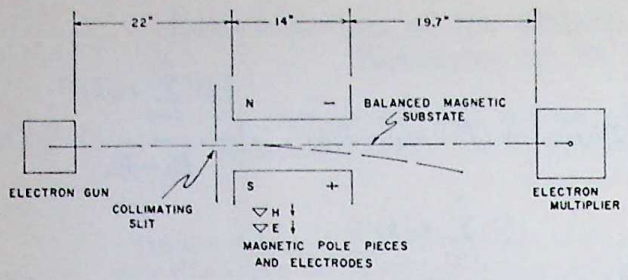

FIG. 1. Schematic diagram of the experiment.

and counted using a preamplifier and scalar. Metastable helium is produced and detected in a similar fashion.

The main chamber contains the magnet pole pieces, which also act as the electrodes for the inhomogeneous electric field. They are insulated from the magnet yoke by a rectangular glass tube which also serves as the vacuum envelope. The electric and magnetic fields between the pole pieces are congruent, since the boundary conditions which they obey are almost identical if the pole pieces are of high permeability and the magnetic fields are sufficiently low to avoid saturation effects.

The pole pieces are 14 in. long, and the ratio of gradient to field is 2.5 cm^{-1} at the beam position, and the gap width is 0.056 in. The beam height as well as its location relative to the pole pieces was fixed by a 0.002-in. $\times$0.050-in. collimating slit mounted directly in front of the pole pieces, at a distance of 0.025 in. from the convex edge. A beam-height limiter 0.060 in. high was mounted at the detector end of the pole piece assembly.

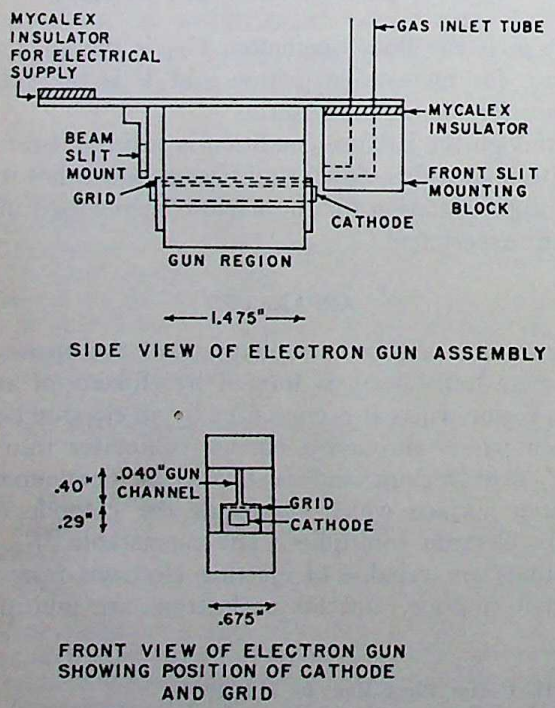

FIG. 2. The electron gun used for metastable production.

A Sensitive Research electrostatic voltmeter was used to measure the applied voltage. Prior to being put into service, its calibration was checked at the National Bureau of Standards. Subsequent calibrations were performed by the manufacturer. The instrument maintained its calibration to within 0.1% throughout the course of the present work.

Figure 2 shows two views of the electron gun.[10]

The gun makes use of a Philips type A cathode, which stands up comparatively well to ion bombardment which results from its operation. The entire gun is mounted between the pole faces of a magnet which produces a field of approximately 1000 G parallel to the electron beam. Recoil broadening was essentially eliminated by the use of a 0.002 in. wide slit mounted at the beam exit of the gun.

The usual operating voltages were 23 V for argon and 26 V for helium, with a current of about 30 mA. At these potentials the photon background was negligible, although it rose rapidly with increasing voltage. For example, at 30 V using argon, about 6% of the detected beam was due to photons. The full beam intensities were typically about 1000 and 200 cpm for argon and helium, respectively. Dark current noise from the multiplier corresponded to only several cpm and so reasonable signal-to-noise was achieved by counting for several minutes, at each pair of E and H field values.

MEASUREMENTS

Measurements were made of the beam intensity as a function of voltage across the electrodes, for a fixed value of magnetic field. Figure 3 presents such a run taken with argon at a field of approximately 260 G. The beam intensity when $V=0$ is due primarily to those atoms with $\mu_{eff}=0$, namely, those in the $^3P_0$ metastable state, and those with $m_J=0$ in the $^3P_2$ metastable state. As voltage is applied across the pole pieces, the beam intensity decreases at first as the atoms without magnetic moment are deflected out by the electric field. The first peak is in balance at about 11 kV and the second peak at 17 kV, and any further increase in voltage results in a monotonically decreasing beam intensity. The curve shape is similar to that of a "zero-moment" curve.[7] Figure 4 shows the region of the single peak for a similar experiment performed with metastable helium at a magnetic field of about 300 G.

Values of the polarizability ratio for the $m_J=+1$ and $m_J=+2$ substates of argon are obtained using a

[10] In the early stages of the experiment an rf discharge was used for metastable production instead of the electron beam. The discharge was pulsed, and a suitably timed gate circuit was used to discriminate the detector against prompt-arrival photons, in favor of the more slowly traveling metastables. Further development of this method was forestalled by satisfactory operation of the electron gun. Nevertheless, the pulse discharge could certainly be improved, and may ultimately prove superior to the gun method in some cases.

modified form of Eq. (7). Thus,

$$\alpha_z(+1)/\alpha_z(+2)=\tfrac{1}{2}(V_2/V_1)^2, \quad (8)$$

where the subscripts specify the substates. Absolute values, normalized to helium are

$$\alpha_z(+1)=\tfrac{1}{2}(1.5)(V_{\mathrm{He}}/V_1)^2\times 46.6\times 10^{-24}\ \mathrm{cm}^3, \quad (9)$$

$$\alpha_z(+2)=\tfrac{3}{2}(V_{\mathrm{He}}/V_2)^2\times 46.6\times 10^{-24}\ \mathrm{cm}^3. \quad (10)$$

The data are sufficient to determine $\alpha_z(m_J)$ only if the magnetic substates associated with the several peaks can be definitely identified. For example, from the positions of the peak in Fig. 3, a ratio $\alpha_{1z}/\alpha_{2z}\approx 1$ can be inferred if α_{1z} represents the $m_J=+1$ substate or $\alpha_{1z}/\alpha_{2z}\approx\frac{1}{4}$ if α_{1z} represent the $m_J=+2$ substate. (Here, the subscripts 1 and 2 refer to the peaks occurring at the lower and higher voltages, respectively.) It is very unlikely that the ratio should differ greatly from unity,

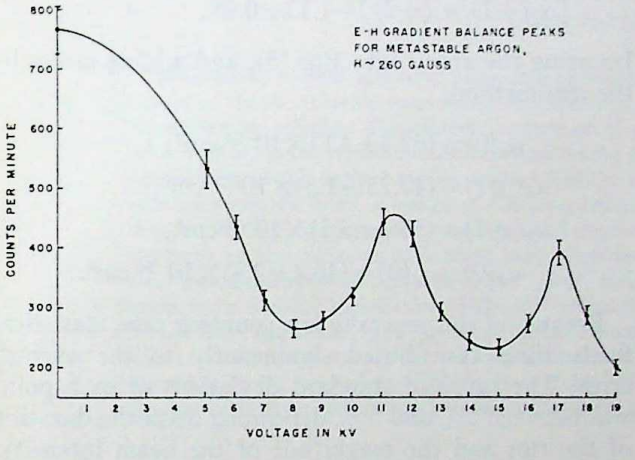

FIG. 3. Beam intensity as a function of applied voltage for metastable argon, at a magnetic field of about 260 G.

since the valence electron, which contributes the principal amount to the polarizability, is in an s state. Nevertheless, a subsidiary experiment was performed in order to definitely identify the substates.

The first peak was brought into balance at a magnetic field of about 260 G and a voltage of 11.1 kV. A beam profile was taken for the balanced substate in steps of 0.001 in. about the beam maximum. The voltage was then dropped to 9.9 kV and a similar profile taken. These two profiles are shown in Fig. 5 The apparatus as used here functioned as a substate selector, and in addition as a relatively crude deflection polarizability spectrometer. A similar deflection experiment was performed on the second balance peak. Beam profiles at balance and at 1.2 kV below balance were taken. Figure 6 shows the results of the second deflection experiment.

An atom experiencing a constant force F transverse to its direction of motion in an atomic beam undergoes a deflection $s=c'F/v^2$, where c' is a constant and v is the

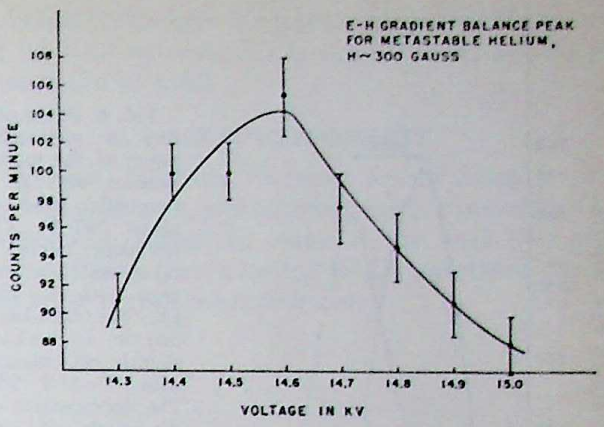

FIG. 4. Beam intensity as a function of applied voltage for metastable helium in the vicinity of the single-balance peak, at a magnetic field of about 300 G.

speed of the atom. In the deflection experiment just described, F is proportional to $\alpha_z(E_0+\delta E)^2-\mu_{\mathrm{eff}}H_0$, where E_0 and H_0 are the balance electric and magnetic fields, and δE, the change in electric field. Dropping the second-order term, F is proportional simply to $\alpha_z E_0\delta E$, or $s=c\alpha_z E_0/v^2$, where c is a constant which includes the δE.

Since δE is the same for the first and second deflection experiments, the ratio of the deflections is given by

$$s_1/s_2=(\alpha_{1z}/\alpha_{2z})(V_1/V_2).$$

Now it can be shown[11] that for deflections small compared to the detector width, a triangular beam is dis-

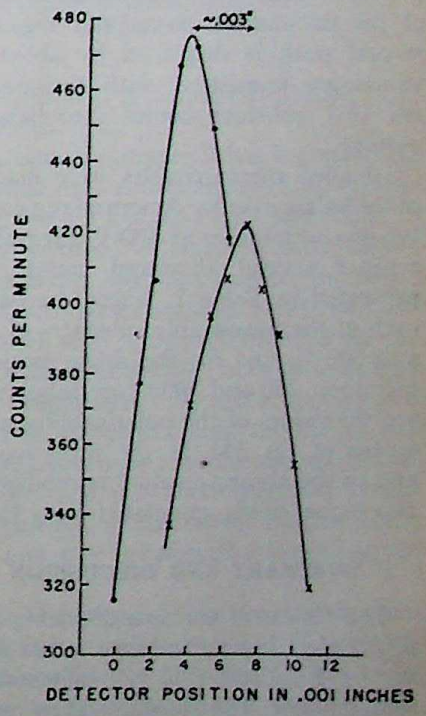

FIG. 5. Beam profiles for metastable argon of the first balance peak, at a magnetic field of about 260 G. The left-hand curve is taken exactly at balance $V=11.1$ kV. The right-hand curve is taken slightly off balance with $V=9.9$ kV. The displacement of the peak of approximately 0.003 in. represents a rough measurement of the polarizability, and therefore serves to identify the balanced substate as $m_J=+1$.

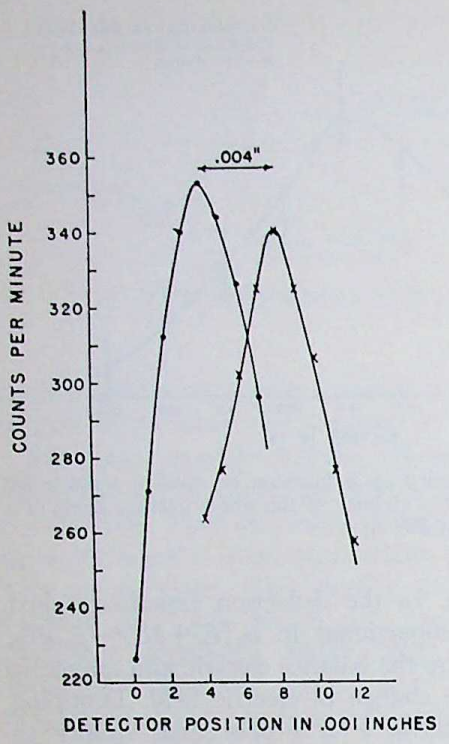

FIG. 6. Beam profiles for metastable argon of the second balance peak at a magnetic field of about 260 G. The left-hand curve is taken exactly at balance with $V=16.9$ kV. The right-hand curve is taken slightly off balance, with $V=15.7$ kV. The displacement of the peak of approximately 0.004 in. represents a rough measurement of the polarizability and therefore serves to identify the balanced substate as $m_J=+2$.

placed with an unaltered profile. That is, velocity broadening of the beam shape is negligible. Our deflections are actually comparable to the beam width, so that some velocity broadening should occur. Nevertheless, the beam shape will be only slightly altered, and it should be possible to determine whether the ratio is of the order of unity or four. Figure 5 shows that the first peak is displaced by approximately 0.003 in. as a result of the unbalanced force, and Fig. 6 shows that the second peak is displaced by about 0.004 in. These values are consistent with the assumption that the $m_J=+1$ substate comes into balance at the lower voltage.

Detailed measurements were made in the vicinity of the balance peaks. A normal run consisted of counting for several minutes at 100-V intervals, usually so as to register several thousand counts. The results are presented in Table I, where the balance voltages for each of the measurable substates of argon at 200, 260, and 300 G, and for the single measurable substate of helium at 260 and 300 G are tabulated. Also tabulated are the values of the polarizability ratios calculated by means of Eq. (8), at the three magnetic fields used, and of the absolute values normalized to helium at the two higher fields, calculated using Eqs. (9) and (10).

SUMMARY AND DISCUSSION OF RESULTS

The results of our measurements of the z component of the electric polarizability tensor of the $m_J=+1$ and $m_J=+2$ substates of $^3P_2$ metastable argon are presented below. The absolute values represent a combined average of the results taken at magnetic fields of 260 and 300 G. The ratio measurement represents a

TABLE I. Summary of experimental results.

Approximate magnetic field (gauss)	Balance voltage (kV)	Magnetic substate and element	$\alpha_z(m_J)$	$\alpha_z(+1)/\alpha_z(+2)$
200	9.9	+1(Ar)		1.13
200	14.9	+2(Ar)		
260	11.2	+1(Ar)	51.5	1.14
260	16.9	+2(Ar)	45.3	
260	13.6	+1(He)		
300	12.3	+1(Ar)	49.3	1.13
300	18.5	+2(Ar)	43.8	
300	14.6	+1(He)	(46.6)[a]	

[a] Calculated by Schwartz and Dalgarno (see Ref. 8).

combined average of the results taken at magnetic fields of 200, 260, and 300 G. We find

$$\alpha_z(+1)=(50.4\pm3.5)\times10^{-24}\ \text{cm}^3,$$
$$\alpha_z(+2)=(44.5\pm3.1)\times10^{-24}\ \text{cm}^3,$$
$$[\alpha_z(+1)/\alpha_z(+2)]=1.13\pm0.08.$$

Inserting the above into Eq. (5), and adding errors by the rms method,

$$\alpha_z(0)=(52.4\pm4.8)\times10^{-24}\ \text{cm}^3,$$
$$\alpha_x(\pm1)=(47.25\pm2.3)\times10^{-24}\ \text{cm}^3,$$
$$\alpha_x(\pm2)=(50.4\pm3.5)\times10^{-24}\ \text{cm}^3,$$
$$\alpha_x(0)=\alpha_y(0)=(46.4\pm2.4)\times10^{-24}\ \text{cm}^3.$$

Because of the generally low counting rate, statistical fluctuations contributed significantly to the over-all error. The range of standard deviations of each point was between 1% and 3%, depending upon the duration of the run and the magnitude of the beam intensity, with the helium data usually having the larger deviations. However, the argon peaks were somewhat broader than the helium peaks, owing to the greater overlapping of the three substates $m_J=+2, +1, 0$ of $^3P_2$ argon, combined with the presence of the single substate of $^3P_0$ argon, as compared to the presence of the two substates $m_J=+1, 0$ of the $^3S_1$ state of helium, combined with the presence of the single substate of $^1S_0$.

Among the other causes of experimental error are the following: an apparent shift in the balance peak due to fast atoms from unbalanced substates; fluctuations of electron gun current, source pressure, and magnetic and electric fields during the course of a run; measurement of the voltage using the NBS calibrated voltmeter; lack of perfect parallelism of the beam with respect to the pole face; and deviations from the balance condition over the finite beam width. A detailed discussion of most of these errors is contained in Ref. 3.

We make an over-all assignment of $\pm7\%$ to the error in measuring $\alpha_z(+1)$ and $\alpha_z(+2)$, based upon conservative estimates of the above error sources.

It was to be expected that the polarizabilities of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

$^3P_2$ argon would be quite large, since its structure is grossly similar to that of ground-state potassium, which has a polarizability of about 36×10^{-24} cm^3. Further, since the valence electron contributes the major amount to the polarizability, the polarizability ratio $\alpha_z(+1)/\alpha_z(+2)$ should be quite close to unity. (The valence electron is in an s state.)

The P configuration of the atom is due to the five p electrons of the incomplete M shell, whose contribution to the polarizability should therefore contain a strong anisotropy. However, since the contribution of the core to the total polarizability is small, the net anisotropy should also be small.

ACKNOWLEDGMENTS

We wish to thank Professor Arthur Salop for his continued interest, and for many useful discussions and suggestions during the course of the work. We also wish to thank Judah Levine for his assistance during the latter part of the experiment.

PHYSICAL REVIEW VOLUME 134, NUMBER 5A 1 JUNE 1964

Studies of the Mechanism of Electron-Ion Recombination. II

WILLIAM A. ROGERS* AND MANFRED A. BIONDI†
Westinghouse Research Laboratories, Pittsburgh, Pennsylvania
(Received 13 January 1964)

Microwave, optical spectrometric, and interferometric techniques have been used to investigate the nature of the electron-ion recombination process in low-pressure, pure helium afterglows at 300 and 77°K. To determine whether dissociative capture of electrons by helium molecular ions, i.e., $He_2^+ + e \rightarrow He^* + He + (KE)$, is the recombination reaction taking place, we have attempted to detect the kinetic energy of dissociation of the excited atoms produced in the recombination process by a study of the widths of the emitted afterglow lines. A model of the low-pressure helium afterglow which reasonably accounts for our electron density, line intensity, and linewidth observations involves principally the creation of He^+ ions and electrons by the collisions of pairs of helium metastable atoms, the three-body conversion of He^+ ions to He_2^+ ions, the ambipolar diffusion of He^+, He_2^+, and electrons, and the diffusion of helium metastable atoms to the walls. The λ5876 radiation (3^3D-2^3P transition) from the later part of the afterglow, when recombination of He_2^+ and electrons is expected to be the source of the excited atoms, exhibits a substantial broadening over the approximately thermal width observed during the discharge and in the early afterglow, when the radiation is expected to originate from electron impact excitation of helium atoms. It is concluded that the dissociative recombination process is the likely source of the observed afterglow line broadening.

I. INTRODUCTION

NUMEROUS experimental studies of the afterglows of pulsed microwave discharges[1–4] have shown that volume electron-ion recombination appears to be an important or dominating process in the removal of free electrons from ionized gases for several different gases. The principal technique in these experiments has involved the determination of spatially averaged electron densities during the afterglow by means of microwave probing techniques (see part I of this paper,[5] hereinafter referred to as I) and an analysis of the time dependence in terms of solutions of the equation of continuity for electrons subject to losses by recombination and diffusion. This analysis, as commonly employed, is outlined in Eqs. (3)–(6) of I.

In the rare gases neon and argon, it has been possible to obtain experimental data consistent with the recombination solution, $1/n_e=[1/n_e(0)]+\alpha t$, and thus to evaluate the recombination coefficient α with reasonable precision. In helium, however, due to the larger ratio of diffusion loss to recombination loss it has not been possible to obtain such a clear distinction. In addition, the helium measurements have been complicated by the fact that at pressures of only a few mm Hg the atomic spectra, which are presumably related to the recombination process, give way to molecular spectra of excited He_2. Thus, serious doubts have been cast on the validity of measurements of the recombination coefficient in helium by means of the afterglow time dependence studies.[6]

By means of a set of controlled mixture experiments in helium and argon, it has been shown (see I) that the large recombination coefficients observed in the pure gases do not appear under circumstances that inhibit

the formation of diatomic molecular ions, thus supporting the hypothesis of Bates[7] that the process under observation is the dissociative recombination of molecular ions with electrons in the reaction,

$$X_2^+ + e \rightarrow X^* + X + \text{kinetic energy}. \quad (1)$$

This naturally leads to the supposition that the same process is responsible for any large recombination loss occurring in moderate-pressure helium afterglows.

The purpose of the experiments reported in this paper has been (a) to establish definitely the presence or absence of the dissociative recombination process in pure helium afterglows at low pressures (2 mm Hg or less) by a technique which avoids the complexity and uncertainty of interpretation inherent in the microwave electron-density determinations under mixed diffusion and recombination conditions, and (b) to provide an estimate of the magnitude of the recombination coefficient, if possible. The principal new technique introduced is the interferometric measurement of the intensity profile of an optical emission line of the helium atomic spectrum.

The significance of this measurement can be understood by reference to Fig. 1 and to Eq. (1) and from the following considerations. The dissociative process can be efficient only if it is exothermic, i.e., the transition from the bound state A to the dissociated state B must be accompanied by the conversion of potential energy into kinetic energy in a significant amount. This converted energy is shown as the vertical scaled length E_D in the figure. The kinetic energy so produced is shared by the fragments which fly out from the dissociating system. In the case of a homonuclear diatomic molecule, this energy of dissociation E_D is shared equally by the two identical atoms. Also, in the case of helium, the relative energies of the molecular-ion ground state and the molecular and atomic states are such that one of the atoms will almost certainly be produced in an electronically excited state.

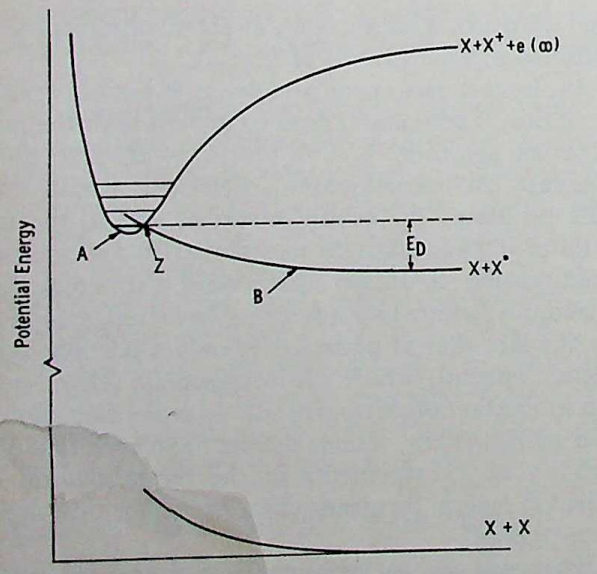

FIG. 1. Schematic representation of the interatomic potential curves of interest in the dissociative recombination of X_2^+ ions with electrons. The upper potential curve is that for a molecular ion and an electron at rest at infinity.

[7] D. R. Bates, Phys. Rev. 77, 718 (1950); 78, 492 (1950); 82, 103 (1951).

If this excited atom is produced in a radiating state of sufficiently short lifetime, it can be expected to radiate some of its excitation energy before it has time either to lose its kinetic energy through collisions or to lose its excitation energy by resonant transfer to a slowly moving atom. If the atom does radiate before experiencing energy loss of either kind, the emitted photon will be shifted from its normal wavelength by the Doppler effect due to the atomic velocity. Since there is no preferred direction for dissociation, the velocities of the dissociating atoms will be randomly directed, and consequently, the observed effect will be a Doppler broadening of the atomic spectral line in excess of the broadening due to the temperature of the molecular ions by an amount corresponding to the kinetic energy $E_D/2$. The direct observation of such anomalous line broadening may be taken as positive evidence of the predominance of the dissociative recombination process in the production of the afterglow emission spectrum.

For this type of measurement helium has been chosen, rather than neon or argon, primarily because of the simplicity of its optical spectrum and the short lifetimes of some of the radiating states. Since the analysis involves considerable computation, a single line (λ5876, corresponding to the transition $3\,^3D$–$2\,^3P$) has been chosen for study.

The linewidth studies have been correlated with electron-density measurements and with time-resolved emission spectra. In addition to the recombination study itself, attention has been given to the early part of the afterglow preceding the "recombination" period which has been the subject of most previous investigations. An attempt has been made to formulate a complete model of the afterglow processes for a simple case.

II. EXPERIMENTAL SYSTEM

The complete experimental arrangement is shown diagrammatically in Fig. 2, except for the ultrahigh-vaccum gas handling system. The apparatus shown may be regarded as comprising three main units: microwave, spectrometer, and interferometer systems.

A. Microwave System

At the center of the figure is the microwave resonant cavity which encloses the discharge vessel and has hollow walls which may be filled with liquid nitrogen. A repeated, pulsed discharge is produced in the quartz discharge vessel by power from the magnetron. Following this pulse a very low power probing signal is applied from the klystron. Power reflected from the cavity

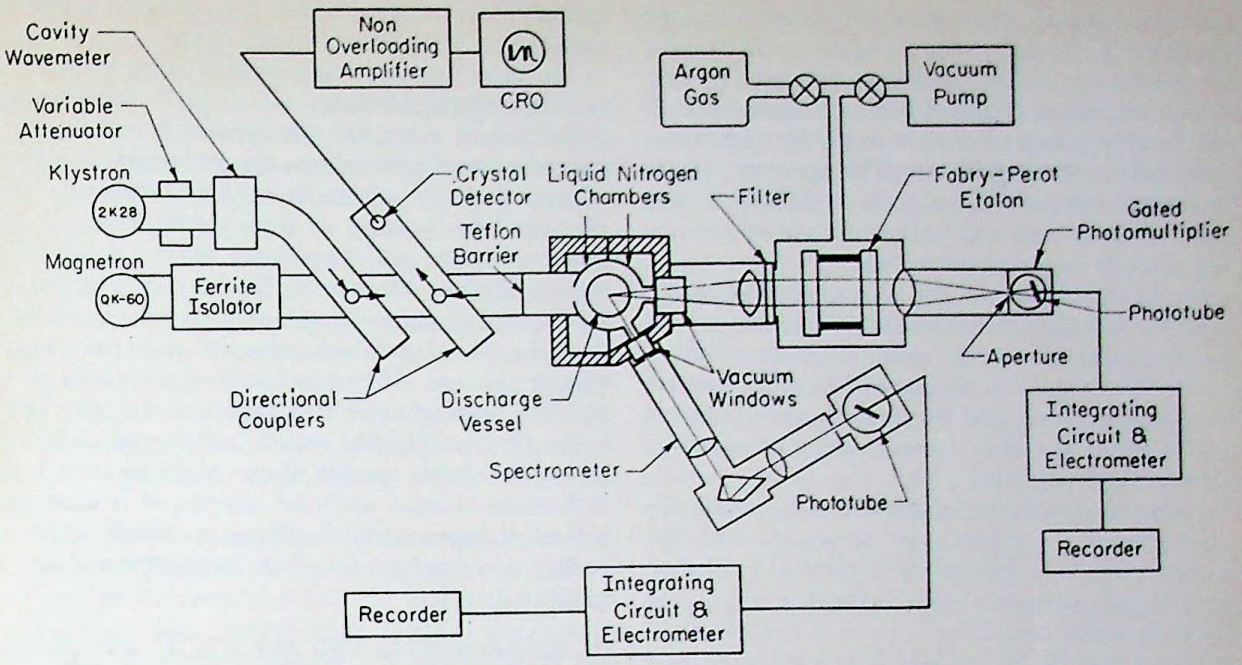

FIG. 2. Block diagram of the combined microwave, optical spectrometric, and optical interferometric systems used to study afterglows.

resonator is detected by the crystal detector and passed through an amplifier, which suppresses the strong magnetron pulse. The resulting signal is displayed on a synchronized oscilloscope.

B. Spectrometer System

A spectrometer port is provided by a narrow slit which tunnels through the double wall of the cavity resonator and an evacuated double glass window which tunnels through the foam insulation. The spectrometer has a synchronous prism table drive motor and an electronically gated multiplier phototube detector, whose output goes to an integrating filter, dc electrometer and synchronously driven strip chart recorder.

C. Interferometer System

A second small opening in the cavity wall, similar to the spectrometer port but circular in cross section, provides a port for the Fabry-Perot etalon. The etalon and detection system used here[8] is similar in principle to that used by Jacquinot and Dufour.[9] It is illustrated in more detail in Fig. 3.

The mechanical support and adjustment of the etalon plates (F) is provided by means of a conventional arrangement of invar spacers (G) and spring mounted compression pins (H) similar to those described in textbooks,[10] with modifications as required to permit operation through the walls of the evacuated housing (C). The photoelectric detection, integrating, and recording system is identical with that of the spectrometer system.

In use the etalon, Fig. 3, is placed so that the focal plane of the collimating lens (A) is near the center of the microwave cavity, i.e., in the middle of the discharge. The collimated beam passes from the lens through a glass color filter and multilayer interference filter (B),

through the optically clear vacuum window (D), the etalon plates (F), and the vacuum window and focusing lens (L). Here it is focused on an opaque disk (N) having in it a circular aperture of 0.051 cm diam which is centered on the interference pattern by the micrometer carriages (M) to within 0.001 cm. This aperture permits a very limited angular range of incident light, including a portion of the central spot of the interference pattern, to pass through to the photocathode.

From simple considerations of geometrical optics, one can calculate the luminous flux reaching the cathode of the multiplier phototube, assuming lossless optical elements. This calculation, together with rough measures of the absorption losses and the photocathode quantum efficiency, forms the basis for estimating absolute intensities in the afterglow.

The observed resolution of the etalon in practice is two parts in 10^6, in approximate agreement with the calculated value. The experimental value of resolution is based on measurements made (a) with a microwave discharge in argon containing a trace of isotopic Hg^{202} using the narrow Hg line at 5461 Å as a standard, and (b) on the assumption that the smallest attainable values of linewidth in helium are due solely to thermal Doppler broadening corresponding to the ambient temperature. The values deduced by the two different methods are in good agreement.

A wavelength scanning system with linear time base is provided for the etalon by continuously increasing the refractive index μ in the space between the etalon plates (see Fig. 2). This is achieved by first evacuating the interior of the sealed etalon housing with a vacuum pump to provide a starting point and then admitting gas through a preset needle valve connected to a source of argon at 200 atm pressure. The gas density in the etalon rises slowly from zero to slightly over one atmosphere, at which point further increase is interrupted by the opening of a safety valve. This system offers a uniform scanning rate over approximately 10 fringes. Since the synchronous motor drive on the recorder provides a linear time base for the chart paper, one obtains a linear presentation of intensity as a function of frequency (wavelength) within each interference order, thus giving us the desired line shapes directly.

D. Vacuum System

The gas is admitted to and removed from the quartz discharge vessel through a small bore tube which passes directly out of the cavity resonator through a close fitting hole at the upper end of the cavity axis. Through this tube the discharge vessel is connected to an ultrahigh-vacuum gas handling system[11] with a bakeable oil manometer[12] and a copper isolation trap.[13] The discharge vessel itself is isolated from the rest of the vacuum system by a liquid-nitrogen trap.

The helium gas for these experiments is prepared by distillation from the liquid into 1-l gas flasks. The flasks, connected to a special glass manifold which can be opened under liquid helium, are first prepared by being outgassed under ultrahigh-vacuum conditions; then the manifold is sealed off from the outgassing system under vacuum and transferred to the liquid-helium storage Dewar. After being filled by distillation from the liquid helium, the flasks are individually sealed off from the special manifold and sealed on to the operating vacuum system. After a bake-out of the whole system at 400°C overnight and the attainment of a vacuum level below 10^{-9} mm Hg, the sealed flask is opened. By comparison of visible spectra of our prepared pure helium with those of mass analyzed samples of reagent grade helium, it appears that in all gas samples used the impurity level has been less than one part in 10^7 and too small to detect.

III. EXPERIMENTAL AND ANALYTICAL PROCEDURES

A. Microwave Procedures

The average electron density as a function of time is determined by the technique of microwave reflection from the cavity resonator. This technique has been discussed in detail elsewhere and will not be reviewed here.[14]

In view of the high Q of the cavity resonator, it is not surprising that the growth of the discharge in response to the applied power should be quite complicated. The initial conditions of the afterglow seem to be most sensitive to the length of the power pulse and less sensitive to the repetition rate and power delivered from the magnetron. With the magnetron frequency set slightly above the resonant frequency of the cavity without discharge, the buildup of plasma density during the power pulse shifts the cavity resonance through the magnetron frequency to a higher frequency, at which point further increase in plasma density is prevented by the self-detuning of the cavity toward still higher frequencies. Observations have shown that in this system the discharge has passed through a maximum of light output and settled down to approximately the steady-state emission rate after about 40 μsec. Therefore, this value of the pulse duration has been set as an arbitrary standard for most of the experiments. Experience also showed that an afterglow period of about 2 msec is the least time in which the essential features of the time-dependent afterglow processes can be exhibited and, therefore, this has been used as the pulse repetition interval in most of the experiments.

B. Spectrometric Procedures

Using the high-speed optical spectrometer with gated multiplier phototube and recorder, comparisons have

been made of the intensities of several atomic lines at various times in the afterglow. The synchronous motor drives on the chart recorder and the spectrometer prism table provide a direct conversion of wavelength to chart length scale. By setting the electronic gate to any desired duration and to any desired onset delay relative to the end of the discharge, the afterglow spectrum has been recorded during each of several short periods (durations of 50–500 μsec) in the afterglow. Also, by stopping the prism table drive on the peak of any desired line and periodically changing the onset delay time of the gate, the time dependences of several individual lines have been traced. Attention was centered mainly on the diffuse series lines λ4472 and λ4922 ($4D$-$2P$) and λ5876 and λ6678 ($3D$-$2P$), although other lines of the sharp, principal, and diffuse series were also monitored.

Even at the low pressures of these experiments the spectrometer indicates the presence of some helium molecular-band intensity, which the etalon cannot resolve but shows as a "white" background to the desired atomic line emission. Therefore, the spectrometer has been used to determine the relative strengths of the bands that fall within the transmission range of the multilayer interference filter used with the etalon. The transmission of the interference filter together with its associated color filter was determined by comparing the spectrum of an incandescent lamp with and without interposition of the filter. Although the spectrometer does not resolve detailed structure of the bands and records atomic lines only as impulses whose shapes are fixed by the time constant of the electronic integrating circuit, the relative total strength (intensity integrated over wavelength range) of a band to a line is given by the ratio of the areas under the respective recorded contours. This information has been used to correct for the apparent line broadening which would result from the superposition of the band radiation on that of the line recorded by the etalon.

C. Linewidth Measurements with the Etalon

Several factors enter into the production of the observed atomic linewidth. Some of these factors are analytically separable; some must be treated as they appear. We now outline the analysis in terms of which the line broadening measurements are interpreted.

1. Single Component Line Shape due to Temperature and Dissociative Recombination

We assume that line broadening is entirely due to Doppler effects arising from temperature motion and from dissociation of the excited molecule. The kinetic-energy distribution of the diatomic ions is assumed to be Maxwellian at the gas temperature, so that it may be written

$$F_0(v)=(\beta/\pi)^{3/2}\exp(-\beta v^2), \qquad (2)$$

where $\beta=M/kT$, M being the mass of a single helium atom. The problem is further simplified by assuming that all dissociations leading to a given excited atomic state originate in a single specific molecular configuration, and, therefore, release a definite total kinetic energy E_D which is shared equally by the two dissociating atoms. Thus, the speed of the excited atom relative to the center of mass of the diatomic ions is $v_1=(E_D/M)^{1/2}$. The direction taken by the atom is assumed to be randomly oriented with respect to the observer, so the distribution F_1 in velocity relative to the center of mass is simply a unit impulse function (δ function) of speed at v_1.

For the computation of Doppler shift we are interested only in the distribution in speed along the observer's line of sight (the z axis). For the thermal distribution we get by integration over the x-y plane

$$F_0(v_z)=(\beta/\pi)^{1/2}\exp(-\beta v_z^2), \qquad (3)$$

while the integration of F_1 over the x-y plane yields

$$F_1(v_z)=1/2v_1 \qquad (4)$$

for $-v_1\leqslant v_z\leqslant v_1$ and zero elsewhere.

The two distributions F_0 and F_1 are combined in the following way. For every v_z' at which atoms are repelled from the center of mass there is a complete Maxwellian distribution of velocities of the center of mass, giving rise to a group of atoms having a Maxwellian distribution centered on the value v_z'. That is, the number of atoms in the speed range dv_z' at v_z-v_z' is

$$dG=F_0(v_z-v_z')F_1(v_z')dv_z'. \qquad (5)$$

The total resultant distribution in v_z is then obtained by integrating Eq. (5) over the entire range of v_z'. If we first substitute for v everywhere the corresponding Doppler wave number shift, $\tilde{\nu}=\tilde{\nu}_0 v/c$, and simplify notation by putting $a=(Mc^2/kT)^{1/2}/\nu_0$ and $b=(E_D/kT)^{1/2}$, we obtain as the resultant intensity contour (normalized to unit area)

$$G(\tilde{\nu})=(a/4b)[\mathrm{erf}(a\tilde{\nu}+b)-\mathrm{erf}(a\tilde{\nu}-b)]. \qquad (6)$$

Analysis of $G(\tilde{\nu})$ shows that at the center of the line ($\tilde{\nu}$ much smaller than $\tilde{\nu}_1\equiv\tilde{\nu}_0 v_1/c$) the slope of $G(\tilde{\nu})$ equals the slope of $F_0(\tilde{\nu})$ multiplied by $\exp(-E_D/kT)$. If E_D is reasonably large compared to kT, the line shape $G(\tilde{\nu})$ will be tend to become very flat topped.

2. Instrumental Broadening of the Single Component Line

The fringe shape for monochromatic light of wave number $\tilde{\nu}$ passing through an etalon at normal incidence is given by Airy's formula[10]

$$I=T^2(1-R)^{-2}[1+K\sin^2(2\pi\mu l\tilde{\nu})]^{-1}, \qquad (7)$$

where T is the transmission and R the reflectivity of the coatings on the etalon plates, μ is the index of refraction of the medium between the plates, l the plate

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

spacing, and $K=4R/(1-R)^2$. For present purposes we will omit the intensity reduction factor $T^2(1-R)^{-2}$ and write for the normalized etalon transmission function,

$$H(f)=(1+K\sin^2\pi f)^{-1}, \tag{8}$$

in which $f=2\mu t\bar{\nu}$. The quantity f is the interference order number; it is used here as a dimensionless frequency variable measured in units of the free spectral range of the etalon. This is a simple scale change, which does not alter the form of G, Eq. (6), and provides a convenient unit for discussion of the etalon measurements.

The line shape resulting from the transmission of the line $G(f)$ through the etalon is obtained by considering the line as the superposition of fringes of all the monochromatic elements whose integral over frequency constitutes $G(f)$. Thus, if the etalon is set or "tuned" for a frequency f (i.e., the interference order is integral for f), then light at frequency f' produces a fringe intensity contribution of $G(f')H(f-f')df'$. The total resultant intensity transmitted at a given etalon setting is then

$$\phi(f)=\int_0^\infty G(f')H(f-f')df'. \tag{9}$$

This integral requires numerical computation. It has been computed at intervals of $f=0.01$ for several values of T and E_D, initially by manual tabulation and then more extensively by the computer facility of the Mathematics Department of the Westinghouse Research Laboratories. From the results so obtained, it was evident that no simple procedure would satisfactorily separate the instrumental contribution from the actual line broadening. For this reason the computed over-all profiles are compared directly with the observed total linewidths.

3. *Choice of the λ5876 Line and the Shape of the Triplet Line in the Etalon*

Although the singlet lines offer the obvious advantage of simplicity in their lack of fine structure, the λ5876 ($3\,^3D-2\,^3P$) line was selected because it has the shortest lifetime among all the visible transitions ($\tau_{\text{rad}}=1.34\times10^{-8}$ sec), is well isolated from neighboring lines, is known to be a bright line in low-pressure afterglows, and is in a wavelength region suited to available photoelectric tubes. Moreover, its terminal state, $2\,^3P$, is itself a radiating state and, therefore, not sufficiently populated to cause any spurious broadening by self-absorption. The high radiative transition rate of nearly 10^8 sec^{-1} was initially considered necessary to assure a high probability of radiation prior to excitation transfer or kinetic energy loss by collisions, which have been estimated to occur at a rate of the order of 10^8 per second at a pressure of one mm Hg. Thus, measurements of line shapes have been carried out at pressures of a few mm Hg or less.

An analysis of the structure of the λ5876 line had been made by Brochard *et al.*[15] using an etalon and a helium source cooled in liquid helium. Their results have been adopted as a basis for the construction of the expected line shapes. In our experiments it is not possible to separate each of the six components of the line because of temperature broadening. The etalon-free spectral range has been chosen to make the one separable component appear as a satellite one and one-half orders removed from the main peak composed of the other five. The fringe contributions of all six have been added graphically over the range of interest in the main peak, and resulting widths at half-intensity have been measured from the composite graph for a variety of parameter values. The half-widths of these lines have been compared with actually observed half-widths to determine E_D.

4. *Spurious Line Broadening Effects*

In addition to the temperature and dissociative recombination line broadening effects, there are two principal spurious effects which may lead to an apparent broadening of the observed lines. These are (a) the presence of molecular band radiation in the light reaching the photocathode, and (b) the effect of electrical integrating networks between the phototube and the electrometer.

Any molecular band radiation which passes through the interference filter and the etalon may be assumed to consist of numerous rotational transition lines, a fact which is corroborated by the shapes of the molecular bands as recorded through the spectrometer. These rotation lines are spaced nonuniformly in frequency and irrationally with the etalon-free spectral range. Consequently, they overlap each other in a random fashion and form what may be regarded as "white" light. To compare the effect of band radiation with that of an isolated atomic line we make the simplifying assumption that the etalon transmission function $H(f)$ is periodic in f with unit period, is unity over a range f_e equal to the etalon half-width, and zero in the remainder of each unit range; that the atomic line intensity $G(f)$ is a constant A over a range f_a equal to the half-width of the line and zero elsewhere, f_a being larger than f_e but less than unity; and that the molecular band intensity is a constant B over a frequency range f_b which is much greater than unity and zero elsewhere. With these very simple line shapes it can be readily shown that the etalon reduces the ratio of total band radiation to line radiation by the factor f_a. Checks on this procedure by graphical area measurements on the carefully computed etalon-Doppler lines show that the simple theory is always conservative in that it overestimates the molecular background by about 10–30%. The effect of a white background on atomic line half-width measurements is to displace the apparent zero intensity reference of the line downward, causing the half-width

[15] J. Brochard *et al.*, J. Phys. Rad. 13, 433 (1952).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

to be measured too low on the line profile, thereby giving too large a value for the half-width. A correction for this effect has been made which is accurate for narrow lines and/or small "white" backgrounds and which overestimates the spurious broadening for wider lines and/or larger "white" backgrounds. Thus, the deduced linewidths in the presence of molecular light background are smaller than the actual widths.

The electrical integrating circuits necessary to suppress noise and to convert the time-gated sample signals into dc signals for amplification and recording place a limit on the speed with which the line profile may be scanned. In practice, if the circuits are characterized by a response time constant τ and the line profile is traced between half-intensity points in a time Δt, care is taken to assure that $\Delta t \gtrsim 5\tau$ for the narrowest line in a set of measurements, leading to a distortion of the recorded profile which increases the apparent line breadth by less than 2%. The error in measured width for broader lines, which take even longer to trace, is even smaller.

IV. MODEL OF THE AFTERGLOW

The variations of the measured electron densities, spectral intensities, and line shapes during the afterglow are sufficiently complicated that it is of considerable help to have in mind the relevant atomic-collision processes which contribute to their behavior. The following model of the afterglow is consistent with previous researches on helium[16–18] and with the observations obtained in the present studies.

At the low pressures (~1 mm Hg) and moderate container size (fundamental diffusion length, $\Lambda_1 = 0.735$ cm) used in these afterglow studies, the principal loss of the electrons, ions, and metastable atoms is by diffusion to the container walls. In addition, there is substantial production of electrons and atomic ions by collisions of pairs of metastable atoms,[19]

$$\mathrm{He}^M + \mathrm{He}^M \rightarrow \mathrm{He}^+ + e + \mathrm{He}. \qquad (10)$$

Since the excitation energy of the metastable state of the helium atom is ~20 eV and the ionization potential ~25 eV, the electrons produced by this reaction have ~15 eV kinetic energy. As will be discussed more fully later, it is to be expected that before this excess kinetic energy is completely dissipated by elastic collisions, there is a substantial probability that these electrons will collide with metastable atoms, raising them to higher, radiating states, i.e.,

$$\mathrm{He}^M + e(\mathrm{fast}) \rightarrow \mathrm{He}^* + e(\mathrm{slow}). \qquad (11)$$

[16] M. A. Biondi and S. C. Brown, Phys. Rev. 75, 1700 (1949).
[17] A. V. Phelps and S. C. Brown, Phys. Rev. 86, 102 (1952).
[18] A. V. Phelps and J. Molnar, Phys. Rev. 89, 1202 (1953); A. V. Phelps, *ibid.* 99, 1307 (1955).
[19] M. A. Biondi, Phys. Rev. 88, 660 (1952). Contrary to the conclusion of H. Myers, Phys. Rev. 130, 1639 (1963), available experimental evidence (Refs. 17–19) strongly supports the conclusion that metastable-metastable ionizing collisions lead to the production of *atomic*, rather than molecular, helium ions.

The atomic ions produced in the ionizing reaction, Eq. (10), are converted to molecular ions in three-body collisions,[17]

$$\mathrm{He}^+ + 2\mathrm{He} \rightarrow \mathrm{He}_2^+ + \mathrm{He}. \qquad (12)$$

While the major loss of molecular ions is by diffusion to the walls, dissociative recombination between molecular ions and electrons is expected to produce radiating atomic excited states according to the reaction

$$\mathrm{He}_2^+ + e \rightarrow \mathrm{He}^* + \mathrm{He}. \qquad (13)$$

If we neglect small terms in the equations governing the production and loss of the atomic ions and the molecular ions, we obtain the following approximate relationships:

$$\partial n_1/\partial t \simeq D_{a1}\nabla^2 n_1 - K_c n^2 n_1 + \beta_i n_m^2 \qquad (14)$$

and

$$\partial n_2/\partial t \simeq D_{a2}\nabla^2 n_2 + K_c n^2 n_1, \qquad (15)$$

where D_{a1} and D_{a2} are the ambipolar diffusion coefficients of the atomic and molecular ions of densities n_1 and n_2, respectively, n is the neutral atom density, n_m the metastable concentration, K_c the three-body conversion coefficient for reaction (12), and β_i is the two-body ionizing coefficient for metastable-metastable collisions, Eq. (10). It is assumed that the above equations apply to thermal energy particles, since the electron- and ion-energy decay times are short ($\lesssim 10$ μsec) compared to the time scale of the measurements.

Since the molecular-ion concentration remains small compared to the atomic-ion density throughout these low-pressure afterglows, we may take the electron density, $n_e \simeq n_1$. Also, at low pressures (<1 mm Hg) the metastable atoms decay principally by diffusion to the walls; thus, the third term on the right of Eq. (14) may be approximated by $\beta_i n_m^2(0) \exp(-2\nu_m t)$, where ν_m is the diffusion frequency of the metastables. From the published values[16–18] of the atomic ion, molecular ion, and metastable atom diffusion coefficients, of K_c and β_i (see Table I), and assuming a metastable atom concentration sufficient to produce the observed maximum value for the electron density in the afterglow, i.e., $n_m(0) \sim 10^{12}$ cm^{-3}, one can calculate the afterglow behavior of the atomic ions, electrons, and molecular ions. The results of a model afterglow calculation at a pressure of 0.54 mm Hg and $T = 300$°K are shown in Fig. 4. Starting from a very small number of electrons

and atomic ions at the beginning of the afterglow, metastable-metastable ionizing collisions cause an increase in n_e and n_1. As the metastable density decreases, leading to a smaller ionization rate, the diffusion to the walls and conversion of atomic ions leads to the final decay of n_1 and n_e. Meanwhile, the molecular-ion density, which also started essentially from zero at the beginning of the afterglow, increases as a result of atomic ion conversion, reaching a considerably smaller maximum value than the electrons somewhat later in the afterglow.

One may account for the intensity variation of the afterglow radiation, as follows; in the early afterglow when metastable atoms are plentiful and molecular ions are absent the radiation should be the result of the production of fast electrons by metastable-metastable collisions which then excite other metastables to radiating states. Thus, the radiation produced by this process should decay at *three* times the metastable atom-decay rate.

Considering the electron's loss of kinetic energy at elastic collisions, it can be shown that approximately 6×10^3 collisions are required to reduce the electron's initial energy from ~15 eV to the threshold value, ~3 eV, for exciting $2\,^3S$ metastable atoms to the observed radiating states (e.g., $3\,^3D$). For the inferred initial metastable density of $\sim10^{12}$ cm^{-3}, the observed early radiation intensity can be accounted for, provided that the average cross section for excitation of the metastable state to a radiating state over the electron energy range from 3–15 eV is comparable to the cross section for scattering of electrons by normal atoms,[20] i.e., $\sim4\times10^{-16}$ cm^2. Although there are no direct measurements of electron impact excitation of metastable states, such a cross section does not seem unreasonable, since it is substantially less than the theoretical maximum value[21] for such a process. The predicted shape of the early afterglow radiation (metastable excitation intensity) is indicated in Fig. 4.

In the late afterglow, when the molecular ions have reached an appreciable concentration and the metastable atoms have diffused away, the radiation should be the result of excited states produced by dissociative recombination, reaction (13). The intensity of this radiation should, therefore, be roughly equal to $(\alpha n_e n_2)$, where α is the dissociative recombination coefficient, on the assumption that recombination predominantly produces the desired state either directly or by cascading from higher states. The recombination radiation intensity curve of Fig. 4 was predicted from the computed electron density and molecular-ion density curves and an assumed recombination coefficient of 1×10^{-8} cm^3/sec.[22] The total predicted intensity is then the sum of the metastable excitation and recombination intensities. The absolute intensities measured in the late afterglow are consistent with this model and the assumed recombination coefficient. However, the difficulties of the absolute intensity determinations are such that the values may be in error by up to a factor of 3.

It should be noted that, with the aforementioned model of the afterglow, the radiation resulting from metastable excitation by electron impact in the early afterglow should exhibit a thermal spectral linewidth. By contrast, the late afterglow radiation, which is assumed to result from the dissociative recombination process, should exhibit a broadened line shape.

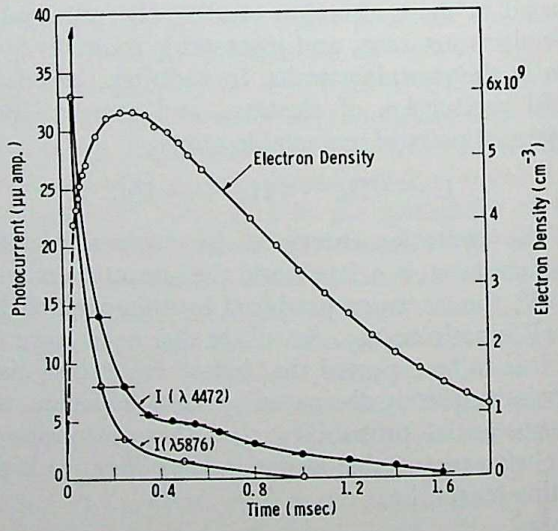

FIG. 5. Observed behavior of the electron density and the intensities of two lines emitted from a helium afterglow at 300°K and $p=0.54$ mm Hg. The line λ5876 corresponds to the $3\,^3D$–$2\,^3P$ transition; λ4472 to $4\,^3D$–$2\,^3P$.

V. RESULTS AND DISCUSSION

The observations which led to the construction of the afterglow model discussed in the previous section suggested a natural subdivision of the afterglow into an early and a late period, based on the line intensity and linewidth variations. In Figs. 5 and 6 are shown the variations of n_e and of the intensities of λ5876 and λ4472 observed during afterglows at $T=300°K$ and 0.54 and 2.05 mm Hg pressure, respectively. It will be seen that the observations at 0.54 mm Hg reproduce qualitatively the predictions of the model shown in Fig. 4, in that the electron density reaches a maximum value at ~300 μsec in the afterglow and the intensity of λ4472 exhibits a slight hump at ~500 μsec. No comparisons with the 2.05 mm Hg data (Fig. 6) are made, since the simplifying assumptions used in the model calculation at 0.54 mm Hg pressure are no longer valid at the higher pressure.

On the basis of the proposed afterglow model one should expect significant changes in the character of the radiation emitted in the early and in the late afterglow. It is noted that in the early afterglow the relative intensities of the various lines emitted are quite similar to those observed during the discharge. In both cases the excited states are presumed to be produced principally by electron impact excitation of lower excited states (ground state or metastable states). From the observed intensities in the early afterglow, one deduces a population of excited states which decreases monotonically with increasing principal quantum number, n. (Lines from upper states $n=3, 4, 5, 6$ were observed.) By contrast, in the late afterglow a change in spectral distribution is noted, the relative population of the states of higher quantum numbers, e.g., $n=5$, increasing markedly in comparison to the early afterglow values. As will be seen in the later discussion, such a behavior is consistent with dissociative recombination into higher excited states.

A principal effort of the present investigation lay in the determinations of the widths of the λ5876 line during the discharge and at various times in the afterglow in order to test the dissociative recombination hypothesis. As discussed in Sec. IIIC, the measured linewidths include contributions from fine structure, Doppler broadening, and instrumental broadening. The results of the line broadening measurements are, therefore, presented in terms of the observed total linewidths, determined at the half-maximum intensity points and expressed as fractions f of the free spectral range of the etalon, $\Delta\tilde{\nu}_{fsr}=(2\mu t)^{-1}=0.667$ cm^{-1}. The "temperature" of excited atoms required to yield the Doppler broadening contribution is then determined from the line-shape calculations as described in Sec. III C.

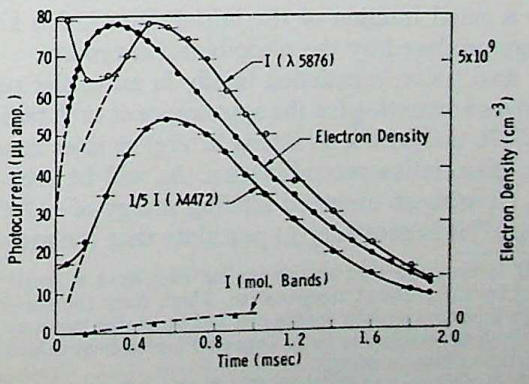

FIG. 6. Observed behavior of the electron density, two line intensities and the molecular band intensities in a helium afterglow at 300°K and $p=2.05$ mm Hg.

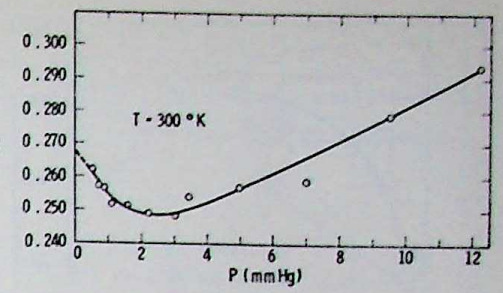

FIG. 7. Observed linewidth (including instrumental width) during the pulsed discharge in helium at 300°K. The linewidths are expressed as fractions f of the free spectral range of the Fabry–Perot etalon, $\Delta\tilde{\nu}_{fsr}=0.667$ cm^{-1}. The minimum width at ~3 mm Hg corresponds to the computed width for an excited atom temperature of ~300°K.

The observed width of the λ5876 line during the *discharge* in helium for various gas pressures is shown in Fig. 7. The minimum width observed at ~3 mm Hg corresponds to the linewidth calculated for an excited atom temperature of ~300°K. The increase in width at >3 mm Hg is the result of the appearance of some molecular light and pressure broadening effects. The increase in linewidth with decreasing pressure below 2 mm Hg can be shown to result from radiation of the excited atoms before they lose their recoil kinetic energy gained at the inelastic impact of the electrons having more than 23 eV kinetic energy which create the excited states. The linewidth data extrapolated to zero pressure are consistent with the expected recoil energy of ~0.004 eV, and the fact that this additional broadening does not disappear until ~3 mm Hg pressure suggests that excitation transfer to slow atoms and loss of kinetic energy by collisions of the excited atoms with normal atoms are slow enough to permit observation of line broadening due to dissociative recombination at pressures ≲2 mm Hg.[23]

The observed λ5876 linewidths in the afterglow, as well as during the discharge, are shown for several gas

[23] An alternative possibility is that narrowing of the discharge line may be due to a change in mode of production of excited states with change of gas pressure. If metastable $2\,^3S$ atoms reach a very large density $>10^{13}$ cm^{-3} as the pressure increases, then impact excitation to the $3\,^3D$ state by ~3 eV electrons will produce the observed intensity of λ5876 and the atom recoil energy will be too small to appreciably add to the thermal linewidth.

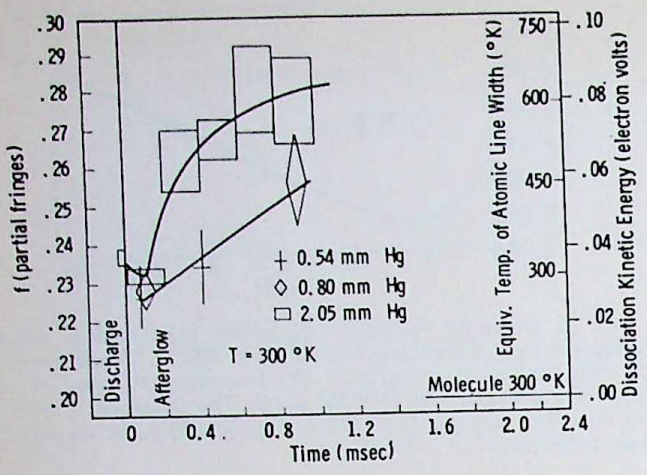

FIG. 8. Variation of the observed linewidths with time during the discharge and in the afterglow of helium at 300°K. The widths are expressed as fractions f of the free spectral range of the etalon. The scales at the right refer, respectively, to the equivalent atom temperature required to yield the observed width and to the dissociation kinetic energy E_D which must be added to the initial molecular ion thermal motion to give the observed width.

pressures at $T=300$°K in Fig. 8 and at $T=77$°K in Fig. 9. Here, improved Fabry-Perot plates were used. They had dielectric reflecting coatings of higher reflectivity and lower absorptivity than the silver films used on the previous plates. Thus, the instrumental broadening was reduced relative to Fig. 7. The horizontal widths of the symbols indicate the time gate during which the photomultiplier was made sensitive to light; the vertical extent of the symbols indicates the uncertainty in the linewidth determinations in these low-signal measurements.

From the temperature scale at the right of the figure, it will be seen that, as noted previously at 300°K, the line during the discharge at 77°K shows broadening in excess of ambient temperature effects, consistent with atom recoil at impact of the exciting electrons. Immediately afterwards, in the early afterglow at 300 and at 77°K, the linewidths decrease to values indistinguishable from the widths appropriate to the ambient temperatures. This observation is consistent with the proposed mechanism for production of the early afterglow radiation by electron impact on metastable atoms, since the ~3 eV electron energy required to excite to the radiating $3\,^3D$ state causes negligible recoil in the struck atom compared to its thermal speed.

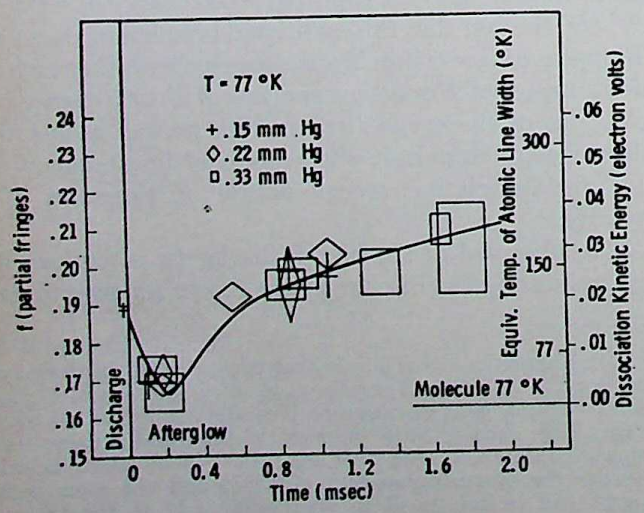

FIG. 9. Variation of the observed linewidths in helium at 77°K.

It will be seen in both Figs. 8 and 9 that the observed linewidths increase with time in the later afterglow. These observations are consistent with the expectation that, as the contribution to the radiation by metastable atom excitation decreases and that due to dissociative recombination increases, the line should increase in width, until a maximum width is attained when recombination alone is important. Unfortunately, the decrease in intensity with time in the afterglow does not permit line width measurements to be carried beyond ~1 msec at 300°K and ~2 msec at 77°K.

Although a pronounced line broadening is detected in the late afterglow, if one calculates the dissociation kinetic energy required to yield the observed width,[24] then, as the second scale at the right of the figures indicates, the inferred change of potential energy between the initial and final states of reaction (13) is rather smaller than one would estimate. As mentioned in Sec. III C.3, it is difficult to assure radiation of the excited, fast moving atom before slowing down by elastic collisions or excitation transfer to slow atoms takes place. If one argues that the momentum transfer cross section for scattering of $3\,^3D$ atoms by normal helium atoms is the same magnitude as for the metastable $2\,^3S$ atoms, namely, $Q_m=8\times10^{-15}$ cm^2,[18,19] then the excess energy of the atoms produced by dissociative recombination decays at the rate $\nu_{coll}\sim10^8$ sec^{-1} at 2 mm Hg pressure. Alternatively, if the excitation transfer cross section is of the same order of magnitude ($\sim10^{-14}$ cm^2) as the momentum transfer cross section, appreciable "narrowing" of the observed line will also occur by the transfer process. Excitation transfer cross sections, even for nonresonant cases, attain large values. For example, Gabriel and Heddle[25] deduce values of $Q_{transfer}\gg10^{-15}$ cm^2 for various $n\,^1P\rightarrow n\,^1D$ transfers ($n=3, 4, 5, 6$) at thermal energy. Thus, it is quite possible that in these studies we have been able to observe only a small fraction of the initial dissociation kinetic energy produced by the recombination process.

A final point, mentioned briefly in an earlier paper,[3] involves accounting for the appearance of such radiation as λ5876 and λ4472 as strong afterglow lines resulting from dissociative recombination. As will be seen from Fig. 10, with an expected binding energy of ~2 eV for (He_2^+),[26] it is necessary to postulate that the molecular

[24] It is assumed that the molecular ions have a speed determined by the ambient temperature. Then, since the dissociation energy is shared equally by the two helium atoms, one may calculate the line broadening to be expected for various values of the dissociation kinetic energy.

ions are in vibrationally excited states as they undergo dissociative recombination in order to produce the high-lying atomic states which yield the observed lines. (The figure is schematic, the vibration levels having been calculated for a Morse potential function.) The formation of the molecular ions in high-lying vibration states is a reasonable consequence of the assumed conversion reaction (12), in which the most likely binding collision is one in which a minimum loss of kinetic energy between two atoms takes place. Recent studies of vibration persistence in gases[27] have indicated that, for such well-separated vibration levels as in He_2^+, the probability of de-excitation by transfer of vibration energy to kinetic energy of relative motion at a collision with a helium atom is likely to be very small, $<10^{-8}$. Thus, on the millisecond time scale of our measurements, the ions should persist in the higher vibration states for an appreciable fraction of the observing interval.

In summary, the initial goal of determining whether or not the dissociative process is responsible for the large electron-ion recombination losses observed in microwave afterglows has not been fully achieved. The observations are consistent with a model of the helium afterglow in which, at later times, recombination becomes an important source of the afterglow radiation. At these times the emitted lines definitely show broadening in excess of thermal width. If one were to argue that the late afterglow broadening is the result of some process other than dissociative recombination, then one is faced with the dilemma of explaining how the excited atom temperature in the early afterglow sinks to thermal values and then increases rather abruptly. Clearly, such effects as pressure broadening cannot explain these observations, and careful monitoring of molecular band

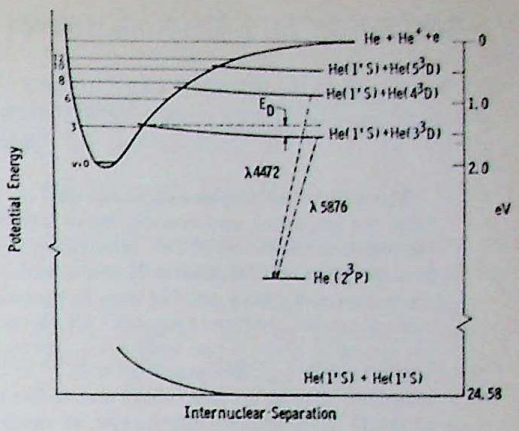

FIG. 10. Schematic representation of the potential curves required to explain the observations of strong λ4472 and λ5876 afterglow lines in terms of dissociative recombination. It will be seen that long-lived vibrationally excited states of the molecular ion are involved.

radiation intensities indicates that such spurious broadening effects do not account for the observed increase in width. Thus, dissociative recombination appears the most likely source of the modestly increased linewidths in the late afterglow. Studies of line shapes in neon afterglows, where recombination is the predominant electron removal process over a wider range of experimental variables, are in progress.[28]

Ionization and Dissociation of Fast H_2 Molecules Incident on H_2 Gas*

G. W. McClure
Sandia Laboratory, Alburquerque, New Mexico
(Received 9 January 1964)

The yield cross sections $\sigma_{H_2^+}$, σ_{H^+}, and σ_H for production of fast H_2^+ and H^+ ions and H atoms resulting from the ionization and dissociation of fast H_2 molecules in single collisions with H_2 gas molecules have been measured in the 6- to 120-keV energy range (collision velocity 0.7 to 3.2×10^8 cm/sec). The neutral primary beam contained a fraction of H atoms which was determined by proportional counter analysis. Secondary particles produced by the H atoms in the primary beam were determined in separate H beam experiments and subtracted from the composite (H,H_2) neutral beam data to yield the production of secondaries due to H_2 primaries alone. Cross section $\sigma_{H_2^+}$ increases monatonically from 0.5 to 2.0 Å^2 in the energy range 6 to 120 keV while σ_{H^+} increases from 0.28 Å^2 at 7.5 keV to a maximum of 0.70 Å^2 at 50 keV. Cross section σ_H, measured only at 10 keV, was found to have an approximate value of 2.5 Å^2 based on an assumed shape of the H atom angular distribution at small angles. The results are compared with data on a number of collision processes in the same velocity range involving various species of hydrogen ions and H atoms incident on H_2 gas molecules.

INTRODUCTION

THERE is a growing need for experimental data concerning ionization and charge exchange in collisions of atomic particles at relative velocities of the order of 10^8 cm/sec. Such velocities are encountered in fusion machines, ionic propulsion engines, high-voltage gaseous dischanges, and nuclear explosions. Experiments with hydrogen ions and molecules are directly applicable to all of these problems and are needed as a guide to further development of collision theory. In the particular velocity range of interest, theoretical calculations of collision cross sections are most difficult because the optical electron velocity of the colliding particles is about the same as the atomic translational velocity. Neither the adiabatic nor the impulsive model of a collision is valid under these circumstances.

The main purpose of this paper is to report measurements of the cross sections for ionization and dissociation of 6- to 120-keV H_2 molecules in collision with H_2 gas molecules. Apparatus used previously for the study of H^+, H_2^+, and H_3^+ collisions with H_2 molecules was employed.[1] The method consists of preparing a monoenergetic beam of fast molecules by charge exchange, passing the beam through a thin target of H_2 gas and measuring the production of fast H^+ and H_2^+ ions and H neutral atoms.

The reactions contributing to the production of the observed species are as follows, neglecting reactions in which negative ions are formed.

$$\text{Reaction 1:}\quad \overset{\circ}{H_2}+H_2\rightarrow H+H+(H_2),$$
$$\text{Reaction 2:}\quad H_2+H_2\rightarrow H_2^+ +(e+H_2),$$
$$\text{Reaction 3:}\quad H_2+H_2\rightarrow H^+ +H+(e+H_2),$$
$$\text{Reaction 4:}\quad H_2+H_2\rightarrow H^+ +H^+ +(e+e+H_2).$$

Here the heavy fragments of the primary H_2 molecules are shown immediately following the arrow while electrons removed from the primary and the post-collision target molecule are shown in parentheses on the right. The target H_2 molecules may be ionized, excited or dissociated, and the product particles H_2^+ and H may carry off some energy in the form of internal excitation, but in the great majority of collisions of the type considered the two constituent protons of the primary molecules, whether bound or dissociated after the collision, suffer very little change of velocity or direction of motion.

The present measurements do not completely resolve the above reactions but rather determine the yield cross sections σ_{H^+}, $\sigma_{H_2^+}$, and σ_H for the three types of fast heavy particles H^+, H_2^+, and H. In terms of the reaction cross sections σ_1, σ_2, σ_3, σ_4 for the above reactions, the measured quantities are:

$$\sigma_{H_2^+}=\sigma_2,$$
$$\sigma_{H^+}=\sigma_3+2\sigma_4,$$
$$\sigma_H=2\sigma_1+\sigma_3.$$

Particle counting was used to measure the intensities of both the primary neutral beams and the secondary ion and neutral beams. The counter employed permitted H_2 and H neutrals of the same velocity to be clearly distinguished by the relative size of electrical impulses they produced. Ability of the counting system to resolve H and H_2 counts placed a lower limit of about 3 keV on the present method of measurement. The narrow slit aperture on the proportional counter (needed to support a thin-film gas barrier) prevented our use of a technique devised by Sweetman[2] which might otherwise have been employed to distinguish the reactions 1 to 4.

The apparatus was designed so that all heavy fragments of the primary molecule having a post-collision angle less than 2.2 deg relative to the direction of the H_2 beam could be detected. At the 6-keV lower energy limit of the present (H_2+H_2) measurements the cross section for Coulomb scattering through an angle greater

than 2.2 deg of one of the two protons of the incident molecule against one of the two protons of the target molecule is 2×10^{-17} cm^2, neglecting screening. This cross section is of the same order of magnitude as the measured H^+ production cross section at 6 keV; hence, some error may be introduced into the H^+ data at this energy. However, throughout most of the present energy range no significant large angle scattering errors are expected due to Coulomb interactions.

At angles up to a few degrees from the forward direction the differential cross section for production of dissociation fragments of fast molecules may exceed that due to Coulomb scattering because of electronic transitions of the incident particle to antibonding states in which the two nuclei repel each other. Resulting production of dissociation fragments at angles outside the detector aperture may cause the measured cross sections to be 10 to 20% below the true total cross section at the lowest energies.

An important problem associated with the present measurements was that of producing a primary beam of neutral H_2 molecules. This was accomplished via the H_2^+ on H_2 reactions, studied previously,[1,2] which give rise to a mixed beam of H_2 molecules and H atoms of the same velocity via the processes

$$\text{Reaction 5:}\quad H_2^+ + H_2 \rightarrow H_2 + (H_2^+),$$

$$\text{Reaction 6:}\quad H_2^+ + H_2 \rightarrow H + H + (H_2^+),$$

$$\text{Reaction 7:}\quad H_2^+ + H_2 \rightarrow H + H^+ + (H_2).$$

In order to calculate the background production of H^+ caused by electron loss from the H atoms in the mixed neutral beam, it was necessary to know the cross section $\sigma_{0,1}$ for the reaction

$$\text{Reaction 8:}\quad H + H_2 \rightarrow H^+ + (e + H_2).$$

Although this cross section has been measured,[3–9] a serious discrepancy existed between the available measurements below 10 keV. Therefore, $\sigma_{0,1}$ was remeasured over the entire energy range 2 to 120 keV. At the same time, remeasurements of $\sigma_{0,-1}$, the cross section for the reaction

$$\text{Reaction 9:}\quad H + H_2 \rightarrow H^- + (H_2^+)$$

were made to resolve a gross discrepancy in previous data on this process. Both measurements involving H atom primaries are discussed in the first portion of the section entitled Results. The second portion of the Results section deals with the (H_2+H_2) measurements.

All cross sections were measured relative to the cross section $\sigma_{1,0}$ for the reaction

$$\text{Reaction 10:}\quad H^+ + H_2 \rightarrow H + (H_2^+).$$

This reaction[10] serves as an excellent basis for calibration of collision experiments of the present type because (1) no excited states are possible in the incident proton beam, (2) the angular distribution of the product H atoms is very strongly peaked in the forward direction, and (3) the absolute value of the cross section has been measured in the neighborhood of 10–100 keV by a number of investigators whose results are in excellent agreement.

A major problem in the interpretation of any experiment using fast neutral beams produced by charge exchange is that of uncertainty concerning the quantum states of the incident particles. In the present work this question is not settled; however, a discussion of the possible states of excitation of the neutral particles is given. Also, the conditions of production of the neutral beams are fairly well defined so that future data on the initial population and decay of excited states produced in charge-exchange collisions may be brought to bear on a more refined interpretation of the present work.

The section entitled Discussion compares the (H_2+H_2) collision data, obtained for the first time in this investigation, with data on related collision processes.

APPARATUS

The ion source, ion accelerator, and magnetic beam analyzer described in Ref. 1 were used without alteration to provide a 1–20-keV beam of either H^+ or H_2^+ ions having an energy spread of approximately one percent. Either of these beams could be directed along the sequence of apertures S_1, S_2, S_3, and S_4 (Fig. 1) which formed the entrance and exit slits of two differentially pumped chambers T_1 and T_2 operated with separate gas controls and pressure gages. These chambers served as a neutralizing chamber and main collision chamber, respectively. Electrostatic deflection plates D_1 located between T_1 and T_2 were used in the neutral beam experiments to deflect unconverted ions emergent from T_1 out of the neutral beam, permitting only neutrals to enter T_2. To change from an ion beam experiment to a neutral beam experiment required only the closing of a bypass valve between T_1 and the main vacuum chamber, the admission of a gas to the neutralizing chamber T_1, and the application of a deflection voltage to plates D_1.

A second set of electrostatic deflection plates D_2 at the

D_1 and D_2, deflection plates for deflecting charged particle beams off the main beam axis. S_1, S_2, S_3, and S_4, circular apertures having diameters 0.01, 0.02, 0.01, and 0.10 in., respectively. S_5, rectangular detector slit 0.001 in.×0.963 in.; long dimension perpendicular to plane of drawing. A, ionization chamber forming lower section of counter assembly shown in Ref. 1. DP, 400 liter/sec oil diffusion pump. B_1 and B_2, bellows-type vacuum joints constrained by external gimbals. B_1 is used to align apertures S_1 and S_3 with direction of primary beam incident on S_1 from the left. B_2 is used for mechanically sweeping detector slit S_5 across the electrostatically analyzed set of particle beams emergent to the right from D_2. B_2 permits detector slit S_5 (and attached assemblies A and DP) to swing through a $\pm 20°$ arc in the plane of the drawing about center of rotation P_2.

exit of T_2 divided the different species of fast charged particles emergent from T_2 into separate beams. Each of these beams was measured by moving the entrance slit S_5 of the proportional counter detector across the beam while recording with single-channel pulse-height analyzers the integrated counts of "single" and "double" amplitude pulses. The single-amplitude pulses came from H^+ or H particles and the double-amplitude pulses came from H_2 or H_2^+. Counts occurred in both channels only when the neutral beam from primary H_2 neutrals was being scanned. In this case pulse-height discrimination was used to distinguish H from H_2 in the composite neutral beam emergent from the collision chamber. The geometry and properties of the proportional counter were discussed thoroughly in Ref. 1. A 256-channel pulse-height analyzer was used in setting the pulse-height acceptance limits of the single-channel analyzers.

A refinement of the original apparatus[1] was the addition of a servo mechanism to drive the counter entrance slit at a speed proportional to the primary ion beam current. This system greatly reduced errors due to beam current fluctuations. The servo drive signal was derived in the neutral beam measurements from a Faraday cup C_2 surrounding the entrance of chamber T_2 into which the unconverted ion beam emergent from T_1 was directed. In all cases only a small fraction of the beam entering T_1 was neutralized and all unconverted ions were received by the Faraday cup. High stability of the neutralizing chamber pressure was obtained with a specially designed gas leak.[11] Constancy of this pressure insured that the neutral beam entering T_1 was exactly proportional to the servo drive signal once the leak was set.

[11] D. L. Allensworth, Rev. Sci. Instr. 34, 448 (1963).

CROSS-SECTION DETERMINATION

Cross sections were determined from the formula

$$\sigma_i(j)=I_i/I_j nd, \tag{1}$$

where $\sigma_i(j)$ is the cross section for production of secondary particles of type i by primaries of type j, I_j is the current of primary particles of type j, I_i is the current of secondary particles of type i, and nd is the equivalent number of gas molecules in the collision chamber per cm^2 of target area normal to the beam direction.

Because molecular flow conditions were present in the collision chamber the following relation holds

$$nd=\alpha p, \tag{2}$$

where p is the collision chamber pressure gage reading and α is a calibration constant having a fixed value for a given target gas and a given statistical distribution of incident-particle paths through the collision chamber. It is assumed that the distribution of ray paths is independent of the type and energy of primary beam used in these experiments.

With the further assumption that

$$N_i/N_j=I_i/I_j, \tag{3}$$

where N_i is the number of counts recorded while the detector is scanned across the type i secondary beam and N_j is the number of counts recorded while the detector is scanned across the type j primary particle beam, Eqs. (1)–(3) yield the following cross-section formula:

$$\sigma_i(j)=(N_i/N_j)(1/\alpha p). \tag{4}$$

Secondary particles produced at the edges of the entrance slit to chamber T_2 or "spurious secondaries"

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

which are present in the incident beam entering the collision chamber are not dependent on the collision chamber pressure p. Either of these effects or the presence in T_2 of a residual gas or vapor having a different cross section than the target gas result in failure of Eq. (4) to give a correct cross section. All three sources of error can be eliminated by plotting N_i versus p and by using the slope $\Delta N_i/\Delta p$ of this curve in place of N_i/p in evaluating Eq. (4). This procedure was used in every cross-section determination of the present work.

To summarize, the general working cross-section formula is

$$\sigma_i(j)=(1/\alpha N_j)(\Delta N_i/\Delta p). \quad (5)$$

CALIBRATION

The calibration of the apparatus consisted of determining a single value of the gas-dependent constant α of Eq. (5) since all measurements were made with H_2 as the target gas. This constant was determined by measuring the conversion of protons to H atoms by electron capture in H_2 gas (reaction 10) and assuming the cross-section value 8.2×10^{-16} cm^2 at the calibration proton energy of 10 keV. The value of α was found to be constant within a range of $\pm5\%$ in several determinations made during the course of the work. The chief cause of variations in successive α determinations was beam current fluctuations. The servomechanism used to compensate for beam current variations in all of the other measurements herein reported could not be used for the calibration because when the H^+ beam current was made low enough that the primary beam could be counted directly at the output of T_2, the fringing portion of the beam entering Faraday cup C_2 was too weak to provide a monitoring signal to drive the servo properly. This difficulty was offset in the calibration by taking a large number of points on the N_i versus p curves.

The use of reaction 10 for calibration continues the practice begun during our earlier work of reducing all hydrogen target measurements to a common basis. Should the value assumed for this cross section prove to be in error in the future, all of our measurements can be corrected accordingly by applying the same multiplicative correction factor throughout.

EXPERIMENTAL CONDITIONS

Hydrogen gas at a pressure between 10^{-4} and 10^{-3} mm Hg was used as the neutralizing gas in all of the neutral beam measurements. These pressures were sufficiently low that less than 10% of the incident ions were neutralized. The residual gas pressure in the neutralizing chamber was about 10^{-5} mm Hg with the gas inlet valve closed and about 10^{-6} mm Hg with the bypass valve open for calibration measurements.

Hydrogen gas of 99.9% purity was used in the collision chamber as the target gas. The residual gas pressure in the main collision chamber was 5×10^{-7} mm Hg with the hydrogen inlet leak closed and was varied between 10^{-5} and 10^{-4} mm Hg in order to obtain

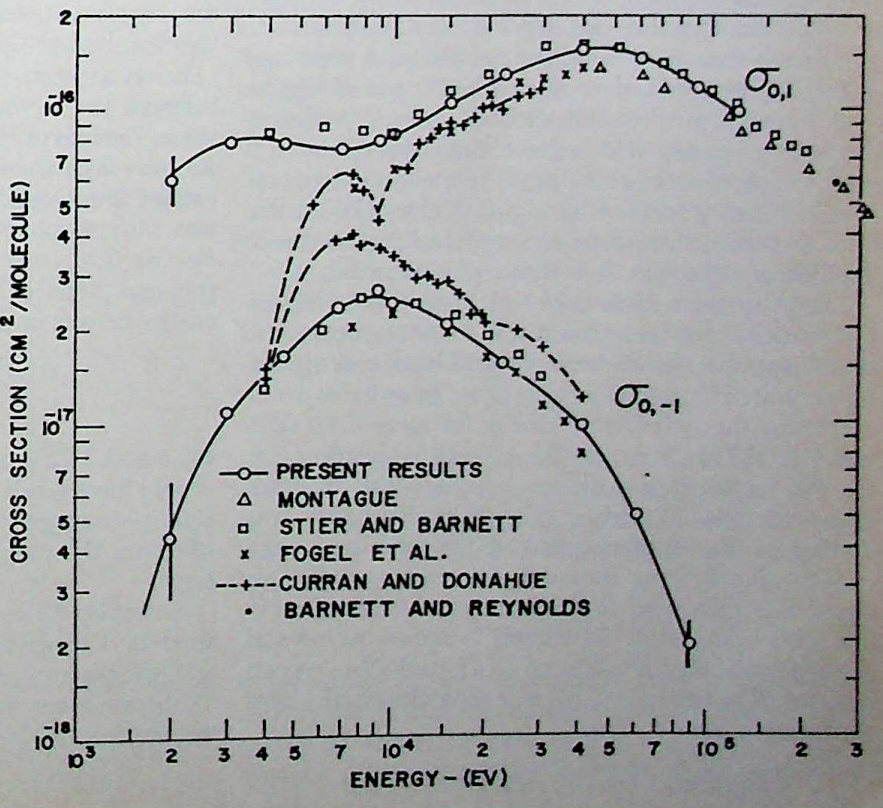

FIG. 2. Cross section $\sigma_{0,1}$ for conversion of primary H atoms to H^+ ions and cross section $\sigma_{0,-1}$ for conversion of primary H atoms to H^- ions. Present results are compared with previous data of Montague (Ref. 3), Stier and Barnett (Ref. 4), Barnett and Reynolds (Ref. 5), Fogel *et al.* (Refs. 6 and 7), and Curran and Donahue (Ref. 8).

the N_i versus p curves. The maximum fraction of incident particles which suffered either charge changing of dissociative collisions in the collision chamber was 0.7% and the maximum fraction of either the primary or secondary particles which underwent charge changing or dissociative collisions in the drift space between the collision chamber and the detector at the maximum drift space pressure of 10^{-6} mm Hg was about 0.07%. Under these conditions the attenuation of both the primary beam and secondary beams during traversal of the collision chamber and drift space could be ignored in evaluating the quantities N_i and N_j. Direct evidence of thin-target conditions was seen in the fact that all of the N_i versus p curves were linear within the statistical uncertainties of the particle counts. This uncertainty varied from 2 to 10%.

Ion beam currents entering chamber T_1 were generally of the order of 10^{-13} A throughout the data runs.

RESULTS

H Primaries

By permitting reaction 10 to occur in chamber T_1 and by applying a suitable deflection voltage to plate D_1 a beam of H atoms cleared of H^+ and H^- ions was directed into the collision chamber T_2. The fast secondaries H^+ and H^- emergent from T_2 due to reactions 8 and 9 were deflected by plates D_2 at angles of ± 3 deg from the unconverted H primary beam. Scans of the detector across all three beams at several energies indicated that a 1-deg scan was sufficient to receive essentially all of the particles emergent from the 4.4-deg-wide collision chamber exit aperture S_4. Consequently, 1-deg scans were used in all the $\sigma_{0,1}$ and $\sigma_{0,-1}$ measurements. For determinations of $\sigma_{0,1}$ the H^+ and H beams were scanned by the detector at several collision chamber pressures. Throughout these scans the H^+ beam emergent from chamber T_1 was collected at cup 2 and used as a servo drive signal. Calculation of the cross section $\sigma_{0,1}$ was then accomplished by the direct application of Eq. (5). Results are plotted in Fig. 2.

Except in the neighborhood of 10 keV the yield of H^- particles from reaction 9 was found to be so low that a large increase in the primary H beam was needed for accurate H^- yield determinations. In order to avoid correcting the recorded H counts for large dead-time losses at the required increased beam intensities, cup C_3 was moved into position to collect the H beam emergent from T_2 and a suitable positive bias was applied to the suppressor ring at the entrance to the cup to give a large secondary electron signal. This signal was then used to drive the servo while the H^+ and H^- beam were alternately scanned at several pressures to obtain plots of N_{H^+} and N_{H^-} versus pressure. The ratio $\sigma_{0,-1}/\sigma_{0,1}$ was then determined from the formula

$$\sigma_{0,-1}/\sigma_{0,1}=[\Delta N_{H^-}/\Delta p]/[\Delta N_{H^+}/\Delta p] \qquad (6)$$

and $\sigma_{0,-1}$ was determined by multiplying this ratio by the values of $\sigma_{0,1}$ from Fig. 2. The results for $\sigma_{0,-1}$ are shown also in Fig. 2.

Uncertainties in the experimental points are $\pm 5\%$ except for the points at 2 and 90 keV where larger uncertainties are indicated.

Previous measurements of $\sigma_{0,1}$ and $\sigma_{0,-1}$ are shown in Fig. 2 together with the present results. At all energies from 4 to 120 keV except in the vicinity of 6 keV our results appear to be consistent with the results of Stier and Barnett.[4] Agreement is excellent for both $\sigma_{0,1}$ and $\sigma_{0,-1}$.

In the energy range 40 to 120 keV our data points and those of Stier and Barnett for $\sigma_{0,1}$ fall about 15% above those of Montague.[3] Between 15 and 40 keV the results of all investigators scatter over a range of $\pm 20\%$ from the mean, but smooth curves drawn through the individual sets of data possess very nearly the same shape. It seems likely, therefore, that the discrepancies in this region could be accounted for by uncertainties in collision chamber pressure determinations.

Schwirtzke[9] has determined a quantity he calls $\sigma_{0,1}$ which we believe is actually $\sigma_{0,1}+\sigma_{0,-1}$. The Schwirtzke result, thus interpreted, has been compared with values of $(\sigma_{0,1}+\sigma_{0,-1})$ calculated from our data and is found to agree within $\pm 15\%$ over the range 10–50 keV.

Below 10 keV the experimental values of $\sigma_{0,1}$ fall into two divergent groups with relatively high values given by the present results and those of Stier and Barnett, and relatively low values given by Curran and Donahue[8] and by Fogel *et al.*[6,7] The Fogel measurements do not extend below 7 keV where an extremely serious departure sets in between the present "high" values and the "low" values of Curran and Donahue.

In an attempt to understand the drastic departure between the $\sigma_{0,1}$ results of Curran and Donahue and the $\sigma_{0,1}$ values of the present investigation below 7 keV we have hypothesized the presence of the well-known excited $2s$ metastable state in our H atom beam which was not completely quenched by the relatively low electric field used between deflection plates D_1. This proposal seemed worthy of investigation since the energy defects in the two reactions

$$H(1s)+H_2 \rightarrow H^+ + (H_2+e),$$
$$H(2s)+H_2 \rightarrow H^+ + (H_2+e)$$

(13.6 and 3.4 eV, respectively) are such that the latter should have a relatively high cross section. Thus even if the percentage of atoms in the $2s$ state were small, the effect on the weighted average value of $\sigma_{0,1}$ could be large.

According to a private communication,[12] the fields used by Curran and Donahue[8] were large enough to give complete quenching of the $2s$ metastable; however, deliberate steps were not taken in our measurements to suppress the $2s$ states completely. The fraction of $2s$

[12] T. M. Donahue (verbal communication, 1963).

atoms surviving after passing through the deflection field at D_1 was calculated from the expression

$$\phi = \exp\left[-\int_0^b \nu(x)\,(dx/v)\right], \qquad (7)$$

where ϕ, the survival probability, is defined as the ratio of the $2s$ atom current leaving the D_1 deflection field region to that entering the D_1 deflection region from chamber T_1, $\nu(x)$ is the local decay rate of $2s$ atoms at distance x from slit S_2, v is the H atom velocity, and b is the length of path from S_2 to the end of the deflection plates. The quantity $\nu(x)$ was calculated from the formula $\nu(x) = A[E(x)]^2$ where E is the estimated electric field strength at distance x and A is a constant equal to 2780 $\text{sec}^{-1}\ \text{V}^{-2}\ \text{cm}^2$.[13] [Equation (7) is based on the assumption that the incremental fraction of $2s$ atoms decaying in time increment dt is equal to the product νdt where ν is an instantaneous decay rate given by the "static-field" formula quoted.]

For the set of points plotted in Fig. 2 the calculated $2s$ survival probabilities are given in Table I. The rather irregular variation of the survival probability is caused by the extreme sensitivity of this quantity to the deflection voltage coupled with the fact that no special attempt was made to choose deflection voltages which would lead to a regular variation of ϕ. In some cases, particularly at low energies, the survival probabilities were somewhat large; hence a subsidiary experiment was performed as a specific test of a possible $2s$ effect.

Two measurements of $\sigma_{0,1}$ were made at 4 keV (not plotted in Fig. 2) in which the deflection voltages used on plates D_1 were 85 and 25 V, respectively, and for which the survival probabilities were 0.02 and 0.71, respectively. The two results were $\sigma_{0,1}(85\ \text{V}) = 7.92 \pm 0.4$ and $\sigma_{0,1}(25\ \text{V}) = 8.28 \pm 0.5$, indicating that the maximum increase in the cross section $\sigma_{0,1}$ due to $2s$ atoms would be about 20%. Therefore, a variable population of the $2s$ level does not seem to afford an explanation for the discrepancy with the Curran-Donahue results.

TABLE I. Calculated survival probabilities [ϕ, Eq. (7)] of $2s$ metastable atoms traversing deflection plates D_1 in the $\sigma_{0,1}$ measurements as a function of H atom energy.

Energy keV	Survival probability
2	0.145
3	0.206
4.5	0.276
6.8	0.095
9	0.270
10	0.575
15	0.056
22.5	0.10
40	0.0057
66	0.4×10^{-4}
120	10^{-3}

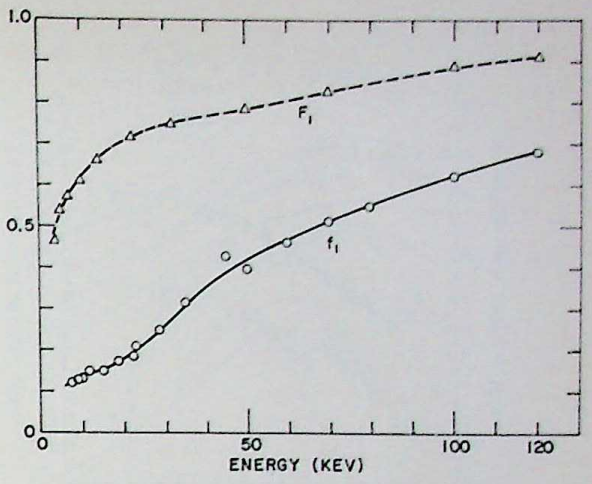

FIG. 3. Ratio $f_1 = N_H/(N_H + N_{H_2})$, where N_H and N_{H_2} are, respectively, the fluxes of H atoms and H_2 molecules in the composite neutral beam entering collision chamber T_2 during the H_2 primary measurements. Ratio $F_1 = \sigma_H/(\sigma_H + \sigma_{H_2})$, where σ_H and σ_{H_2} are, respectively, the cross sections for production of fast H and H_2 secondaries in collisions of fast H_2^+ ions with H_2 molecules. F_1 is calculated from the experimental data of Ref. 1.

H_2 Primaries

A composite neutral beam comprising fast H_2 molecules and H atoms was formed by passing magnetically analyzed H_2^+ ions into the neutralizing chamber. Fast H_2 and H neutrals produced in reactions 5, 6, and 7 emerged from the neutralizing chamber and entered the collision chamber while the emergent H_2^+ and H^+ ions were deflected out of the beam by deflector D_1.

The intensity and composition of the neutral beam emergent from T_2 was determined by making detector scans 1 deg wide. These scans were shown to be ample to cover the entire beam by trial runs at various widths. (The maximum angle of divergence of a primary neutral from the collision chamber axis was 0.38 deg as determined by the sizes of apertures S_2 and S_3.) Figure 3 shows the composition of the composite neutral beam emergent from T_2 as a function of the H_2 beam energy. The composition is described by the quantity

$$f_1 = N_H/[N_{H_2} + N_H], \qquad (8)$$

where N_H and N_{H_2} are, respectively, the H and H_2 counts recorded in a scan of the neutral beam. It may be seen that the composition varies considerably with beam energy and follows a form quite different from the function F_1 given by

$$F_1 = \sigma_H/[\sigma_H + \sigma_{H_2}], \qquad (9)$$

where σ_H and σ_{H_2} are, respectively, the production cross sections for H and H_2 secondaries in the reactions 5–7 calculated from the data of Ref. 1. This difference between f_1 and F_1 results from the small solid angle

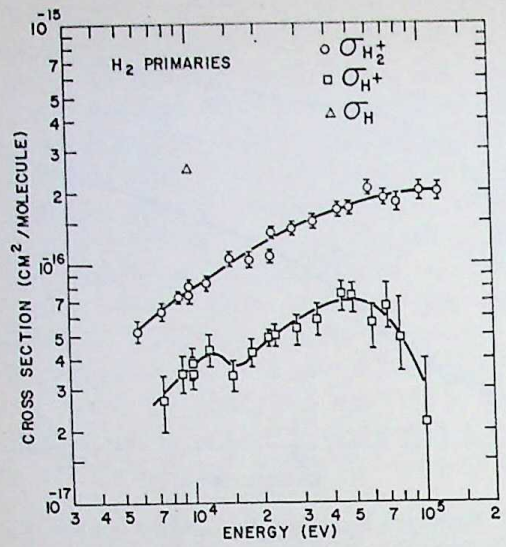

FIG. 4. Cross sections for conversion of fast H_2 molecules into fast secondaries H^+, H_2^+, and H in collisions with H_2 molecules. σ_{H^+}, $\sigma_{H_2^+}$, and σ_H are, respectively, the production cross sections of the secondaries H^+, H_2^+, and H.

subtended by aperture S_3 at the neutralizing chamber coupled with the fact that the H_2 molecules have a more strongly forward-peaked differential angular distribution than do the H dissociation products.

Because of the very narrow angular spread of the H_2 beam and the small size of apertures S_1 and S_3, it was necessary to carefully align the S_1–S_3 axis in order to achieve a minimum value of f_1 needed for optimum H_2 measurement accuracy. Owing to unexplained slight differences in the direction of the H_2^+ beam entering S_1 for various energies, care was taken to achieve good alignment at every accelerator energy. The slight departure of the point at 45 keV from the smooth curve f_1 probably resulted from misalignment which slightly favored H atoms at this energy.

To determine the cross sections for H_2^+ and H^+ production from H_2 primaries, a deflection voltage was applied to plates D_2 which deflected the secondary H_2^+ beam 3 deg from the main axis and the H^+ beam 6 deg. The neutral beam and the H_2^+ and H^+ beams were scanned repeatedly at several collision chamber pressures, providing curves of $N_{H_2^+}$ versus p and N_{H^+} versus p and values of N_H and N_{H_2}. Scan widths were adjusted to achieve complete collection of the H^+ and H_2^+ secondaries at each energy. One-deg scans sufficed for H_2^+ at all energies and 2-deg scans were sufficient for H^+ at all but the lowest energies. Below 10 keV the full 4.4-deg scans were used and considered to be adequate. The cross section $\sigma_{H_2^+}$ for H_2^+ production was straightforwardly determined from the formula

$$\sigma_{H_2^+}=-\frac{1}{\alpha}\frac{1}{N_{H_2}}\frac{\Delta N_{H_2^+}}{\Delta p} \qquad (10)$$

obtained from Eq. (5) with appropriate substitutions.

Cross section σ_{H^+} for production of H^+ by H_2 primaries was determined by first calculating

$$\sigma_T=-\frac{1}{\alpha}\frac{1}{(N_{H_2}+N_H)}\frac{\Delta N_{H^+}}{\Delta p}, \qquad (11)$$

which represents the average cross section for H^+ production by both the H_2 molecules and H atoms in the primary beam. The cross section σ_{H^+} for H^+ production by the H_2 primaries alone and the cross section $\sigma_{0,1}$ for production of H^+ by H primaries alone are related to σ_T by the equation

$$\sigma_T=f_1\sigma_{0,1}+f_2\sigma_{H^+};\quad f_2=1-f_1, \qquad (12)$$

which can be rearranged in the form

$$\sigma_{H^+}=\sigma_T/f_2-\sigma_{0,1}f_1/f_2. \qquad (13)$$

All the quantities on the right of Eq. (13) are known from the measurements described. Values of $\sigma_{0,1}$ were taken from the present data shown on Fig. 2 using the cross section for H atoms of one-half the H_2 beam energy. Deduction of correct values of σ_{H^+} by use of this formula rests on the assumption that the H atoms produced by H_2^+ dissociation in the neutralizing chamber have the same electron loss cross section as H atoms produced by proton neutralization in the neutralizing chamber.

The results of the σ_{H^+} and $\sigma_{H_2^+}$ measurements are shown in Fig. 4. The uncertainties associated with counting statistics (standard deviations) are indicated by the error flags. These are believed to dominate all other sources of error. The relatively large uncertainties in the σ_{H^+} values are associated with the relatively

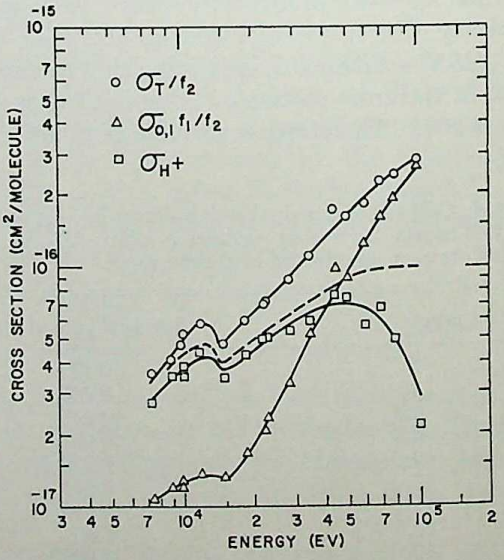

FIG. 5. Cross section σ_{H^+} for fast proton production by H_2 primaries and the two quantities σ_T/f_2 and $\sigma_{0,1}f_1/f_2$ [see Eq. (13)] which enter into the calculation of σ_{H^+}. The small difference between the upper curves at the higher energies leads to the large statistical uncertainties in σ_{H^+} at high energies. Dashed curve is the curve for σ_{H^+} obtained by using the lower values of $\sigma_{0,1}$ given by Curran and Donahue (Ref. 8) and Fogel (Ref. 7) instead of the $\sigma_{0,1}$ values from the present work in evaluating Eq. (13).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

small cross sections as well as the fact that σ_{H^+} is a difference between two quantities [Eq. (13)], each of which has associated statistical errors. This difference became quite small at high energies, leading to quite large percentage uncertainties. The two terms appearing on the right-hand side of Eq. (13) and the difference σ_{H^+} are plotted in Fig. 5 to show clearly the relative magnitude of the quantities as they occurred in the σ_{H^+} determinations.

The effect on σ_{H^+} of assuming the lower set of $\sigma_{0,1}$ values given by Curran and Donahue (4- to 40-keV H atom energy) and Fogel (40- to 50- keV H atom energy) is indicated by the dashed curve in Fig. 5. This curve is believed to represent a less reliable estimate of σ_{H^+} than the solid curve since the "low" values of $\sigma_{0,1}$ used in calculating the dashed curve may have resulted from calibration disparities which were eliminated in the present set of measurements by our use of a common basis of calibration in the $\sigma_{0,1}$ and σ_T measurements.

The cross section σ_H for fast H atom production in reactions 1 and 3 could not be determined accurately because the high flux of H atoms in the primary neutral beam tended to mask the production of secondary H atoms at small angles. However, an estimate of σ_H was made at 10 keV as follows. Careful measurements of the angular distribution of fast H atoms emergent from the collision chamber were made at two collision chamber pressures with results shown in Fig. 6. At angles greater than $\frac{1}{2}$ deg a very distinct pressure-dependent H atom component is present corresponding to an H atom production cross section of 1.25×10^{-16} cm². The portion of this cross section due to H_2 dissociation is estimated as 1.17×10^{-16} cm² by subtracting the calculated amount expected from Coulomb scattering of H atoms in the primary beam. By making a linear extrapolation of the large-angle H atom distributions to zero angle, the estimated ratio of total H atom production to production outside $\frac{1}{2}$ deg was found to be 2.14, giving a final estimate of 2.5×10^{-16} cm² for the value of σ_H.

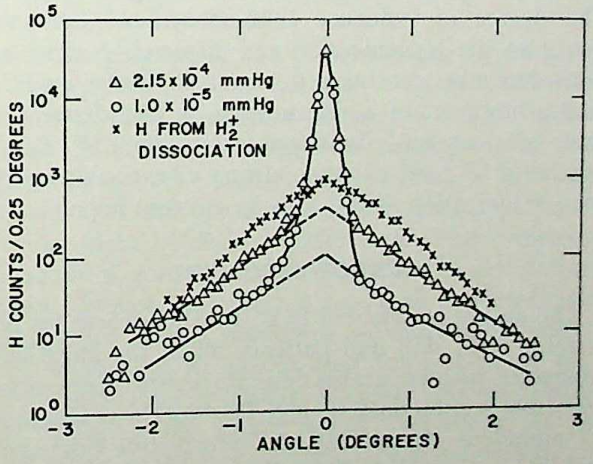

FIG. 6. Angular distribution of fast H atoms measured in order to estimate σ_H the cross section for production of fast H atoms from H_2 primaries. The large peak in the center is due principally to H atoms present in the primary beam and, consequently, shows no dependence on collision chamber pressure over the indicated pressure range 1.0×10^{-5} to 2.15×10^{-4} mm Hg. Dashed lines show extrapolations used in estimating the small-angle production of H atoms due to H_2 dissociation. Crosses indicate angular distribution of H atoms from H_2^+ dissociation in collision with H_2. All distributions are for 10 keV primaries and were obtained with a long slit (S_5) as the detector window. The distributions are, therefore, not the same as "differential angular distribution" in the usual sense of the term.

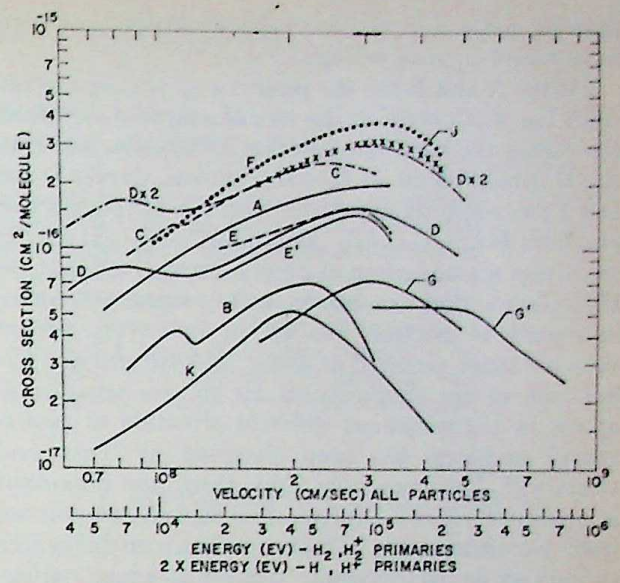

FIG. 7. Curve A: $\sigma_{H_2^+}$ the cross section for conversion of fast H_2 molecules to H_2^+ ions from Fig. 4. Curve B: σ_{H^+} the cross section for conversion of fast H_2 molecules to H^+ ions from Fig. 4. Curve C gives the sum of σ_{H^+} and $\sigma_{H_2^+}$ which equals the total cross section for electron loss from fast H_2 molecules. Curves D and D×2 are, respectively, 1 and 2 times the cross section $\sigma_{0,1}$ for electron loss from H atoms from Fig. 2. Curve E: ionization of H_2 by H primaries, including $\sigma_{1,-1}$ the ion production due to electron capture by the primary ions from Schwirtzke (Ref. 9). Curve E': curve E minus $\sigma_{1,-1}$ from Fig. 2. Curve F: cross section for free electron production in $H_2^+ + H_2$ collisions from Afrosimov (Ref. 15). Curve G and G' are, respectively, the results of Guidini (Ref. 16) and Sweetman (Ref. 2) for electron loss from H_2^+ ions in collision with H_2. Curve J: curve F with curve G subtracted to give cross section for electron removal from H_2 when struck by H_2^+. Curve K: cross section for production of slow H^+ ions in collision of H_2^+ with H_2 from Afrosimov (Ref. 15). A portion of curve D×2 between abscissa values 1.5 and 3×10^8 cm/sec was deliberately left out to avoid confusion with curve J.

The use of the linear extrapolation in estimating the small-angle H atom yield could not be rigorously justified, but seemed reasonable in view of the shape of the angular distribution of H atoms from H_2^+ primaries obtained with the same apparatus and shown superimposed in Fig. 6 for comparison.

DISCUSSION

No directly applicable theoretical calculations are available for comparison with the present experimental results; however, it is instructive to compare the previously available cross section data on several different hydrogen atom and molecule collisions with the new data on H_2+H_2 collisions. To facilitate such a com-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

parison, a number of cross section vs velocity curves have been compiled in Fig. 7.

Curves A and B are the present $\sigma_{H_2^+}$ and σ_{H^+} results from Fig. 4. Curve C is the sum of $\sigma_{H_2^+}$ and σ_{H^+} which represents the total cross section for electron loss from the H_2 projectile in an H_2+H_2 collision. Curves D and D×2 are, respectively, the cross section $\sigma_{0,1}$ for electron loss from H atoms and $\sigma_{0,1}$ multiplied by two. It may be seen from a comparison of curves C and D×2 that the H_2 molecule does not behave as two separate H atoms in regard to electron loss except in a very narrow velocity range centered at about 1.7×10^8 cm/sec. The question of the similarity of H_2 to two separate H atoms in the somewhat different situation of proton charge exchange has been discussed by Tuan and Gerjuoy.[14] They conclude that there are important interference effects between the capture amplitudes from two interacting H atoms which can make the capture cross section quite dependent upon nuclear separation. The above noted disparity between curves C and D×2 does not seem surprising in view of the possibility of analagous interference effects in the electron loss process. Curve E is the cross section given by Schwirtzke[9] for ionization of H_2 by H atoms while curve E′ is the same cross section with $\sigma_{1,-1}$ subtracted to eliminate the ionization contribution due to electron capture by the H primaries. It may be seen that curve C lies about a factor of 2 above curve E′, indicating that H_2 molecules are about twice as effective in removing electrons from H_2 molecules as are H atoms of the same velocity.

Curve F is the cross section for slow electron production in collisions of H_2^+ and H_2 as determined by Afrosimov *et al.*,[15] and curves G and G′ are, respectively, the results of Guidini[16] and Sweetman[2] for electron loss from fast H_2^+ ions in collisions with H_2. Curve J, the difference between curves F and G, represents the ionization of H_2 by H_2^+, not counting loss of electrons from the H_2^+ primaries. In the velocity range 1.7 to 2.2×10^8 cm/sec, curve J lies quite close to curve C, indicating that H_2^+ and H_2 are roughly equivalent in their power to remove electrons from H_2.[17] However, at 3×10^8 cm/sec there appears to be a real difference of about 50% between the two cross sections.

The cross section for removal of one electron from H_2 to form H_2^+ (curve A) is about three times larger than the cross section for removal of an electron from H_2^+ (curve G). This large difference seems reasonable since the first ionization potential of H_2 is 15 eV while the ionization potential of H_2^+ is 30 eV, indicating that the second electron is much more strongly bound than the first.

Curve K is the cross section for slow proton production in collisions of fast H_2^+ with H_2. This curve lies somewhat below curve B, indicating that the fast primary in H_2+H_2 collisions converts to H^+ with a slightly higher probability than the target particle in $H_2^++H_2$ collisions.

One of the more interesting results of this study is that the fast H atom yield from the pair H_2+H_2, measured at 10 keV, is only $\frac{1}{3}$ as great as the yield of fast H atoms from the pair $H_2^++H_2$ from Ref. 1. This may perhaps be explained by the fact that the lowest repulsive state of H_2 is the triplet state $1^3\Sigma_u$ which can only be reached from the ground state of H_2 by a spin flip or by electron exchange. Both of these processes are theoretically very unlikely compared with the simple near resonant process of electron transfer from an H_2 molecule to an H_2^+ ion, placing the newly formed molecule in a $1\,^3\Sigma_u$ repulsive state.

It is quite probable that the H_2 molecules which form the primary beam in our H_2 primary measurements (Fig. 4) are not in their ground vibrational states. This follows from the fact that the H_2^+ ion has a nuclear potential minimum at a nuclear spacing somewhat larger than that of the H_2 molecule. This has the effect of causing the H_2^+ ions to be formed preferentially in their third or fourth vibrational quantum level in which the vibrational excursion of nuclear spacing is quite large.[18] When the H_2^+ ions are subsequently converted back to H_2 by electron capture, the molecule may therefore be forced into very high vibrational levels. The degree of influence that vibrational excitation exerts on the H_2 ionization and dissociation cross sections has not yet been determined. Some evidence exists, however, of a dependence of H_2^+ dissociation cross sections on vibrational excitation.[1,19,20] Recent calculations[21] have shown a strong vibrational dependence of ionization of H_2^+ ions by electron impact.

ACKNOWLEDGMENT

The author is indebted to D. L. Allensworth for performing with skill and patience all of the hard labor connected with apparatus design, accelerator operation, and cross section data taking. PHYSICAL REVIEW VOLUME 134, NUMBER 5A 1 JUNE 1964

Bound States in a Debye-Hückel Potential

CHARLES RAY SMITH
National Bureau of Standards, Boulder, Colorado

(Received 13 June 1963; revised manuscript received 4 November 1963)

This is a study of some of the properties of the discrete energy levels of an electron in an exponentially shielded Coulomb potential, which is known in plasma physics as the Debye-Hückel potential and in nuclear physics as the Yukawa potential. A system with this potential possesses a finite number of bound states and these states are not degenerate with respect to the orbital angular momentum. First-order perturbation theory is used to obtain simple, analytical expressions for estimating the energy levels; the approximations appear to be quite accurate for large values of the Debye length. The perturbation calculations lead to an estimate of the number of bound states as a function of the Debye length. The matrix elements of the Hamiltonian for this potential are calculated in the representation of the hydrogen atom wave functions. The Hamiltonian matrix may serve as a convenient starting point for several other methods of computing the energy levels.

1. INTRODUCTION

ALTHOUGH the two-component gas with Coulomb interactions has not yet been adequately treated, certain results are available for various temperature and density regions. Specifically, the Debye-Hückel potential is reported to be the effective two-body interaction in the high-temperature, low-density region.[1] This result is often interpreted to mean that in a hydrogen plasma a bound electron moves in the potential given by the Debye-Hückel theory. By virtue of their spectra, atoms in a plasma serve as noninterfering probes, and a study of the effects of the Debye shielding on the energy levels of atomic hydrogen may be of more than academic value. For example, in the highly excited bound states of atoms in a plasma the Debye shielding may be approximately realized, and one wishes to examine the effects of this shielding on the atomic partition function.

It is the purpose of the present paper to estimate the energy levels of an electron in a Debye-Hückel potential (which, in nuclear physics, is known as the Yukawa potential). Although certain aspects of the problem have been investigated by others,[2–5] it is not apparent that the problem has been treated as generally as might be desired. Ecker and Weizel[2] restrict their study to s states and their method of calculation is open to question.[6] Harris[3] has used a variational technique for making numerical estimations of several energy levels, but it appears that her results are not useful for laboratory plasmas, since she chooses mostly small values for the Debye length. Her energy levels for the larger Debye lengths are in agreement with those calculated from analytical expressions obtained in the present paper.

2. PERTURBATION CALCULATIONS

The Debye (or Debye-Hückel) potential for an electron in the shielded field of a singly-charged ion is

$$V(r)=-\epsilon^2(e^{-r/d}/r). \tag{1}$$

Here ϵ is the unit of charge and d is the Debye length.

$$d=(kT/4\pi\epsilon^2 n)^{1/2}, \tag{2}$$

where k is the Boltzmann constant, T is the equilibrium temperature of the plasma, and n is the electron density. The potential in Eq. (1) possesses a finite number of energy levels, and these energy levels are not degenerate with respect to the angular momentum.

Atomic units are employed, so that the unit of distance is $\hbar^2/\mu\epsilon^2$ and the unit of energy is $-\mu\epsilon^4/2\hbar^2$, where μ is the reduced mass of the electron. Instead of the radial wave function $R(r)$, it is desirable to use $P(r)\equiv rR(r)$ so that the radial Schrödinger equation with the potential of Eq. (1) becomes

$$\frac{d^2P}{dr^2}+\left(\frac{2e^{-r/d}}{r}-W\right)P-\frac{l(l+1)}{r^2}P=0, \tag{3}$$

where l is the angular-momentum quantum number and W is the negative of the energy eigenvalue of the electron. Note that $W\geq 0$ for bound states. The Debye length for a hydrogen plasma is usually larger than 10^{-6} cm, which, in terms of atomic units, means $d\geq 10^3$.

The potential in Eq. (1) may be written as a Coulomb potential plus a perturbation $U(r)$:

$$V(r)=2/r+U(r)=2/r+2((e^{-r/d}-1)/r). \tag{4}$$

It is seen that the perturbing potential $U(r)$ becomes comparable to $V(r)$ when $r\sim d$. For the unperturbed case the average value, $\langle r\rangle$, of r goes as N^2, where N is the principal quantum number. Thus, it is expected that first-order perturbation theory will be accurate as long as $N^2\ll d$ and becomes progressively less accurate as N^2 approaches d. It is to be noted that the Debye potential is not meaningful for the lowest energy levels, since the electron orbits will not encompass

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

enough charged particles to realize any screening at all. Furthermore, for the lower states the orbital frequency of the electron may be large compared to the plasma frequency so that any static potential will be inapplicable to the problem.

The first-order energy shift ΔW_1 is given by

$$\Delta W_1=(P_{Nl},UP_{Nl})\equiv\int_0^\infty [P_{Nl}(r)]^2U(r)dr\,, \quad (5)$$

where the $P_{Nl}(r)$ are the normalized zero-order eigenfunctions of Eq. (3) and in this case are the radial hydrogen functions

$$P_{Nl}(r)=-\frac{1}{N}\left[\frac{(N-l-1)!}{[N+l)!]^3}\right]^{1/2}\times e^{-r/N}\left(\frac{2r}{N}\right)^{l+1}L_{N+l}^{2l+1}\left(\frac{2r}{N}\right), \quad (6)$$

where $L_{N+l}^{2l+1}(2r/N)$ is the associated Laguerre polynomial. The integration in Eq. (5) may be performed and yields

$$\Delta W_1=\frac{2^{2l+3}(N+l)!\,{}_2F_1(-N+l+1,\,-N+l+1,\,2l+2,\,4d^2/N^2)}{N^{2l+4}(2l+1)!(N-l-1)!(2/N+1/d)^{2N}d^{2N-2l-2}}-\frac{2}{N^2}, \quad (7)$$

where ${}_2F_1$ is the hypergeometric function.

If second and higher order terms in $1/d$ are neglected, Eq. (7) reduces to

$$\Delta W_1\cong -2/(d+N^2). \quad (8)$$

Hence, to first order in $1/d$, first-order perturbation theory provides the following expression for the energy levels of Eq. (3):

$$W\cong 1/N^2-2/(d+N^2). \quad (9)$$

Although Eq. (9) indicates that energy levels of Eq. (3) are not degenerate with respect to the angular momentum, it is to be noted that the degeneracy still exists if second and higher order terms in $1/d$ are neglected.

A useful approximation to ΔW_1 is obtained by expanding $U(r)$ in a power series in $1/d$. If this is done Eq. (5) becomes

$$\Delta W_1=-\frac{2}{d}+\frac{1}{d^2}\langle r\rangle-\frac{1}{3d^3}\langle r^2\rangle+\frac{1}{12d^4}\langle r^3\rangle-\frac{1}{60d^5}\langle r^4\rangle+\cdots. \quad (10)$$

For $P_{Nl}(r)$ in the form given in Eq. (6) Bethe and Salpeter[7] have an explicit formula for evaluating $\langle r^\nu\rangle$ through $\nu=4$. Equation (10) then becomes[8]

$$\Delta W_1\cong-\frac{2}{d}+\frac{1}{2d^2}[3N^2-l(l+1)]-\frac{N^2}{6d^3}[5N^2+1-3l(l+1)]+\frac{N^2}{96d^4}[35N^2(N^2-1)-30N^2(l+2)(l-1)+3(l+2)(l+1)l(l-1)]-\frac{N^4}{480d^5}[63N^4-35N^2(2l^2+2l-3)-5l(l+1)(3l^2+3l-10)+12]. \quad (11)$$

Once the $l=0$ values are obtained for a given N, a useful approximation for ΔW_1 with higher l values is

$$\Delta W_1=(P_{Nl},UP_{Nl})\cong(P_{N0},UP_{N0})-[l(l+1)/2d^3](d-N^2). \quad (12)$$

Again, it is noted from Eq. (12) that the angular momentum corrections are of order $1/d^2$ and higher.

Values of the perturbed eigenvalues W for a few values of N, l, and d are presented in Table I. The calculations are based on Eq. (11). (The lower N values are included only for completeness.)

If accurate estimates of the eigenvalues of the Debye potential become necessary, an efficient method for computing the eigenvalues is the Rayleigh-Ritz method.[9] This method involves diagonalizing the Hamiltonian matrix computed in some convenient representation. Good accuracy of this method depends on a judicious choice of base vectors, which, in this case, should be the unperturbed eigenfunctions given by Eq. (6). The matrix for the Hamiltonian for a given l (H is central

	5	0.0233	0.0232	0.0230	0.0400

so that l values are not mixed) in this representation is

$$(P_{Nl},HP_{N'l})=(1/N^2)\delta_{NN'}+(P_{Nl},UP_{N'l}), \quad (13)$$

where

$$(P_{Nl},UP_{N'l})\equiv\int_0^\infty P_{Nl}2\left(\frac{e^{-r/d}-1}{r}\right)P_{N'l}dr. \quad (14)$$

With P_{Nl} given by Eq. (6) the matrix elements of $U(r)$, Eq. (14), become

$$A(N,N',l)\frac{\lambda_1^{\alpha+\alpha'-\gamma}}{(\lambda_1-k)^\alpha(\lambda_1-k')^{\alpha'}}\times{}_2F_1\left(\alpha,\alpha',\gamma,\frac{kk'}{(\lambda_1-k)(\lambda_1-k')}\right)$$
$$-A(N,N',l)\frac{\lambda_2^{\alpha+\alpha'-\gamma}}{(\lambda_2-k)^\alpha(\lambda_2-k')^{\alpha'}}\times{}_2F_1\left(\alpha,\alpha',\gamma,\frac{kk'}{(\lambda_2-k)(\lambda_2-k')}\right), \quad (15)$$

where

$$A(N,N',l)=\tfrac{1}{2}(2l+1)!\left(\frac{4}{NN'}\right)^{l+2}\times\left[\frac{(N+l)!(N'+l)!}{(N-l-1)!(N'-l-1)!}\right]^{1/2},$$

$$\gamma=2l+2, \qquad k=2/N, \quad k'=2/N',$$
$$\alpha=-N+l+1, \quad \lambda_1=1/N+1/N'+1/d,$$
$$\alpha'=-N'+l+1, \quad \lambda_2=1/N+1/N'.$$

The evaluation of these matrix elements is rather tedious but could be rapidly executed on an electronic computer.

3. THE NUMBER OF ENERGY LEVELS FOR A DEBYE-HÜCKEL POTENTIAL

If Eq. (9) were exact, then the principal quantum number would satisfy the condition

$$N^2\leq d \quad (16)$$

since it is required that $W\geq 0$ for bound states. In spite of the limited accuracy of first-order perturbation theory and the approximation made in arriving at Eq. (8), the result in Eq. (16) compares favorably with results of others.[2,4] In fact, Eq. (16) is identical to an expression obtained by Ecker and Weizel.

In connection with a hydrogen plasma, such an expression as Eq. (16) is of limited usefulness, since other perturbations in the plasma must also be considered,[10] especially for $N^2\sim d$. For example, if the l degeneracy is neglected, it is not to be assumed that $N=d^{1/2}$ energy levels must be included in the atomic partition function.

4. CONCLUDING REMARKS

The principal value of the results of this study is that several approximate expressions are made available, which reveal some of the interesting properties of the exponentially shielded Coulomb potential. It does not appear that these results alone have immediate application to the calculation of thermodynamic functions, since other large perturbative effects must also be superposed on the perfect gas behavior of a hydrogen plasma. At this point it is desirable to re-emphasize that the preceding calculations are relevant to plasmas only for large electron-protron separations and not for low-lying states. As already indicated, Eq. (16) should not be used in terminating the atomic partition function. In this connection it should be mentioned that the well-known work of Inglis and Teller,[10] which treats the effects of the interatomic Stark broadening, likewise should not be used in terminating the partition function. Their work is applicable only to estimating the number of distinct spectral lines emanating from a radiating gas: Even though the higher energy levels are Stark broadened to such an extent that the spectral lines coalesce into a continuum, these broadened levels still represent bound states and must be included in the atomic partition function. It is not at all clear how one should sum over such broadened levels.

Slow Neutron Inelastic Scattering from Liquid Sodium*

P. D. RANDOLPH
Atomic Energy Division, Phillips Petroleum Company, Idaho Falls, Idaho
(Received 24 September 1963; revised manuscript received 7 February 1964)

Partial differential cross sections for slow neutron scattering from liquid sodium have been measured at 100, 150, and 200°C. The Materials Testing Reactor phased-chopper velocity selector was used with a 95% transmission sample at incident neutron energies of 0.025, 0.07, and 0.10 eV at eight scattering angles (16 to 85°). In the scattering law obtained from these cross sections, prominent coherent scattering maxima appear for energy transfers $\Delta E \leqq 0.2\ k_BT$, but disappear beyond $\Delta E = 0.3\ k_BT$. At each temperature, time-dependent widths $\rho(t)$ of the intermediate scattering function have been obtained by Fourier transformation of the scattering law for large momentum transfers. At times $<1\times10^{-13}$ sec these functions confirm the prediction of gas-like behavior, but at larger times are solid-like. The $\rho(t)$'s are also momentum-dependent at larger times indicating that the self-correlation function is not strictly Gaussian. Measurements of the zeroth and first moments of the energy transfer have been obtained from the scattering law at each temperature for several values of momentum transfer. The zeroth moment is in agreement with neutron diffraction experiments, but the first moment is as much as a factor of 2.5 larger than predicted theoretically.

I. INTRODUCTION

THIS report gives the results of an experimental measurement of the partial differential cross sections for slow neutron scattering by liquid sodium. Besides the cross sections themselves, which are of interest to reactor technology, information about the dynamics of the motions of atoms in the liquid can be obtained from them. Extensive investigations of this type have been made for water[1,2] and for liquid lead.[3] Sodium was chosen as the sample for this experiment because it meets the following requirements: (A) The liquid is monatomic so that no molecular effects occur. (B) The isotopic abundance is 100% Na^{23} so that the scattering from only a single isotope is involved. (C) It is one of the few elements meeting the first two requirements whose incoherent scattering cross section (1.85 b) is a large fraction of the total scattering cross section (3.4 b), and which also has a reasonably low absorption cross section (0.5 b). A relatively large incoherent cross section is desirable since it is only the incoherent scattering which yields information about the motions of individual atoms. A cold-neutron study of sodium has been made by Cocking[4] who studied the inelastic scattering in the range 80 to 200°C.

The present experiment was performed using the Materials Testing Reactor (MTR) slow-neutron phased-chopper velocity selector at incident neutron energies of 0.025, 0.07, and 0.10 eV at sample temperatures of 100, 150, and 200°C. The experimental data show that marked inelastic interference scattering occurs up to energy transfers $\Delta E \approx 0.2 k_BT$. Time-dependent width functions obtained from the data show that the self-part of the space-time correlation function is fitted well by the Gaussian approximation at very short time, but at intermediate times, Gaussian width functions differ by as much as a factor of 2 for different momentum transfers. We have also measured the first energy transfer moment of the scattering law at several fixed values of momentum transfer including corrections for multiple scattering and find that these are as much as a factor of 2.5 larger than predicted.

II. EXPERIMENTAL PROCEDURE

The MTR 4-rotor phased-chopper velocity selector used in this experiment has been described elsewhere in detail.[5] This velocity selector produces bursts of nearly monochromatic neutrons of thermal energies by the use of two Fermi choppers spinning at the same speed (5000 rpm) and phased with each other. The scattering target is placed 0.5 m beyond the second chopper and the scattered neutrons are detected simultaneously at eight scattering angles by BF_3 counter banks located 2 m from the sample. These detectors were at scattering angles of 16.3, 20.1, 26.0, 36.4, 47.6, 59.5, 72.1, and 84.7°, and subtended 7.5° in the scattering plane except the detector at 20.1° which subtended 3.5°.

The energy, flux, and time resolution of the incident neutrons are determined by a U^{235} fission chamber located in the transmitted beam 2 m from the sample. For each data run at a given temperature, the sample and empty sample are cycled alternately into the beam at 10-min intervals for a total running time of 48 h or longer. The data from each of the two holders are stored in a separate matrix of the 8192 channel time-of-flight analyzer. For this experiment, 256 10-μsec channels were used to time-analyze the data for each

angle and also for the beam monitor. Background corrections are made by subtracting the empty-holder data from the filled sample-holder data. If necessary, these data are normalized to the same counting rate at long and short flight times. After corrections for detector efficiency, the data are then converted to cross section and scattering law. The data of this experiment comprise runs made at 100, 150, and 200°C at each of the incident energies of 0.025, 0.07, and 0.10 eV. The runs at 100 and 150°C were taken at the 8

angles mentioned. At 200°C, additional detector angles of 84.4, 96, 107, 120, and 133° were used with a chopper speed of 6000 rpm.

The liquid-sodium sample used in this experiment was in the form of a rectangular slab having a thickness of 0.25 in. It was made as thin as possible in order to reduce effects of multiple scattering, and the above thickness is a compromise between this criterion and reasonable counting rates. The calculated transmission for thermal neutrons incident normally on the slab is 95%. In practice, the sample was oriented at 45° to the incident beam and was viewed in transmission by the detectors so that the effective transmission for this orientation was 91.5%. Multiple scattering in this sample is estimated to be less than 10% of the single scattering.

The sample holder was made of two hardened aluminum frames having a 0.25-in.-thick spacer between them. The frames sandwiched 0.001-in.-thick stainless steel windows against the spacer. The total window area of the holder was $5\frac{1}{2}\times 3$ in. Gasketing was accomplished by a narrow metal-to-metal contact around the edges of the window. No evidence of any leakage occurred at any time during the experiment. The difference in the thermal expansion coefficients of the aluminum and stainless steel kept the windows taut and no evidence of bulging of the sample was seen. The holder was made

	0.10	30	0.0657	0.131	0.160

taller than needed and was filled to less than capacity to allow for expansion of the sodium on melting. This further reduced any chance of bulging. The holder was not sealed from the atmosphere and in order to prevent excessive oxidation, it was operated under an argon purge. The purge volume was above the top of the beam so that there was no scattering from the argon. The window area was made large enough to accommodate the entire beam area (4×1.30 in.) and the frame was covered with cadmium to reduce the possibility of secondary scattering from the frame. Both the filled and empty holders were heated by 150-W cartridge heaters inserted into the top and bottom edges of each sample holder frame. The temperature was controlled automatically using a chromel-alumel thermocouple located at the edge of the spacer frame. After completion of the experiment, the sample holder was disassembled and the sodium sample analyzed. Spectrographic analysis showed only traces of Al, Ca, Cu, Fe, Mg, and Si. X-ray reflection patterns showed a thin film ($\sim$100 μ) of NaOH and NaO on the surfaces. The NaOH is believed not to have been present during the experiment but was formed afterward due to H_2O contamination of the kerosene used to store the disassembled sample.

III. EXPERIMENTAL RESULTS

Typical partial differential cross sections for liquid sodium are shown in Figs. 1–3 for an E_0 of 0.025 eV at each of the three temperatures. The counting rate data used for these figures were not smoothed. The "five-point data smoothing" technique[6] previously used, although it works very well for gases, is not satisfactory for sodium because the narrow quasielastic peaks (especially at forward angles) are comparable in width to the number of channels used to smooth the data. The result is that the smoothing gives counting rates that are too low (or even negative) at the base of the peak where the slope is changing rapidly. The error flags shown in the figures are counting statistics only. The 150 and 200°C data are of somewhat better quality than that at 100°C since the run times for these

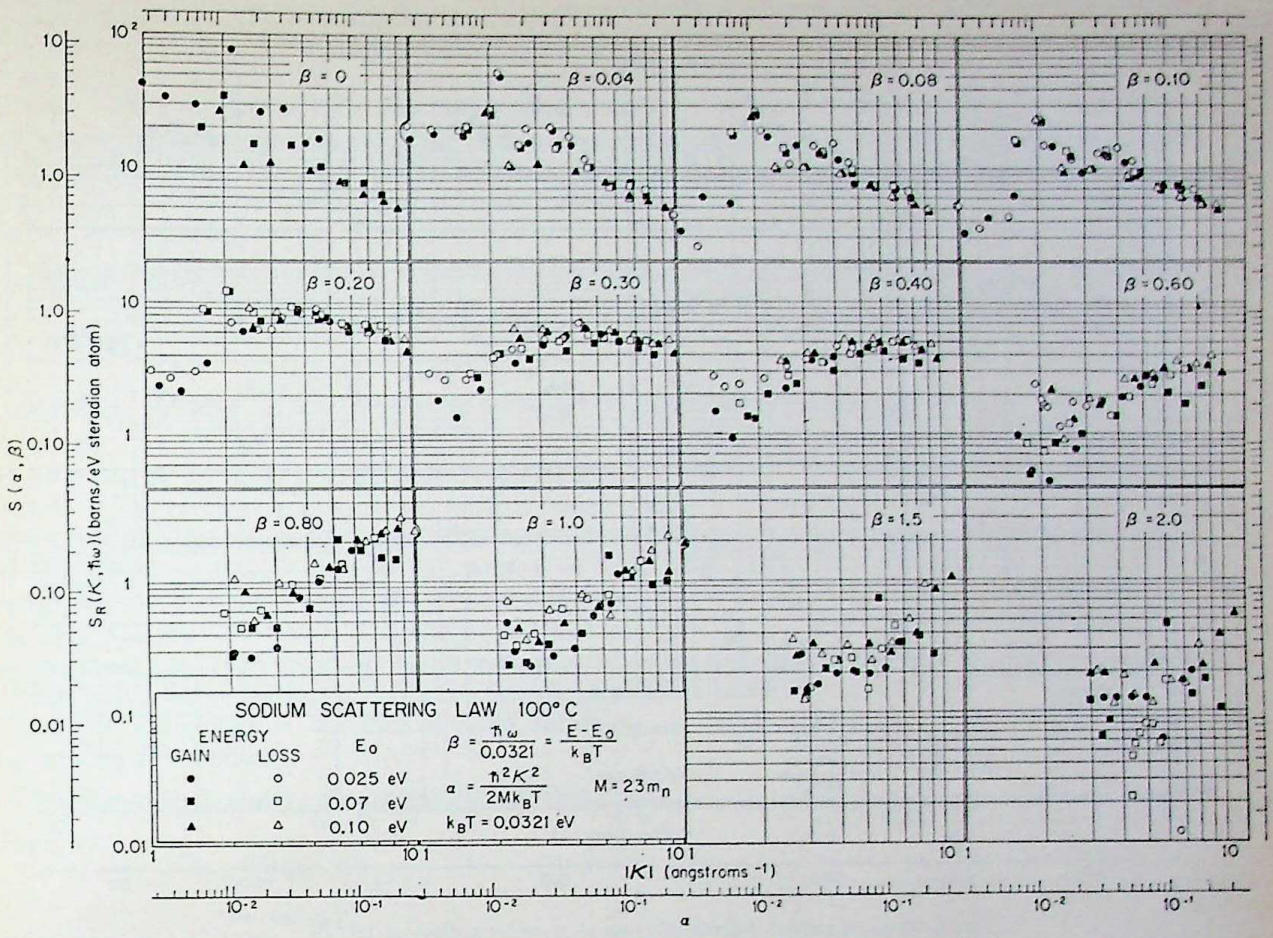

FIG. 5. Reduced partial differential cross sections for sodium at 100°C.

were each of 64 h, whereas the 100°C data were run only for 48 h.

A measure of the energy resolution for elastic scattering is given by the burst shapes of the incident beam which are also shown in the figures. Table I gives a summary of the widths of the bursts Δt (full width at half-maximum) measured by the beam monitor 2 m from the sample. This is calculated by $\Delta t/t_0$ where t_0 is the sample-to-detector time-of-flight at the incident energy E_0 and $\Delta E/E_0=2(\Delta t/t_0)$. The resolution is also expressed in terms of $\Delta\beta=\Delta E/2k_BT$, where T is the sample temperature.

The improvement in resolution at 200°C is due to the higher chopper speed (6000 rpm) used at this temperature.

The spectra for each temperature show two general features, a narrow quasielastic peak and a low broad spectrum of inelastically scattered neutrons. At the three forward angles, where the momentum transfers are small, the quasielastic scattering dominates and the inelastic scattering is very small. At 36°, the quasielastic peak is quite large compared with the other angles and the inelastic scattering has become larger. The momentum transfer for this quasielastic peak corresponds to the first maximum in the diffraction pattern so that this peak has a large contribution from coherent scattering. As the scattering angle continues to increase, the quasielastic peak becomes small or disappears and the inelastic scattering dominates the spectrum. The fact that at 200°C a quasielastic peak is seen at all angles is probably due to the improved resolution used at this temperature. Except for this, the spectra at each angle are qualitatively the same, and only small quantitative differences in the inelastic spectrum are present. At the 0.07 and 0.1 eV incident energies which are not shown, the data cannot be easily resolved into a quasielastic and an inelastic part. The cross sections shown in these figures are normalized to the total cross section value of 3.4 b.

Figure 4 shows the diffraction pattern obtained at 100 and 150°C by integrating the observed cross sections over the scattered wavelength. These are plotted as $d\sigma(\lambda_0)/d\Omega$ versus $s=\sin\frac{1}{2}\theta/\lambda_0$, and each plot includes the data from each of the three incident energies. The solid curve is the 100°C result of Gingrich and Heaton[7] obtained using a neutron crystal spectrometer and is normalized to the data at large s. The agreement is good except at the smaller values of s, where the finite

angular resolution of the detectors becomes important. The two major diffraction maxima are clearly evident.

The complete presentation of all the data is given in Figs. 5–7 in terms of the scattering law. This form is used since it is representative of all the data and is a very compact form. The form of the scattering law used is the "reduced partial differential cross section[8]" $S_R(|\kappa|,\hbar\omega)$ and is defined by

$$d^2\sigma(E_0,E,\theta)/dEd\Omega = [E/E_0]^{1/2}\exp[-\hbar\omega/2k_BT]S_R(\kappa,\hbar\omega), \quad (1)$$

where

$$\hbar\omega = E - E_0,$$
$$\boldsymbol{\kappa} = \mathbf{k} - \mathbf{k}_0,$$

where E_0, E, $\mathbf{k}_0$, and $\mathbf{k}$ are the energy and reduced wave vectors of the incident and scattered neutron, respectively, and θ is the scattering angle. This form obeys the conditions of detailed balance and is even in the energy transfer and in the magnitude of the momentum transfer. The results at each temperature are plotted as S_R versus κ for fixed values of $\hbar\omega$ (in units of k_BT). This form has the dimensions of a cross section (b/eV sr atom) and is related to the dimensionless form[9] of the scattering law $S(\alpha,\beta)$ by

$$S_R(\kappa,\hbar\omega) = (\sigma_b/4\pi k_BT)S(\alpha,\beta), \quad (2)$$

where

$$\alpha = \hbar^2\kappa^2/2Mk_BT,$$
$$\beta = \hbar\omega/k_BT.$$

The mass of the scattering atom is given by M, T is the absolute temperature of the sample, and σ_b is the bound-atom cross section. Scales for $S(\alpha,\beta)$ are also shown in the figures.

The range of momentum transfers spanned at each incident energy overlap so that in these regions, the scattering law is overdetermined. At any fixed incident energy, the smallest scattering angle has the smallest κ value. At low-energy transfer ($\beta \lesssim 0.1$) the effects of finite energy resolution cause the data from the different incident energies to form separate curves at the smaller angles, the higher energy curves being below the lower. At larger angles where resolution effects are small, the different incident energies give a single curve. In spite of the energy resolution, the effects of interference scattering are clearly present. The interference maxima are seen, corresponding to those seen in Fig. 4. These maxima are present at each temperature out to energy transfer $\hbar\omega \lesssim 0.25\ k_BT$, and disappear beyond this. This fact demonstrates that in sodium, the convolution approximation[10] is not adequate for energy transfers larger than about $0.25\ k_BT$ since it predicts contributions to the coherent scattering that have magnitudes which are independent of the energy transfer. For small energy transfers at low-momentum transfers, however, cold-neutron results[4] show that the convolution approximation is in agreement with the experiment.

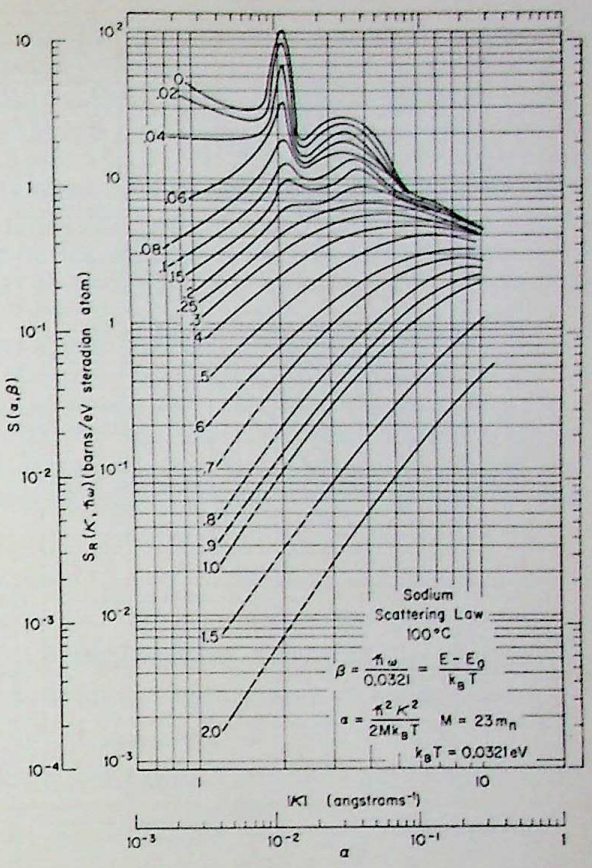

FIG. 8. Smooth curve scattering law for sodium at 100°C.

Smooth-curve scattering laws were obtained for each temperature by making a hand-drawn fit to the data. These are shown in Figs. 8–10. They are plotted as reduced partial differential cross sections $S_R(\kappa,\hbar\omega)$. Also shown are scales for the Egelstaff scattering law $S(\alpha,\beta)$. In drawing these, an attempt was made to reduce the effects of energy resolution by drawing the curve at low κ values for $\beta < 0.3$ to follow or lie above the lowest incident energy data.[11] Qualitatively, these curves are quite similar at each of the three temperatures indicating that from 100 to 200°C little change occurs in the properties of the liquid. All the smooth $S_R(\kappa,\hbar\omega)$ curves and the data plots are normalized to the total cross section using the value $\sigma = 3.4$ b.

IV. GAUSSIAN WIDTH FUNCTIONS

As was first shown by van Hove,[12] the scattering law is related to a time-dependent pair-correlation function for the system by a double Fourier transformation.

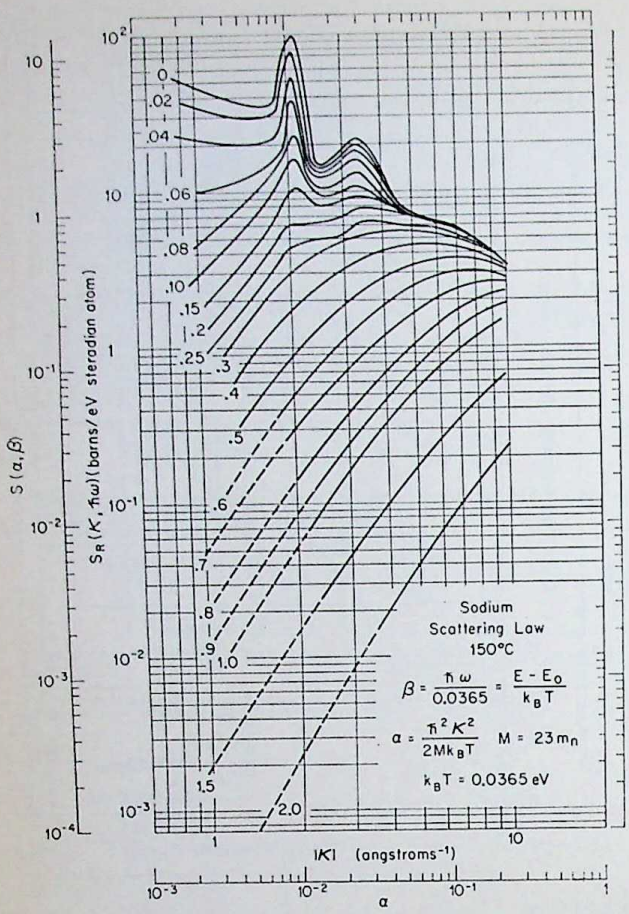

FIG. 9. Smooth curve scattering law for sodium at 150°C.

Various theoretical models for this correlation function have been studied for simple liquids. Vineyard[10] was the first to propose a specific model for the self-part of the correlation function which describes the self-diffusion of the liquid. The model proposed by Vineyard is that the self-part of the space-time correlation function is Gaussian in its space dependence with a time-dependent width. This model was shown to hold for a perfect gas, an oscillator, a Debye lattice, and for an atom obeying the classical equation of diffusion. This model is usually assumed to hold for simple liquids, at least as a first approximation. Indeed, it has been shown by Rahman *et. al.*,[13] that the Gaussian assumption enters as the first-order term in an expansion of the so-called intermediate scattering function in powers of κ^2.

In order to find out from experiment how well the Gaussian assumption holds, it is more convenient to work with this intermediate scattering function rather than with the correlation function or the scattering law. Defining a width function $\rho(t)$ by the Gaussian self-correlation function $G_s(r,t)$,

$$G_s(r,t)=[\pi\rho(t)]^{-3/2}\exp[-r^2/\rho(t)] \qquad (3)$$

then the intermediate scattering function $I_s(\kappa,t)$, which is the Fourier transform of G_s over space, may be written as a Fourier transform of the scattering law over the energy transfer.

$$I_s(\kappa,t)=\exp[-\kappa^2\rho(t)/4]=2\int_0^\infty \cos(\beta\tau)S_s(\alpha,\beta)d\beta, \qquad (4)$$

where in the right-hand member, we have used the symmetric form of the scattering law, and $\tau=(k_BT/\hbar)t$.

The use of the symmetric form of the scattering law implies that $\rho(0)=\hbar^2/2Mk_BT$ rather than $\rho(0)=0$. This constant term is of purely quantum-mechanical origin and is very small. From Eq. (4), if the Gaussian assumptions hold exactly, measurement of $S(\alpha,\beta)$ at fixed α (i.e., fixed κ^2) in principle allows a determination of $\rho(t)$ as was first pointed out by Vineyard.[10] Since $S(\alpha,\beta)$ is known for a range of α, then $\rho(t)$ is overdetermined. If the Gaussian assumption is exact, then the $\rho(t)$ obtained by Fourier transforming S at different values of α should give the same function and, hence, furnishes a test of the assumption.

Fourier transformation of the scattering law for liquid sodium has been performed at each of the three temperatures for several values of α using a program previously written.[11] Since it is only the noninterference portion of S that contains information about the diffusive motions, the range of α at which the trans-

formation was computed for $\alpha \geq 0.1$ at each temperature using the smooth curve scattering laws shown in Figs. 8–10. It is seen that for $\alpha \gtrsim 0.1$, the strong interference effects have disappeared. The advantage of this region of α space is that no approximate method need be used to separate the interference and the noninterference parts of the scattering. The disadvantage of this is that Fourier transformation at large α restricts the range for which $\rho(t)$ can be obtained to relatively short times. In making these transformations, $S(\alpha,\beta)$ was assumed to go linearly to zero beyond $\beta=2$. In all cases, this gave a zero value for $S(\alpha\beta,)$ at $\beta \lesssim 2.4$.

Figure 11 shows the resulting width functions plotted as a function of time for various fixed values of α. Also, there is shown for comparison, the slope characteristic of a simple diffusion model and the width functions for a perfect gas. Generally, the shapes of the various $\rho(t)$ are the same for each temperature. In none of the cases is $\rho(t)$ independent of α for $t \gtrsim 1\times10^{-13}$ sec, so that in this time range, the Gaussian assumption does not hold exactly. At a given time, the experimental $\rho(t)$ values drop by a factor of about 2 in the α range covered. For times less than 1×10^{-13} sec, the curves agree well and follow the gas behavior expected for very short times. The apparent large differences in the $\rho(t)$'s for $t \lesssim 0.1\times10^{-13}$ sec are due to the use of the logarithmic ordinate; on a linear plot these portions of the curves fall very close to each other and the average value of $\rho(0)$ is $\rho(0) \cong \hbar^2/2Mk_BT$. At larger times ($t > 1\times10^{-13}$ sec.), the slopes of the $\rho(t)$ curves are in all cases much less than that of the simple diffusion model. Assuming that the experimental $\rho(t)$ behavior is ap-

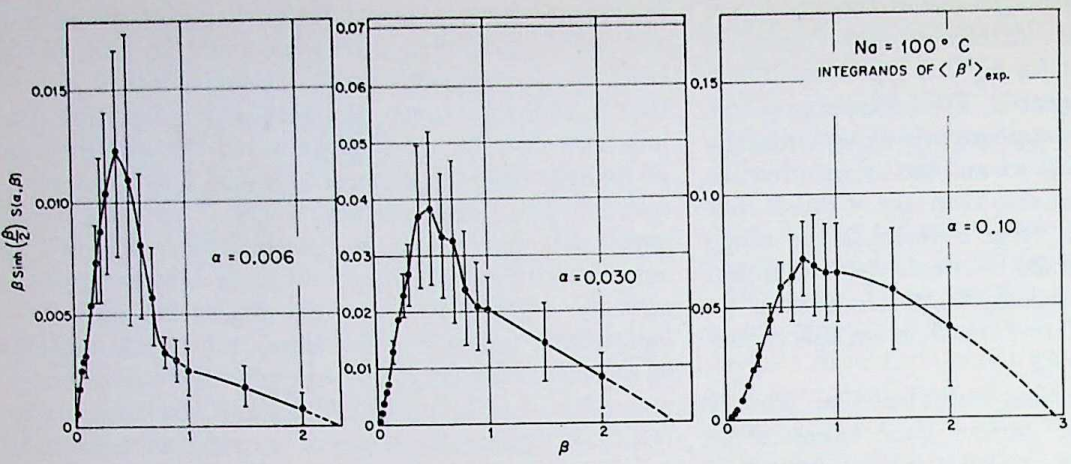

FIG. 12. Representative integrands of the first energy transfer moment of the scattering law for sodium at 100°C.

proximately Gaussian, and that at sufficiently long times it should be proportional to t, characteristic of simple diffusion, it is seen that in the time range available, such diffusive behavior has not yet occurred. The flatness of the curves indicates that for $t<10\times10^{-13}$ sec, the behavior is more nearly that characteristic of a solid. Taking $\rho(t)=0.5\times10^{-16}$ cm^2 at $t=10\times10^{-13}$ sec then the rms value of r obtained assuming Eq. (3) is 0.87 Å. The nearest neighbor distance r_0 is 3.83 Å so that at such a time the atom is still within the cage of its nearest neighbors and diffusive behavior is not expected. On the other hand at $t\cong0.8\times10^{-13}$, the end of the region of gas-like behavior, $\rho(t)=2\times10^{-16}$ cm^2 and the rms radius is $r=0.55$ Å. Thus, the sodium atoms move as free particles for only 15% of the nearest neighbor distance before feeling the effects of binding.

V. MOMENTS OF THE SCATTERING LAW

The results obtained in this experiment have also been used to obtain the first two moments of the energy transfer with respect to the scattering law.[14] Theoretical expressions for these moments were first obtained by Placzek[15] and have been discussed for classical systems by DeGennes.[16] Rahman *et. al.*,[13] have recently rederived the moment relations for the quantum case in a very clear and concise fashion.

Letting $\langle\beta^0\rangle$ be the zeroth and $\langle\beta^1\rangle$ the first, then the two lowest energy moments are given in terms of the symmetric scattering law by

$$\langle\beta^0\rangle\equiv2\int_0^\infty \cosh(\tfrac{1}{2}\beta)S(\alpha,\beta)d\beta = (1/\sigma_b)\{\sigma_{\rm inc}+\sigma_{\rm coh}[1+\gamma(\kappa)]\}\,, \quad (5)$$

$$\langle\beta^1\rangle\equiv2\int_0^\infty \beta\sinh(\tfrac{1}{2}\beta)S(\alpha,\beta)d\beta=\alpha\,, \quad (6)$$

where σ_b, $\sigma_{\rm inc}$ and $\sigma_{\rm coh}$ are the total bound, incoherent, and coherent scattering cross sections, respectively, and $1+\gamma(\kappa)$ is the structure factor for the liquid. These relations include the effects of both coherent and incoherent scattering. The integrations are to be performed at constant momentum transfer (i.e., constant α) rather than for a fixed scattering angle. Equation (5) is essentially a statement that the integration of the double differential cross section over outgoing energies for fixed momentum transfer is proportional to the diffraction pattern. Equation (6) is a sum rule, the longitudinal f-sum rule which is well known in other aspects of the many-body problem. It is rigorously correct for systems which are reflection invariant and for which the interactions between particles of the system are velocity-independent.[17] Roughly speaking, it states that the mean energy transferred by the neutron is equal to the translational recoil kinetic energy of the scatterer.

The integrations in Eq. (5) and (6) were performed, using a planimeter, for several fixed values of momentum transfer in the range $0.004\leq\alpha\leq0.2$ at each temperature. Figure 12 shows some representative integrands of $\langle\beta^1\rangle$ at the middle and the extremes of the range of logα. The values of $S(\alpha,\beta)$ were taken from the normalized smooth scattering law curves of Figs. 8–10. The error flags on the plotted points were estimated at each β by using the lower limit of the spread of the $S(\alpha,\beta)$ data points of Figs. 6–8. The curve drawn through the points indicates the area of intergration. In all cases beyond $\beta=2$, the integrand was extrapolated to zero in the manner shown.

The results of the moment measurements for each temperature are shown in Fig. 13. These are shown as the ratio of the observed experimental moments to calculated value at the various values of α. The theoretical zeroth-moment ratios [the right-hand side of Eq. (5)] at all three temperatures were calculated using for $1+\gamma(\kappa)$ the experimental diffraction results

[a] Values corrected for multiple scattering.

of Gingrich and Heaton[7] at 100°C. The results for the zeroth-moment ratios cluster near the value 1 in agreement with Eq. (5). The measured first moments, however, are in marked disagreement with the expected values, being as much as a factor 3 larger than the calculated value. In addition, the discrepancy is temperature-dependent being largest at the lowest temperature. At each temperature, the first-moment ratio also exhibits an apparent α dependence, the ratio decreasing at large and small α. The decrease at large α would be expected since for sufficiently large momentum transfers, the system would act like an ideal gas, and hence, would obey the sum rule. Also, the experimental trend indicates that for α sufficiently small, the sum rule may also be obeyed. In Table II are shown the mean values of the moment ratios plotted in Fig. 13. Also shown are the maximum values of the first moment ratio.

The errors on the first-moment ratio values in Fig. 13 are estimated to be $\pm 35\%$ as obtained from the spread in the scattering-law data points at the various beta values. It is seen that even on the low-limit side of the errors, the first-moment ratios would still disagree with the predicted values. The two major sources of systematic error which could lead to high values of $\langle\beta^1\rangle_{obs}$ are the finite energy resolution of the velocity selector and multiple inelastic scattering in the target. Qualitative corrections for finite resolution, which were made when drawing the scattering law, were checked at 100°C by convoluting the known velocity-selector burst shape with the partial differential cross section regenerated from this smooth-curve scattering law at the smallest scattering angle (16.3°) and the highest incident energy (0.1 eV), where resolution effects are the largest. The resulting cross section agrees within $\pm 10\%$ with data for that angle. Also, the effects of energy resolution are in general most pronounced for the smallest energy transfers ($\beta \leq 0.2$), and this region contributes little to the first moment integral (see Fig. 12). In any case, at large scattering angles (large alpha) where the cross section peaks are broad compared with the burst width, energy resolution effects would be small.

Since the target is thin, scattering only 8% of the incident beam, multiple scattering effects should be small. In order to determine to what extent multiple scattering affects the first moment, an estimate of the multiple scattering was made by fitting $S(\alpha,\beta)$ to a polynomial in α and assuming that the zeroth-order

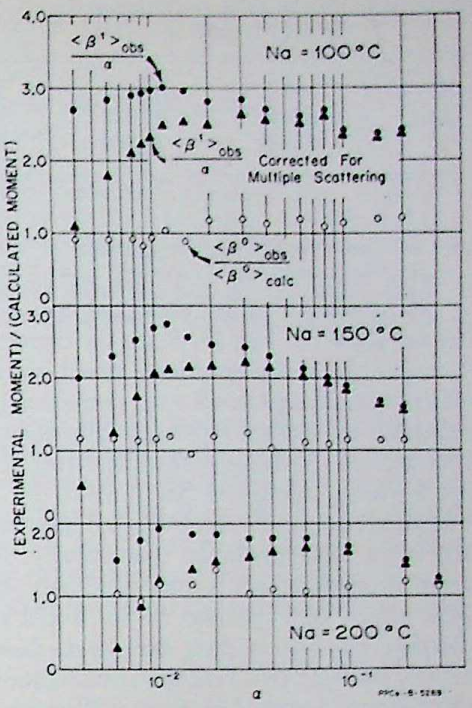

FIG. 13. Ratios of the observed to the calculated zeroth and first energy transfer moments of the scattering law for sodium at 100, 150 and 200°C.

term arises from multiple scattering,[1] i.e.,

$$S(\alpha,\beta)=A_0(\beta)+A_1(\beta)\alpha+A_2(\beta)\alpha^2+A_3(\beta)\alpha^3+\cdots.$$

Since the first term in a theoretical expression of $S(\alpha,\beta)$ is proportional to α and since multiple scattering is expected to be roughly isotropic and hence independent of α, it is assumed that the term $A_0(\beta)$ is due to multiple scattering. The first moment ratio, corrected for multiple scattering is then given by

$$\langle\beta^1\rangle_{corr}/\alpha=(\langle\beta^1\rangle_{obs}/\alpha)-(\langle\beta^1{}_c\rangle/\alpha),$$

where the correction term $\langle\beta_c{}^1\rangle$ is obtained from the same integral as Eq. (6) with $S(\alpha,\beta)$ replaced by $A_0(\beta)$. This correction is not expected to be exact, but the procedure is a reasonable one and is the best practical one available at the present time. Its accuracy is unknown and cannot be determined until experimental measurements of multiple inelastic scattering are available.

The $S(\alpha,\beta)$ curves of Figs. 8–10 for $\beta \geq 0.25$ were least-squares fit to a third-order polynomial in α in order to obtain $A_0(\beta)$. Scattering-law values for $\beta<0.25$ were not used since the extrema in $S(\alpha,\beta)$ caused by coherent scattering would necessitate a much higher order polynomial. The values of $A_0(\beta)$ for $\beta<0.25$ were obtained by extrapolating $A_0(\beta)$ to $\beta=0$. Table III shows the amount of multiple scattering compared to the peak value of $S(\alpha,\beta)$, i.e., $A_0(0)/S(\alpha,0)$ at each temperature together with the value of $\langle\beta_c{}^1\rangle$, the correction to the observed first moment. Table II gives

the values of the average and maximum of the first-moment ratio, corrected for multiple scattering. The resulting first-moment ratios corrected for multiple scattering are shown in Fig. 13. Since the correction to the first-moment ratio is proportional to α^{-1}, the largest effect occurs at small α. At small α the correction is large and accounts for most of the measured ratio and may be an over correction. At large momentum transfers the correction becomes negligible. In general, for alpha $\gtrsim 0.010$ at all temperatures the corrected moments are still much larger than predicted theoretically. A conceivable explanation for this is that velocity-dependent interactions might be important in the liquid or else that reflection invariance does not hold. However, it is extremely unlikely that reflection invariance would fail in a monatomic liquid. Also there is little reason to expect, nor is there other evidence to support the hypothesis that velocity-dependent interactions play any great role in a liquid. Additional scattering experiments of higher precision would be needed to make such hypotheses tenable.

SUMMARY AND CONCLUSIONS

The scattering law for liquid sodium between 100 and 200°C has been measured in the range of momentum transfer $1 \lesssim \kappa \lesssim 10$ Å^{-1} for energy transfers out to about 0.06 eV. The scattering law shows pronounced maxima due to inelastic coherent scattering for energy transfers below 0.2 k_BT, but which disappear for larger energy transfer, demonstrating that the convolution approximation does not hold in general for liquid Na. Time-dependent Gaussian width functions obtained by Fourier transformation of the scattering law at several momentum transfers show that sodium behaves as an ideal gas for times less than 1.0×10^{-13} sec corresponding to an rms atomic displacement of 15% of the nearest neighbor distance, but for larger times behaves more like a solid. In the time range available, $\lesssim 10\times10^{-13}$ sec, there is no evidence that simple diffusive behavior has been approached. The width functions for times greater than 1×10^{-13} sec are momentum-dependent, showing that the Gaussian assumption for the self-correlation function does not hold rigorously for momentum transfers larger than $K \approx 6$ Å^{-1}. Measurements of the two lowest moments of the energy transfer show that the zeroth moment gives the expected results but that the first moment is much larger than the theoretical values for a wide range of momentum transfers. The cause of this discrepancy remains to be explained. Whatever the underlying physical reasons for the discrepancy, it should not be peculiar to sodium, but should also appear in other metals. In any case, it would be of interest if energy transfer moments were measured in other metallic liquids.

PHYSICAL REVIEW VOLUME 134, NUMBER 5A 1 JUNE 1964

Theory of Solid Neon at 0°K

WILLIAM J. MULLIN
Aerospace Research Laboratories, Wright-Patterson Air Force Base, Ohio
(Received 12 November 1963)

A quantum-mechanical variational calculation of the energy per particle, the equilibrium nearest-neighbor distance, and the pressure-volume relationship for solid neon at 0°K is performed. Use is made of a Jastrow-type trial wave function, a phenomenological Mie-Lennard-Jones 12-6 potential, and a cluster expansion evaluation of the energy expectation value. It is found that correlation effects are negligible at equilibrium, contrary to the speculations of some authors, and that good agreement with the experimental data can be achieved if one of the interparticle potential parameters, ϵ, is changed by a small amount from its accepted gas-phase value. This parameter change is discussed.

I. INTRODUCTION

THE atoms of the inert gases have closed electronic shells which minimizes the importance of the details of their atomic structure in any discussion of the solid phase of these elements. The fact that only the gross properties are significant makes these elements ideal for testing basic principles of quantum mechanics and solid-state theory. Despite the straightforwardness of theoretical treatment, some discrepancies have been found in comparison of theory and experiment. For one, it is found that the predicted cohesive energy of solid neon at 0°K is too small.[1,2] (One writer[3] has predicted a cohesive energy which is in agreement with experiment; we will discuss this result in Sec. IV.)

Some authors[1,2] have speculated that the disagreement of the theoretical and measured values is caused by correlation effects. We will study this conjecture by using a Jastrow-type trial wave function[4] in a variational calculation. A cluster expansion will be used to evaluate the energy expectation value. The Mie–Lennard-Jones 12-6 potential is used to describe phenomenologically the electron interaction energy. We will show that correlation effects are negligible in solid neon near the equilibrium density and that theory and experiment can be brought into reasonable agreement by altering a Mie–Lennard-Jones potential parameter value by a small amount.

II. THE SCHRÖDINGER EQUATION AND THE TRIAL WAVE FUNCTION

The Schrödinger equation for both electrons and nuclei of the solid is

$$H\Psi(\mathbf{x},\mathbf{x}_e)=E\Psi(\mathbf{x},\mathbf{x}_e)\,, \tag{1}$$

where

$$H=H(\mathbf{x},\mathbf{p},\mathbf{x}_e,\mathbf{p}_e)=(1/2m)\sum_i \mathbf{p}_i^2+(1/2m_e)\sum_j \mathbf{p}_{ej}^2 +U(\mathbf{x},\mathbf{x}_e)\,, \tag{2}$$

with m, $\mathbf{x}_i$, $\mathbf{p}_i$, the mass, position vector, and momentum operator of the ith nucleus, respectively; m_e, $\mathbf{x}_{ej}$, $\mathbf{p}_{ej}$, the mass, position vector, and momentum operator of the jth electron. $U(\mathbf{x},\mathbf{x}_e)$ is the total electrostatic energy of the system, with the symbol $\mathbf{x}$, for example, representing the set of vectors $\mathbf{x}_1$, $\mathbf{x}_2$, $\cdots$. The Born-Oppenheimer approximation[5] can be applied to Eq. (1) to yield an equation for the nuclear motion alone,

$$[(1/2m)\sum_i \mathbf{p}_i^2+V(\mathbf{x})]\psi(\mathbf{x})=E\psi(\mathbf{x})\,. \tag{3}$$

The wave function $\psi(\mathbf{x})$ is that of the nuclei; $V(\mathbf{x})$ is the electronic energy.

The most widely used form for $V(\mathbf{x})$ is the phenomenological Mie–Lennard-Jones 12-6 potential

$$V(\mathbf{x})=4\epsilon\sum_{i<j}[(\sigma/x_{ij})^{12}-(\sigma/x_{ij})^{6}]\,, \tag{4}$$

where $x_{ij}=|\mathbf{x}_i-\mathbf{x}_j|$. Gas data are normally used to evaluate σ and ϵ.

If we now let

$$\lambda^2=\hbar^2/(2m\sigma^2\epsilon)\,, \tag{5}$$

then the combination of Eqs. (3) and (4) gives

$$[-\lambda^2\sum_i \nabla_i^2+4\sum_{i<j}(x_{ij}^{-12}-x_{ij}^{-6})]\psi(\mathbf{x})=E\psi(\mathbf{x})\,, \tag{6}$$

where x_{ij} and E are now dimensionless, i.e., we have made the substitutions $x_{ij}/\sigma\rightarrow x_{ij}$ and $E/\epsilon\rightarrow E$.

Our procedure is to solve Eq. (6) by means of a variational technique. Because of the large repulsive term, x_{ij}^{-12}, in the potential (4), a wave function for the solid must tend to zero when any two nuclei approach closely. One way to provide for this is to approximate the total wave function $\psi(\mathbf{x})$ by a product of single-particle, localized, nonoverlapping wave functions,

$$\psi(\mathbf{x})=\prod_{i=1}^{N}\phi(\mathbf{x}_i-\mathbf{R}_i)\,. \tag{7}$$

$\mathbf{R}_i$ is the position of the ith lattice site. Bernardes[1,3] chose $\phi(\mathbf{x}_i-\mathbf{R}_i)$ to be the wave function of a particle moving freely in a sphere centered at $\mathbf{R}_i$. The radius

Digitized by Arya Samaj Foundation Chennai and eGangotri

of the sphere was used as a variational parameter. In this theory an atom feels a force exerted on it by each of the other atoms, but otherwise its motion is independent or "uncorrelated" with that of the others.

A more realistic wave function is one of the Jastrow-type

$$\psi(\mathbf{x})=\prod_{i=1}^{N}\phi(\mathbf{x}_i-\mathbf{R}_i)\prod_{j<k}f(x_{jk}), \tag{8}$$

where

$$\begin{aligned} f(x_{jk})&\to 0 \quad \text{if} \quad x_{jk}\to 0 \\ f(x_{jk})&\to 1 \quad \text{if} \quad x_{jk}\to\infty . \end{aligned} \tag{9}$$

The factor $f(x_{jk})$ is the "correlation" function. The wave function (8) gives each nucleus a larger effective potential well than (7) since it allows it to move more freely toward and in between neighboring lattice sites. Divergences in the expectation value of $V(\mathbf{x})$ are avoided, even if the $\phi(\mathbf{x}_i-\mathbf{R}_i)$ are overlapping, by the vanishing of $f(x_{jk})$ as $x_{jk}\to 0$.

As normalized single-particle wave functions we choose

$$\phi(\mathbf{x}_i-\mathbf{R}_i)=(2A/\pi)^{3/4}\exp[-A(\mathbf{x}_i-\mathbf{R}_i)^2], \tag{10}$$

where A is a constant.

We write

$$f(x_{jk})=\exp[S(j,k)], \tag{11}$$

and take

$$S(j,k)=-\tfrac{1}{2}(C/x_{jk}{}^n), \tag{12}$$

where C, n are positive constants. It is clear that our $f(x_{jk})$ satisfies the conditions of Eqs. (9). The constants C, A, and n are variational parameters.

III. THE ENERGY EXPECTATION VALUE AND ITS CLUSTER EXPANSION

The expectation value of the energy is given by

$$E=\frac{\int e^S\Phi[-\lambda^2\sum_i\nabla_i^2+V(\mathbf{x})]e^S\Phi d\mathbf{x}}{\int e^{2S}\Phi^2 d\mathbf{x}}, \tag{13}$$

where $\Phi=\prod_i\phi(\mathbf{x}_i-\mathbf{R}_i)$ is real; $S=\sum_{i<j}S(i,j)$, and $d\mathbf{x}=d\mathbf{x}_1d\mathbf{x}_2\cdots d\mathbf{x}_N$. If we integrate by parts we find

$$\int\Phi e^S\nabla_i^2\Phi e^S d\mathbf{x}=\int e^{2S}\{[\tfrac{1}{4}\nabla_i^2(\Phi^2)-(\nabla_i\Phi)^2]+\tfrac{1}{2}\Phi^2\sum_{j(j\neq i)}\nabla_i^2S(i,j)\}d\mathbf{x}. \tag{14}$$

(See Ref. 6 for details. Note the absence of three-particle terms which occur in earlier Jastrow-type calculations.[7]) For our Gaussian wave functions, the term in square brackets of Eq. (14) becomes simply $(-3A\Phi^2)$. By Eq. (12)

$$\nabla_i^2S(i,j)=-(C/2)[n(n-1)/x_{ij}{}^{n+2}]. \tag{15}$$

Thus Eq. (13) becomes

$$E=3A\lambda^2N+\frac{\sum_{i<j}\int e^S\Phi\tilde{V}(i,j)e^S\Phi d\mathbf{x}}{\int e^{2S}\Phi^2 d\mathbf{x}}, \tag{16}$$

where the "effective" two-body potential is

$$\tilde{V}(i,j)=4(x_{ij}{}^{-12}+px_{ij}{}^{-(n+2)}-x_{ij}{}^{-6}), \tag{17}$$

with

$$p=(C/8)\lambda^2n(n-1). \tag{18}$$

We evaluate the matrix elements of $\tilde{V}_{ij}$ in Eq. (16) by means of the cluster expansion technique.[6-8] Following the method of Iwamoto and Yamada[8] we write

$$\frac{\sum_{i<j}\int e^S\Phi\tilde{V}(i,j)e^S\Phi d\mathbf{x}}{\int e^{2S}\Phi^2 d\mathbf{x}}=\frac{\partial}{\partial\beta}\ln I_N(\beta)\Big|_{\beta=0}, \tag{19}$$

where the "generalized normalization integral," $I_N(\beta)$, is defined by

$$I_N(\beta)=\int\exp(2S+\beta\tilde{V})\Phi^2 d\mathbf{x}, \tag{20}$$

and $\tilde{V}=\sum_{i<j}\tilde{V}(i,j)$. Define the "subnormalization" integrals by

$$I_i=(i|i)\equiv\int\phi^2(\mathbf{x}_1-\mathbf{R}_i)d\mathbf{x}_1=1, \tag{21a}$$

$$I_{ij}=(ij|g(1,2)|ij)\equiv\int\int\phi^2(\mathbf{x}_1-\mathbf{R}_i)\times\phi^2(\mathbf{x}_2-\mathbf{R}_j)g(1,2)d\mathbf{x}_1d\mathbf{x}_2, \tag{21b}$$

$$I_{ijk}=(ijk|g(1,2)g(2,3)g(3,1)|ijk), \tag{21c}$$

$$\vdots \qquad\qquad \vdots$$

$$I_{i_1i_2\cdots i_m}=(i_1i_2\cdots i_m|\prod_{1\leqslant\gamma<\delta\leqslant m}g(\gamma,\delta)|i_1i_2\cdots i_m), \tag{21d}$$

where

$$g(\gamma,\delta)=\exp[2S(\gamma,\delta)+\beta\tilde{V}(\gamma,\delta)]. \tag{22}$$

Digitized by Arya Samaj Foundation Chennai and eGangotri

Using the subnormalization integrals we define the cluster integrals

$$Y_i=I_i, \tag{23a}$$

$$Y_{ij}=I_{ij}-I_iI_j, \tag{23b}$$

$$Y_{ijk}=I_{ijk}-I_{ij}I_k-I_{jk}I_i-I_{ki}I_j-I_iI_jI_k, \tag{23c}$$

etc.

We find

$$Y_i=1, \tag{24a}$$

$$Y_{ij}=(ij|h(1,2)|ij), \tag{24b}$$

$$Y_{ijk}=(ijk|[h(1,2)h(2,3)h(3,1)+h(1,2)h(3,1)+h(1,2)h(2,3)+h(2,3)h(3,1)]|ijk), \tag{24c}$$

where

$$h(\gamma,\delta)=g(\gamma,\delta)-1. \tag{25}$$

In Ref. 8 it is shown that

$$I_N(\beta)=\prod_i Y_i e^G, \tag{26}$$

where

$$G=\tfrac{1}{2}\sum_{i,j}{}' y_{ij}-\tfrac{1}{4}\sum_{i,j}{}' y_{ij}^2-\tfrac{1}{2}\sum_{i,j,k}{}' y_{ij}y_{jk}+\tfrac{1}{6}\sum_{i,j,k}{}' y_{ijk}+\cdots, \tag{27}$$

and, for example, $y_{ij}=Y_{ij}/Y_iY_j$. The prime on each of the summations of Eq. (27) means omit those terms for which two or more indices are equal. Equation (27) is an expansion in powers of the function $h(\gamma,\delta)$. We will consider only terms with two or fewer factors of $h(\gamma,\delta)$. Those terms symbolized by the dots in Eq. (27) are of higher order in $h(\gamma,\delta)$ than we wish to consider.

We find from Eqs. (16)–(27)

$$E=3A\lambda^2N+\tfrac{1}{2}\sum_{i,j}{}'(ij|W(1,2)|ij)-\tfrac{1}{2}\sum_{i,j}{}'(ij|W(1,2)|ij)(ij|\eta(1,2)|ij)-\sum_{i,j,k}{}'(ij|\eta(1,2)|ij)(jk|W(1,2)|jk)+\sum_{i,j,k}{}'(ijk|W(1,2)\eta(1,3)|ijk)+\cdots, \tag{28}$$

where

$$W(\gamma,\delta)=e^{2S(\gamma,\delta)}\bar{V}(\gamma,\delta), \tag{29}$$

and

$$\eta(\gamma,\delta)=h(\gamma,\delta)|_{\beta=0}=(e^{2S(\gamma,\delta)}-1). \tag{30}$$

Equation (28) includes terms no higher than first order in the function $\eta(\gamma,\delta)$. Succeeding terms will be higher order in $\eta(\gamma,\delta)$. We will discuss the contribution of such terms later. Note that the new "effective" potential $W(\gamma,\delta)$ contains a factor

$$\exp[2S(\gamma,\delta)]=\exp[-Cx_{\gamma\delta}{}^{-n}],$$

which insures convergent results for the matrix elements in Eq. (28).

IV. REVIEW OF PREVIOUS THEORETICAL TREATMENTS

Bernardes has made two variational calculations, each of which involves the use of a trial wave function which is a product of single-particle wave functions each spherically symmetric around a lattice site. In his first calculation[1] he found an energy per particle of -420 cal/mole compared to the experimental value of -450 ± 10 cal/mole.[9] His second calculation[2] gave a value of -445 cal/mole in good agreement with experiment. Nosanow and Shaw,[2] however, have done a Hartree calculation resulting in a theoretical value of -431 cal/mole. They used the same potential parameters, σ and ϵ, in Eq. (4), as did Bernardes. The Hartree technique used by Nosanow and Shaw yields the best result in a variational computation of the energy with a trial wave function which is a product of single-particle wave functions each of which is spherically symmetric about a lattice site. We may speculate that Bernardes' first result does not agree with that of Nosanow and Shaw either because his wave function lacks sufficient variational flexibility or because an expansion he makes does not converge sufficiently rapidly. As he discounts both of these possibilities we are unable to resolve the discrepancy. Bernardes' second calculation leads to an energy which is actually lower than the result of the Hartree technique. Since our results, given in the next section, agree with those of the Hartree technique we are inclined to believe that Bernardes' agreement with experiment is fictitious. Possibly he did not keep a sufficient number of terms in an expansion made in powers of λ.

V. NUMERICAL TECHNIQUES AND RESULTS

As a first approximation we keep only the first two terms of Eq. (28), giving

$$E=3A\lambda^2N+\sum_{i<j}(ij|W(1,2)|ij). \tag{31}$$

We have

$$(ij|W(1,2)|ij)=\int\int\phi^2(\mathbf{x}_1-\mathbf{R}_i)\phi^2(\mathbf{x}_2-\mathbf{R}_j)\times W(x_{12})d\mathbf{x}_1d\mathbf{x}_2$$

$$=\left(\frac{2A}{\pi}\right)^3\int\int\exp[-2A(\mathbf{x}_1-\mathbf{R}_i)^2]\times\exp[-2A(\mathbf{x}_2-\mathbf{R}_j)^2]\times W(x_{12})d\mathbf{x}_1d\mathbf{x}_2. \tag{32}$$

Let $\mathbf{z}_1=\mathbf{x}_1-\mathbf{x}_2$, $\mathbf{z}_2=\mathbf{x}_2-\mathbf{R}_i$. Then

$$(ij|W(1,2)|ij)=\left(\frac{2A}{\pi}\right)^3\int d\mathbf{z}_1 W(|\mathbf{z}_1|)$$
$$\times\exp[-2A\mathbf{z}_1^2]\int d\mathbf{z}_2\exp[-4A(\mathbf{z}_2+\mathbf{R}_{ij})^2]$$
$$\times\exp[-2A(\mathbf{z}_2^2+2\mathbf{z}_1\cdot\mathbf{z}_2)], \quad (33)$$

with $\mathbf{R}_{ij}=\mathbf{R}_i-\mathbf{R}_j$. Carrying out the $\mathbf{z}_2$ integration yields

$$(ij|W(1,2)|ij)=(2A/\pi)^3\int d\mathbf{z}_1 W(|\mathbf{z}_1|)$$
$$\times\exp[-A(\mathbf{z}_1+\mathbf{R}_{ij})^2]$$
$$=(A/\pi)^{1/2}(1/R_{ij})\int_0^\infty dz\, zW(z)$$
$$\times\{\exp[-A(z-R_{ij})^2]$$
$$-\exp[-A(z+R_{ij})^2]\}, \quad (34)$$

where $R_{ij}=|\mathbf{R}_{ij}|$ and $z=|\mathbf{z}_1|$.

Our procedure is to choose initial values for n and C and minimize E as a function of A. We then choose a new value for C and again minimize with respect to A. In this way we find the minimum of E as a function of C. The whole procedure is repeated for a second value of n, etc. All of the above is done for various values of the nearest-neighbor distance R until we find the equilibrium or zero pressure nearest-neighbor distance R_0 which is the value of R when E is an absolute minimum. The procedure is greatly simplified by the fact that the energy expectation value has a broad minimum as a function of C and n. The computations were performed numerically using an IBM-7090 computer.

In computing the lattice sums indicated in Eq. (31) we found sufficient accuracy was obtained if we summed over the first sixty "shells" of particles, all particles on a "shell" being a given distance from the particle at the origin. This involved summing over the nearest 3126 neighbors to each nucleus. Values for the numbers of particles on the shells and for the shell distances for the face-centered cubic lattice were taken from Ref. 10.

First we make use of Bernardes' potential constants $\sigma=2.74$ Å and $\epsilon=50.0\times10^{-16}$ erg. (Second virial coefficient gas-phase data give $\sigma=2.75$ Å, $\epsilon=49.2\times10^{-16}$ erg.[11]) Initially we take the convenient value $n=10$. We find that the value of C which minimizes the energy at a nearest-neighbor distance near the experimental equilibrium value is less than 10^{-4}. In fact, we find that the lowest energy value given by Eq. (31) occurs if, in our numerical computations, we set $C=0$ and begin our integration in Eq. (34) at that value of z for which $\exp[-A(z-R_{ij})^2]$ is negligibly small, say, less than 10^{-5} in comparison with its maximum of unity. Of course, C cannot be precisely zero since then the matrix element $(ij|W(1,2)|ij)$ would diverge. We will describe this situation by saying $C=0+$.

A good measure of the importance of correlation is the relative size of the term $px_{ij}^{-(n+2)}$ in comparison with the other potential terms in Eq. (17). For $n=10$, the ratio of this term to x_{ij}^{-12} is $p=90(\lambda^2C/8)<10^{-5}$. Because C is so small the result does not depend on the value of n chosen. To demonstrate this statement explicitly we consider the case $n=4$. Again we find $C=10^{-4}$ and the ratio of $px_{ij}^{-(n+2)}$ to x_{ij}^{-6} is less than 10^{-6}. Thus we have the important result that near equilibrium correlation effects are negligible in solid neon. Table I summarizes the results.

Because the value of C minimizing the approximate E value of Eq. (31) is small, the neglected terms in the expansion, Eq. (28), do not contribute. To see this consider the matrix element $(ij|\eta(1,2)|ij)$. Using the derivation leading to Eq. (34), we can show

$$(ij|\eta(1,2)|ij)=(A/\pi)^{1/2}(1/R_{ij})$$
$$\times\int_0^\infty dz\, z\{\exp[-Cz^{-n}]-1\}\{\exp[-A(z-R_{ij})^2]$$
$$-\exp[-A(z+R_{ij})^2]\}. \quad (35)$$

The factor $\exp[-Cz^{-(n+2)}]$ is unity over the entire range of integration for which the Gaussian functions are appreciable, so that $(ij|\eta(1,2)|ij)$ is essentially zero. Similar arguments hold for the other terms first order in $\eta(\gamma,\delta)$ in Eq. (28). Other terms in the expansion are of even higher order in $\eta(\gamma,\delta)$ and also do not contribute.

TABLE I. Energy expectation value as a function of the variational parameters C and n, using Bernardes' potential constants[a] $\sigma=2.74$Å, $\epsilon=50.0\times10^{-16}$ erg. All quantities are expressed in reduced units, length in units of σ, energy in units of ϵ. A_0 is the value of the parameter A which yields the minimum energy per particle, E_0/N, for a given C and n, at a fixed value $R=1.138$ of the nearest-neighbor distance near equilibrium. (For the sake of comparison we have quoted values of E_0/N to four significant figures. Although we claim only three figure absolute accuracy, the relative accuracy between the values of E_0/N for various values of C is four figures.)

TABLE II. Comparison of various theoretical results with experiment for the energy per particle $\epsilon E_0/N$ and the equilibrium nearest-neighbor distance σR_0.

	Theory $\sigma=2.74$ Å, $\epsilon=50.0\times10^{-16}$ erg			Theory $\sigma=2.75$ Å, $\epsilon=51.7\times10^{-16}$ erg		Experiment
	Bernardes (Ref. 1)	Bernardes (Ref. 3)	Nosanow-Shaw (Ref. 2)	This work	This work	Refs. 9 and 12
$-\epsilon E_0/N$ (cal/mole)	420	445[a]	431[b]	431	449	450±10
σR_0 (Å)	3.14	3.13[a]	—	3.12	3.13	3.13

[a] See Sec. IV of text.
[b] Computed at the experimental value of R_0 only.

If we transform from our reduced units we find the minimum energy per particle at the equilibrium density to be $\epsilon E_0/N=-431$ cal/mole, in precise agreement with the Hartree computation. This result shows that we do not need additional variational parameters in our wave function. The nearest neighbor distance at equilibrium is found to be $\sigma R_0=3.12$ Å in comparison with the experimental values[12] of 3.13 Å.

To find the pressure-volume relationship for the solid, we use $P=-\partial E/\partial V$, where P is the pressure, and V the volume. We analytically differentiate Eq. (31) with respect to the nearest-neighbor distance R and use

$$P=-\frac{\partial E}{\partial V}=-\frac{2^{1/2}}{3}\frac{1}{R^2}\frac{\partial E}{\partial R} \tag{36}$$

which holds for the face-centered cubic lattice. In this equation P is expressed in units of ϵ/σ^3. We find

$$P=(8A/\pi)^{1/2}(1/3R^3)(F_0-2AF_1)\,, \tag{37}$$

where

$$F_0=\sum_{i<j}(1/R_{ij})\int_0^\infty dz\, zW(z)\{\exp[-A(z-R_{ij})^2]-\exp[-A(z+R_{ij})^2]\}\,, \tag{38}$$

$$F_1=\sum_{i<j}\int_0^\infty dz\, zW(z)\{(z-R_{ij})\exp[-A(z-R_{ij})^2]-(z+R_{ij})\exp[-A(z+R_{ij})^2]\}\,. \tag{39}$$

Given an R value we find that value of A, which minimizes E (with $C=0+$ and $n=10$) and compute the corresponding pressure by Eq. (37). (Note that by taking $C=0+$, we have assumed correlation to be negligible at all pressures.) Our results for Bernardes' σ and ϵ are shown as curve A in Fig. 1, where we have plotted pressure in kg/cm² versus V/V_0, V_0 being the molar volume at equilibrium. The dots are the experimental data of Stewart.[13] We note that there is some disagreement between curve A and the experimental points in contrast to the good agreement each of Bernardes' calculations give. (Bernardes' curves are not shown in Fig. 1.)

The question arises concerning the possibility of obtaining agreement between our theory and all of the experimental data by merely adjusting the potential constants σ and ϵ by a few percent. Consider the values $\sigma=2.75$ Å and $\epsilon=51.7\times10^{-16}$ ergs. The performance of the same operations as described above gives a value of -449 cal/mole for the energy per particle at an equilibrium distance of 3.13 Å. Table II compares the various theoretical results with experiment. Curve B in Fig. 1 is the resulting P-V relationship which is in good agreement with the data up to about 15×10^3 kg/cm². Above that pressure it is possible that correlation effects become nonnegligible. Our discussion of correlation applies only to equilibrium.

VI. DISCUSSION

Our results show that it is possible to explain the properties of solid neon on the basis of a two-body (Mie–Lennard-Jones 12-6) potential and a simple product trial wave function. Correlation effects are

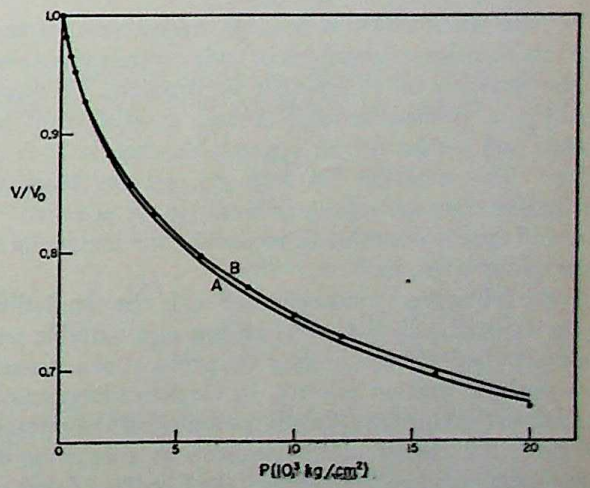

FIG. 1. Pressure-volume relationship for solid neon. The dots are the experimental values of Stewart (Ref. 13). Curves A and B are the theoretical relationships corresponding, respectively, to the potential constants of Bernardes, $\sigma=2.74$ Å, $\epsilon=50.0\times10^{-16}$ erg, and to those discussed in the text, $\sigma=2.75$ Å, $\epsilon=51.7\times10^{-16}$ erg.

negligible at low pressures. The values of the potential constants which give a fit to the data, $\sigma=2.75$ Å, $\epsilon=51.7\times10^{-16}$ ergs, differ at most by only a few percent from those given by gas phase data, $\sigma=2.75$ Å, $\epsilon=49.2\times10^{-16}$ ergs.

The fact that different constants are needed to explain the gas and solid-phase data of neon should not be at all surprising. The Mie–Lennard-Jones potential is a phenomenological interaction and should be expected to vary somewhat from one type of phenomenon to another.[14] A similar situation occurs, for example, in the treatment of argon. Second virial coefficient data[15] give, $\epsilon=165\times10^{-16}$ ergs, gas viscosity data[16] give $\epsilon=171\times10^{-16}$ ergs, and crystal data[17] give $\epsilon=169\times10^{-16}$ ergs.[18]

Positronium in a LiH Crystal*

S. M. Neamtan and R. I. Verrall
Department of Mathematical Physics, The University of Manitoba, Winnipeg, Canada
(Received 9 December 1963; revised manuscript received 30 January 1964)

The question as to whether the existence of a bound positronium-like system in an ionic crystal is energetically possible is considered with particular reference to lithium hydride. The crystal field of LiH is simulated by a potential expressed as a sum of central field potentials centered on the ion sites. An upper bound is obtained for the ground-state energy of a system of an electron and a positron in Coulomb interaction with each other and moving in the crystal potential, and comparison is made with estimates of the energies of the positron and the electron moving independently in the crystal. The result is energetically favorable to the formation and persistence of positronium in the crystal through capture by a positron of an electron from the valence band.

I. INTRODUCTION

CONSIDERATION of possible mechanisms for the annihilation of positrons in ionic crystals gives rise to the question as to whether positronium, or more precisely a positronium-like bound system, can be formed and persist for an appreciable time in such a crystal. This question has formerly, on the basis of qualitative arguments, been answered in the negative.[1,2] It would appear desirable to reconsider the matter on a more quantitative basis.

In the following, we consider in Sec. II the simulation of the crystal field of LiH by means of a suitable potential. In Sec. III we consider the problem of a system of a positron and an electron in Coulomb interaction moving in the constant periodic potential of the crystal, the potential energy of the positron as a function of position being taken to be simply the negative of that of the electron. By treating the effect of the crystal field as a perturbation of the Hamiltonian for free positronium, the energy shift of the ground state is calculated to second order of perturbation theory. An improved result is then obtained in the form of an upper bound to the ground-state energy by calculating the average of the Hamiltonian with the aid of a wave function given by perturbation theory. In Sec. IV the procedure used in estimating the ground-state energy of a positron in the crystal field is outlined. In Sec. V use is made of the results obtained in a discussion of the energetics of positronium formation in the crystal. Section VI contains an assessment of the results and their relation to experiment.

II. CRYSTAL POTENTIAL OF LiH

The lithium hydride crystal, being an ionic crystal, has a relatively open structure. We therefore make the approximation of treating the potential as being made up of a sum of spherically symmetric potentials centered on the ion sites. The first problem, then, is to obtain an

approximation to the potential due to a lithium ion and that due to a hydride ion.

We shall take the potential due to a lithium ion to be of the form

$$\mathcal{U}_1(R)=(e/R)+(2e/R)e^{-\alpha R}, \quad (1)$$

where e is the charge on a proton and α is a parameter which is to be determined. This potential has the correct behavior for both large and small R. It has the advantage of being simple in its mathematical form. Similarly, the potential of the hydride ion is taken to be

$$\mathcal{U}_2(R)=(2e/R)e^{-\beta R}-(e/R), \quad (2)$$

where β is a parameter which is to be determined.

The parameter α is obtained by observing that the potential $\mathcal{U}_1(R)$ is effectively the potential in which the third electron of a lithium atom moves. The ground-state energy of this third electron is known. We may, therefore, set up the Schroedinger equation for this particle, wherein only the parameter α is unknown. With a fixed value of α we may solve the equation numerically. The parameter α can be varied until we obtain a solution which has one radial node and which behaves properly as $r\rightarrow\infty$. This procedure was carried out on a computer, and the value for α obtained was

$$\alpha=4.152\ \text{Å}^{-1}. \quad (3)$$

The value for the parameter β in the hydride ion potential was obtained in a different fashion. Using a wave function for the hydride ion, the charge density is

$$\rho(\mathbf{R}_1)=-2e\int_\tau|\psi(\mathbf{R}_1,\mathbf{R}_2)|^2 d\tau_2. \quad (4)$$

The potential due to this charge density, $v(R)$, is given by

$$\nabla^2 v(\mathbf{R})=-4\pi\rho(\mathbf{R}). \quad (5)$$

The wave function for the hydride ion was taken to be of the form used by G. Darewych.[3]

$$\psi(\mathbf{R}_1,\mathbf{R}_2)=(1+\nu R_{12})(e^{-(\lambda R_1+\mu R_2)}+e^{-(\mu R_1+\lambda R_2)}), \quad (6)$$

where

$$R_{12}=|\mathbf{R}_2-\mathbf{R}_1|, \quad (7)$$

and

$$\lambda=0.9033\ \text{Å}^{-1},\quad \mu=2.0315\ \text{Å}^{-1},\quad \nu=0.5898\ \text{Å}^{-1}. \quad (8)$$

Using this wave function, it is possible to carry out the integration in Eq. (4) and to solve the Poisson equation to give an explicit form of the potential. This potential was approximated with high accuracy by the form

$$\mathcal{U}_2(R)=(2e/R)e^{-\beta R}-(e/R). \quad (9)$$

[3] G. Darewych (private communication).

The value of β for the best fit is

$$\beta=1.715\ \text{Å}^{-1}. \quad (10)$$

The crystal potential is now taken to be

$$V(\mathbf{R})=\sum_j[\mathcal{U}_1(\mathbf{R}-\mathbf{R}_j)+\mathcal{U}_2(\mathbf{R}-\mathbf{R}_j-\mathbf{a})], \quad (11)$$

where $\mathbf{R}_j$ is the position vector of the jth positive ion and $\mathbf{a}$ is the position vector of a negative ion with respect to an origin at the location of a positive ion.

III. GROUND-STATE ENERGY OF POSITRONIUM IN THE CRYSTAL

We shall now investigate the problem of positronium in this potential. The Hamiltonian for the two-particle system in this field is

$$H=-(\hbar^2/2m)(\nabla_1^2+\nabla_2^2)-(e^2/|\mathbf{r}_2-\mathbf{r}_1|)+eV(\mathbf{r}_1)-eV(\mathbf{r}_2), \quad (12)$$

where $\mathbf{r}_1$ and $\mathbf{r}_2$ are the positions of the positron and electron, respectively. It is to be noted that the potential energies of the electron and of the positron due to the crystal field differ only in sign.

The Hamiltonian may be expressed in terms of the center-of-mass coordinate $\mathbf{R}$ and the relative coordinate $\mathbf{r}$, where we have

$$\mathbf{R}=(\mathbf{r}_1+\mathbf{r}_2)/2 \quad (13)$$

and

$$\mathbf{r}=\mathbf{r}_2-\mathbf{r}_1. \quad (14)$$

The Hamiltonian becomes

$$H=-\frac{\hbar^2}{4m}\nabla_R^2-\frac{\hbar^2}{m}\nabla_r^2-\frac{e^2}{r}+eV\left(\mathbf{R}-\frac{\mathbf{r}}{2}\right)-eV\left(\mathbf{R}+\frac{\mathbf{r}}{2}\right). \quad (15)$$

In accordance with perturbation theory, we write this Hamiltonian as the sum of two parts:

$$H=H_0+H_1, \quad (16)$$

where

$$H_0=-\frac{\hbar^2}{4m}\nabla_R^2-\frac{\hbar^2}{m}\nabla_r^2-\frac{e^2}{r} \quad (17)$$

and

$$H_1=eV\left(\mathbf{R}-\frac{\mathbf{r}}{2}\right)-eV\left(\mathbf{R}+\frac{\mathbf{r}}{2}\right). \quad (18)$$

H_1 will be treated as a perturbation on the Hamiltonian H_0.

H_0 consists of the sum of two noninteracting parts,

$$-(\hbar^2/4m)\nabla_R^2 \quad (19)$$

and

$$-(\hbar^2/m)\nabla_r^2-(e^2/r). \quad (20)$$

CC-0. In Public Domain.

Digitized by Arya Samaj Foundation Chennai and eGangotri

The first is the Hamiltonian of a free particle and the second is the Hamiltonian of the positronium atom. Therefore, the eigenfunctions of H_0 may be written

$$\psi_{\mathbf{k},nlm}=e^{i\mathbf{k}\cdot\mathbf{R}}\phi_{nlm}(\mathbf{r}), \tag{21}$$

where $\phi_{nlm}(\mathbf{r})$ is a positronium wave function, where the quantum numbers n, l, m have the usual meaning. The energy corresponding to this state is

$$(\hbar^2k^2/4m)+E_n, \tag{22}$$

where E_n is the energy of the nth level of positronium.

Let us examine the effect of the perturbation on the ground-state energy. The first-order perturbation energy is

$$[\psi_{0,100}(\mathbf{r}),H_1\psi_{0,100}(\mathbf{r})]. \tag{23}$$

Since H_1 is of odd parity in the $\mathbf{r}$ space, this vanishes. From similar parity arguments, it can be seen that all odd-order perturbation energies vanish. Thus the second-order perturbation, which we shall now calculate, is in fact accurate to third order.

The second-order perturbation energy is

$$\sum_{\mathbf{k},nlm}\frac{|[\psi_{0,100}(\mathbf{r}),H_1\psi_{\mathbf{k},nlm}(\mathbf{r})]|^2}{E_1-[(\hbar^2k^2/4m)+E_n]}. \tag{24}$$

The inner product in the above expression involves an integration over both the $\mathbf{R}$ and the $\mathbf{r}$ spaces. The functions of $\mathbf{R}$ are not quadratically integrable, so we must resort to a box quantization procedure. The inner product becomes

$$\operatorname*{Lim}_{L\to\infty}\frac{1}{L^3}\int_{\tau_R,\tau_r}\phi_{100}^*(r)\left[eV\left(\mathbf{R}-\frac{\mathbf{r}}{2}\right)-eV\left(\mathbf{R}+\frac{\mathbf{r}}{2}\right)\right]\times\phi_{nlm}(\mathbf{r})e^{i\mathbf{k}\cdot\mathbf{R}}d\tau_R d\tau_r, \tag{25}$$

where $1/L^3$ is the square of the normalization constant used in the box quantization procedure. By suitable shifts of origin, expression (25) can be reduced to the form

$$\left[\operatorname*{Lim}_{L\to\infty}\frac{1}{L^3}\int_{\tau_R}e^{i\mathbf{k}\cdot\mathbf{R}}eV(\mathbf{R})d\tau_R\right]\times\left[\int_{\tau_r}\phi_{100}^*(r)\phi_{nlm}(\mathbf{r})(e^{i\mathbf{k}\cdot(\mathbf{r}/2)}-e^{-i\mathbf{k}\cdot(\mathbf{r}/2)})d\tau_r\right]. \tag{26}$$

Now $V(\mathbf{R})$ has the periodicity of the crystal. It may therefore be expanded as a Fourier series.

$$V(\mathbf{R})=\sum C_{\mathbf{K}}e^{2\pi i\mathbf{K}\cdot\mathbf{R}}, \tag{27}$$

where $\mathbf{K}$ is a vector of the reciprocal lattice.

The integral

$$\operatorname*{Lim}_{L\to\infty}\frac{1}{L^3}\int_{\tau_R}e^{i\mathbf{k}\cdot\mathbf{R}}V(\mathbf{R})d\tau_R \tag{28}$$

is equal to $C_{-\mathbf{K}}$, if $\mathbf{k}$ is 2π times a reciprocal lattice vector and is zero otherwise. Also, it is obvious that $C_{\mathbf{K}}=C_{-\mathbf{K}}$. Substituting these results into Eq. (26), we find that the second-order perturbation, expression (24), reduces to

$$4\sum_{\mathbf{K}}|C_{\mathbf{K}}|^2\sum_{nlm}\frac{\left|\int\phi_{100}^*(\mathbf{r})\phi_{nlm}(\mathbf{r})\sin\left(\frac{\mathbf{k}\cdot\mathbf{r}}{2}\right)d\tau_r\right|^2}{E_1-\left(\frac{\hbar^2k^2}{4-m}+E_n\right)}. \tag{29}$$

Now $E_n=E_1/n^2$. As n increases E_n quickly becomes small. We set E_n equal to zero, in the above, in order to facilitate summations. We shall come back later and correct for the first few terms. Using this approximation, (29) may now be written

$$4\sum_{\mathbf{K}}|C_{\mathbf{K}}|^2\sum_{nlm}\frac{\int\phi_{100}^*(r)\phi_{100}(r')\phi_{nlm}(\mathbf{r})\phi_{nlm}^*(\mathbf{r}')\sin\left(\frac{\mathbf{k}\cdot\mathbf{r}}{2}\right)\sin\left(\frac{\mathbf{k}\cdot\mathbf{r}'}{2}\right)d\tau_r d\tau_{r'}}{E_1-\frac{\hbar^2k^2}{4m}}. \tag{30}$$

We now sum over n, l, and m. Since $\{\phi_{nlm}(\mathbf{r})\}$ is a complete orthonormal set of functions, we have

$$\sum_{nlm}\phi_{nlm}^*(\mathbf{r}')\phi_{nlm}(\mathbf{r})=\delta(\mathbf{r}'-\mathbf{r}). \tag{31}$$

Integration over the $\mathbf{r}'$ space reduces the integral to

$$4\sum_{\mathbf{K}}|C_{\mathbf{K}}|^2\frac{\int|\phi_{100}(r)|^2\sin^2\left(\frac{\mathbf{k}\cdot\mathbf{r}}{2}\right)d\tau_r}{E_1-\frac{\hbar^2k^2}{4m}}, \tag{32}$$

which is equal to

$$2\sum_{\mathbf{K}}|C_{\mathbf{K}}|^2\frac{\{1-[1/(1+a_0^2k^2)^2]\}}{E_1-(\hbar^2k^2/4-m)}. \tag{33}$$

We must now evaluate $C_{\mathbf{K}}$. From Eq. (27) we obtain

$$C_{\mathbf{K}}=\frac{1}{\Delta}\int V(\mathbf{R})e^{-2\pi i\mathbf{K}\cdot\mathbf{R}}d\tau_R, \tag{34}$$

where Δ is the volume of a unit cell of the crystal lattice and the integration is carried out over this volume.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Substituting Eq. (11) in (34) we obtain

$$C_{\mathbf{K}}=\frac{1}{\Delta}\int\sum_j[\mathcal{V}_1(\mathbf{R}-\mathbf{R}_j)+\mathcal{V}_2(\mathbf{R}-\mathbf{R}_j-\mathbf{a})]\times e^{-2\pi i\mathbf{K}\cdot\mathbf{R}}d\tau_R. \quad (35)$$

It is easily seen that this is equal to

$$\frac{1}{\Delta}\int[\mathcal{V}_1(\mathbf{R})+\mathcal{V}_2(\mathbf{R}-\mathbf{a})]e^{-2\pi i\mathbf{K}\cdot\mathbf{R}}d\tau_R, \quad (36)$$

where this integration is carried out over all space. We now let

$$\mathbf{K}=n_1\mathbf{b}_1+n_2\mathbf{b}_2+n_3\mathbf{b}_3, \quad (37)$$

where $\mathbf{b}_1$, $\mathbf{b}_2$, and $\mathbf{b}_3$ are a set of basis vectors in the reciprocal lattice, and n_1, n_2, and n_3 are integers. On substituting the functions $V_1(R)$ and $V_2(R)$ into the integral we obtain

$$C_{\mathbf{K}}=\frac{2\pi e^2}{L^3}\left\{\frac{2}{k^2+\alpha^2}+\frac{1}{k^2}+(-1)^{n_1+n_2+n_3}\left[\frac{2}{k^2+\beta^2}-\frac{1}{k^2}\right]\right\}, \quad (38)$$

where L is the shortest distance between positive and negative ions in the crystal. It is to be remembered that

$$\mathbf{k}=2\pi\mathbf{K}=2\pi(n_1\mathbf{b}_1+n_2\mathbf{b}_2+n_3\mathbf{b}_3). \quad (39)$$

Substitution of this expression for $C_{\mathbf{K}}$ into Eq. (33) leaves only the summation over $\mathbf{K}$ to be performed.

It is recalled that this value is an approximation to expression (29) wherein we took E_n to be zero. We shall now go back and correct for the first few values of n.

From parity considerations it is clear that the integral in expression (29) vanishes when l is even. We therefore need consider only the odd values of l in the correction calculations. This implies immediately that we need not consider $n=1$ for which l has only the value 0. The correction term to be added to (33) is, therefore,

$$4\sum_{\mathbf{K}}|C_{\mathbf{K}}|^2\sum_{n=2}^{5}\sum_{\text{odd }l,m}\int\phi_{100}^*(r)\phi_{100}(r')\phi_{nlm}(\mathbf{r})\phi_{nlm}^*(\mathbf{r}')\times\sin\left(\frac{\mathbf{k}\cdot\mathbf{r}}{2}\right)\sin\left(\frac{\mathbf{k}\cdot\mathbf{r}'}{2}\right)d\tau_{r'}d\tau_r\times\left\{\frac{1}{E_1-E_n-\dfrac{\hbar^2k^2}{4m}}-\frac{1}{E_1-\dfrac{\hbar^2k^2}{4m}}\right\}, \quad (40)$$

where the summation over n is terminated at $n=5$.

Consider the sum

$$\sum_{\text{odd }l,m}\int\phi_{100}^*(r)\phi_{100}(r')\phi_{nlm}(\mathbf{r})\phi_{nlm}^*(\mathbf{r}')\times\sin\left(\frac{\mathbf{k}\cdot\mathbf{r}}{2}\right)\sin\left(\frac{\mathbf{k}\cdot\mathbf{r}'}{2}\right)d\tau_r d\tau_{r'}. \quad (41)$$

We express $\sin(\mathbf{k}\cdot\mathbf{r}/2)$ in terms of complex exponentials and use the relation

$$e^{i\mathbf{k}\cdot\mathbf{r}}=\sum_{l'=0}^{\infty}(2l'+1)i^{l'}P_{l'}(\cos\theta)j_{l'}(kr), \quad (42)$$

where $j_{l'}(kr)$ is a spherical Bessel function. We also write $\phi_{nlm}(\mathbf{r})$ as

$$\phi_{nlm}(r)=R_{nl}(r)Y_l^m(\theta,\phi). \quad (43)$$

On summation over m and integration over angle, the expression (41) reduces to

$$4\pi\sum_{\text{odd }l}(2l+1)\left[\int\phi_{100}(r)R_{nl}(r)j_l\left(\frac{kr}{2}\right)r^2dr\right]^2. \quad (44)$$

The energy shift given by Eq. (40) therefore reduces to

$$16\pi\sum_{\mathbf{K}}\sum_{n=2}^{5}|C_{\mathbf{K}}|^2\sum_{\text{odd }l}(2l+1)\times\left[\int\phi_{100}(r)R_{nl}(r)j_l\left(\frac{kr}{2}\right)r^2dr\right]^2\times\left[\frac{1}{E_1-E_n-(\hbar^2k^2/4m)}-\frac{1}{E-(\hbar^2k^2/4m)}\right], \quad (45)$$

wherein the integrals can be explicitly evaluated. The summations in expressions (33) and (45) were evaluated on a computer.

These computations yield a second-order energy shift of -4.51 eV. Since the unperturbed energy is -6.802 eV, this places the energy of the positronium system at $-6.802-4.51=-11.31$ eV.

Since this energy shift is quite large, it was decided to obtain a check on the result by calculating an upper bound to the energy. This was done by evaluating the expected average of the Hamiltonian using the wave function given by the perturbation theory. This perturbed ground-state wave function is given by

$$\psi=\psi_{0,100}+\sum_{klm}\frac{(\psi_{0,100},H_1\psi_{k,nlm})}{E_1-E_n-(\hbar^2k^2/4m)}\psi_{k,nlm}. \quad (46)$$

Using this wave function, we wish to calculate $(\psi,H\psi)/$

CC-0. In Public Domain.

Digitized by Arya Samaj Foundation Chennai and eGangotri

(ψ,ψ). The numerator reduces to

$$(\psi,H\psi)=E_1+2\sum_{\mathbf{k},nlm}\frac{|(\psi_{0,100},H_1\psi_{\mathbf{k},nlm})|^2}{\left[E_1-E_n-\dfrac{\hbar^2k^2}{4m}\right]}$$

$$=\sum_{\mathbf{k},nlm}\frac{[E_n+(\hbar^2k^2/4m)]|(\psi_{0,100},H_1\psi_{\mathbf{k},nlm})|^2}{[E_1-E_n-(\hbar^2k^2/4m)]^2}. \quad (47)$$

The denominator reduces to

$$(\psi,\psi)=1+\sum_{\mathbf{k},nlm}\frac{|(\psi_{0,100},H_1\psi_{\mathbf{k},nlm})|^2}{[E_1-E_n-(\hbar^2k^2/4m)]^2}. \quad (48)$$

The first sum in Eq. (47) is the same as that in expression (24). The other two sums in Eqs. (47) and (48) are evaluated in much the same fashion. The result of this calculation is

$$(\psi,H\psi)/(\psi,\psi)=-13.43\text{ eV}. \quad (49)$$

It is to be recalled that this is an upper bound to the energy.

It can be shown that the error in the above result, arising from the approximation procedure used in the summations, is less than 0.01 eV. If, in (47) and (48) we attempt to approximate by taking the discrete sum only up to $n=5$, the result obtained for $(\psi,H\psi)/(\psi,\psi)$ is -7.044 eV. The large discrepancy between this and the more accurate value obtained above indicates that there is a substantial contribution to the wave function ψ from the higher excited states of positronium. This, in turn, implies (since the $l=0$ states do not contribute) that there is a significant departure of the wave function from spherical symmetry.

IV. GROUND-STATE ENERGY OF A POSITRON IN THE CRYSTAL

We must now estimate the ground-state energy of a positron in the simulated potential. An upper bound to this energy is calculated by making use of the variational principle. Since we are seeking the ground state, the wave function must have all the symmetries of the potential. A trial wave function ψ is expanded into a Fourier series, where the basis functions have the form

$$\sum_{P(n_1,n_2,n_3)}P(n_1,n_2,n_3)\cos\frac{2\pi n_1X}{a}\times\cos\frac{2\pi n_2Y}{a}\cos\frac{2\pi n_3Z}{a}. \quad (50)$$

The X, Y, Z coordinates are chosen along the fundamental lattice vectors, each of length a. The symbol $P(n_1,n_2,n_3)$ represents a permutation of the three integers n_1, n_2, and n_3. The sum is carried out over all six permutations. This function has the complete symmetry of the potential.

The Fourier coefficients in the expansion of ψ are used as the variable parameters in the variational technique.

The Hamiltonian for the positron is

$$H=-(\hbar^2/2m)\nabla^2+eV(\mathbf{R}), \quad (51)$$

where $V(\mathbf{R})$ is the crystal potential obtained previously. It can be easily seen that the inner product $(\psi,H\psi)$ is a homogeneous quadratic function of the Fourier coefficients, i.e.,

$$(\psi,H\psi)=\sum_{ij}a_{ij}C_iC_j, \quad (52)$$

where C_i is a Fourier coefficient and a_{ij} is a constant. Similarly, the inner product (ψ,ψ) has the form

$$(\psi,\psi)=\sum_i b_i{}^2C_i{}^2, \quad (53)$$

where the coefficients $b_i{}^2$ are constants.

The variational procedure involves minimizing $(\psi,H\psi)$ with respect to the variable parameters. In other words, we wish to minimize $(\psi,H\psi)$ subject to the condition that $(\psi,\psi)=1$. By the introduction of a Lagrange undetermined multiplier this problem reduces to finding the smallest eigenvalue of the matrix whose (i,j)th element is a_{ij}/b_ib_j. A total of 15 Fourier coefficients were chosen, the corresponding values of a_{ij} and b_i were calculated, and the 15×15 matrix was diagonalized with the aid of a computer.[4] The ground-state energy of the positron was found to be $+7.317$ eV.

V. POSITRONIUM FORMATION IN THE CRYSTAL

We consider now the energetics of positronium formation following the usual type of argument. Let E_p be the ground-state energy of the bound positronium system in the crystal, E^+ the actual energy of the positron, and $E_0{}^+$ the energy of its ground state, $-V_i$ the energy of an electron at the top of the valence band, and $-V_1$ the energy of an electron at the bottom of the conduction band.

In order for it to be energetically possible for a positron to capture an electron from the valence band to form positronium, the positron energy must be large enough to satisfy the inequality,

$$E^+-V_i\geqslant E_p. \quad (54)$$

In order for the positronium so formed to persist, energy considerations should forbid the separation of the bound system with the deposition of the electron at the bottom of the conduction band. Thus we require

$$E_0{}^+-V_1>E^+-V_i. \quad (55)$$

[4] The computation of the matrix elements and the diagonalization of the matrix was performed by A. G. Heinicke at the University of Manitoba.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Values of V_i and V_1 for LiH are not available, but for purposes of the present argument it will turn out that rough estimates of these quantities are sufficient. For the alkali halides, V_i ranges up to about 9 eV, and V_1 has been estimated of the order of 0.5 eV[5] or less. For use in (54) and (55) we shall set $V_i=10$ eV and $V_1=1$ eV. With the value of E_p obtained in Sec. III, (54) becomes

$$E^+ \geqslant -13.4+10=-3.4 \text{ eV}. \quad (56)$$

This is certainly satisfied even if we set E^+ equal to the value of $E_0^+=7.3$ eV obtained in Sec. IV.

It can, of course, be argued that the value used for E_0^+ is probably much too large, since in obtaining this value the positron was considered as moving in a fixed potential, no regard being taken of polarization effects. In the actual crystal the positron would be expected to concentrate the electron cloud about itself, with a resultant lowering of its energy. The amount by which the energy would thus be lowered would, however, not exceed the free positronium binding energy of 6.8 eV. Making allowance for this, even if we set $E^+=E_0^+=0$ in (55), the inequality is satisfied. Thus, the energy requirement for positronium formation is satisfied for positrons of energies down to the ground-state energy, E_0^+.

The inequality (55) can be rewritten

$$E^+-E_0^+<V_i-V_1\sim 9 \text{ eV}, \quad (57)$$

the right-hand side being now the measure of the width of the Ore gap. Thus, we have that a positron in the crystal with an energy anywhere within a range of some 9 eV above the ground-state energy can, by capture of an electron from the valence band, form a positronium-like bound system, which will be energetically stable against dissociation by deposition of the electron in the conduction band.

VI. DISCUSSION AND CONCLUSIONS

A number of questions arising out of the preceding treatment would seem to merit discussion at this point. These comprise the use of perturbation theory, the perhaps surprisingly low value for the upper bound to the positronium energy, the mean life for electron-positron annihilation from the bound state, and the neglect of exchange in treating the electron and positron of the bound system as being subject to the same effective crystal field.

Perturbation theory is used in the preceding treatment to the extent that it provides a wave function with which to calculate an upper bound to the positronium energy. It is not suggested that this function gives a particularly close approximation to the state of the system. The use of a better function would, however, result in a lower value of the upper bound, and this would strengthen the energetics argument of Sec. V. For the sake of completeness only, the above wave function is used in Appendix A to estimate the mean life of the positronium system, but obviously no great weight can be attached to the numerical result obtained.

The result obtained in Sec. III for the upper bound to the positronium energy might at first appear to be surprisingly low. It would be expected that the positronium in the crystal would suffer distortion such as to increase its internal energy; and this is indeed the case. However, positronium being an extended system, its constituent electron and positron will not have the same distribution in the crystal, with the result that the two particles may on the average occupy (different) positions of low respective potential energy. It is in fact the very distortion tending to raise the internal energy of the system which enables the positronium to "fit" the shape of the crystal field so as to lower its potential energy. An examination[6] of the expression (49) for the positronium energy reveals a very slow convergence of the series. This indicates the importance of the terms involving large quantum numbers. These higher terms do not greatly affect the internal energy, but through providing high angular momentum components in the wave function they give a distortion of the positronium which results in a large downward shift of the potential energy.

The use of the same form of crystal potential for both particles of the positronium system implies neglect of effects of exchange between the electron of the bound system and electrons in Bloch states of the crystal. An examination of this question, details of which are given in Appendix B, reveals that the exchange energy in the interaction between the electron of the positronium and an electron of the crystal is zero. This constitutes the justification for the neglect of exchange and for the use of the same form of crystal potential for the electron and the positron of the bound system.

The present investigation indicates that positronium formation is probably an important part of the process of positron annihilation in lithium hydride. Pending further investigation, one is tempted to speculate that this might also be the case in other ionic crystals such as other alkali hydrides and alkali halides. If positronium is formed in such a crystal in the triplet state, the subsequent two-photon annihilation of the positron with an electron through a "pick-off" process would be expected to contribute to a τ_2 component of the positron annihilation radiation. Such a τ_2 component has been observed[7] in a number of ionic crystals.

state function ψ of Eq. (46), it is sufficient to calculate for this state the density of the electron at the location of the positron (averaged over all positions of the center of mass) and compare this with the corresponding density in the ground state of free positronium. The ratio of the two densities will then be equal to the ratio of the corresponding annihilation rates, that of free positronium being known.

It will be recalled that the terms involving excited states of positronium which occur in the expansion (46) all have $l>0$, and these terms vanish for $\mathbf{r}=0$. Thus, it is only the ground-state term, $\psi_{0,100}$, which contributes to the electron density desired, and the contribution of this term differs from that in free positronium only through the fact that ψ is not normalized to unity. Thus the electron density at the positron for positronium in the crystal is to the corresponding density in the ground state of free positronium in the ratio of $1/(\psi,\psi)=1/1.16$. Thus, for the wave function ψ the mean life of singlet positronium in the crystal is 1.16 times the mean life of singlet, ground-state, free positronium.

APPENDIX B: EXCHANGE EFFECTS

An examination will now be made of the nature of possible exchange effects, hitherto neglected. For this purpose we consider the system of positronium in the crystal in interaction with an electron in a Bloch state.

Let the wave function for positronium in the crystal be of the form of a superposition of free positronium functions similar to (46), i.e.,

$$\psi(1,2)=\sum A(\mathbf{k},nlm) \times\exp[\pi i\mathbf{K}\cdot(\mathbf{r}_1+\mathbf{r}_2)]\varphi_{nlm}(\mathbf{r}_1-\mathbf{r}_2), \quad (58)$$

where the subscripts 1 and 2 refer to the positron and electron, respectively. For the electron in the Bloch state we write the wave function (3). For the two systems in interaction we take a symmetrized function

$$\Psi=(1/\sqrt{2})[\psi(1,2)\chi(3)\pm\psi(1,3)\chi(2)]. \quad (59)$$

To examine the effect of exchange, we consider for definiteness the Coulomb interaction between the two electrons. Its average will be proportional to $(\Psi,(1/r_{23})\Psi)$. The direct term in this inner product is equal to

$$\int|\psi(1,2)|^2|\chi(3)|^2\frac{1}{r_{23}}d\tau, \quad (60)$$

while the exchange term is

$$\int\psi^*(1,2)\chi^*(3)\psi(1,3)\chi(2)(1/r_{23})d\tau. \quad (61)$$

In order to compare these two expressions, we select a typical term from the summation which results in each from the substitution of the expansion (58).

Out of the expansion of (60) we take the term

$$I=\int\exp[\pi i(\mathbf{K}'-\mathbf{K})\cdot(\mathbf{r}_1+\mathbf{r}_2)]\varphi_{nlm}^*(\mathbf{r}_1-\mathbf{r}_2) \times\varphi_{n'l'm'}(\mathbf{r}_1-\mathbf{r}_2)|\chi(\mathbf{r}_3)|^2d\tau. \quad (62)$$

By a coordinate transformation this can be rewritten

$$I=\int\exp[\pi i(\mathbf{K}'-\mathbf{K})\cdot\mathbf{r}_1]\varphi_{nlm}^*(\mathbf{r}_1)\varphi_{n'l'm'}(\mathbf{r}_1)d\tau_1 \times\int\exp[2\pi i(\mathbf{K}'-\mathbf{K})\cdot\mathbf{r}_2]\frac{1}{r_2}d\tau_2 \times\int|\chi(\mathbf{r}_3)|^2\exp[2\pi i(\mathbf{K}'-\mathbf{K})\cdot\mathbf{r}_3]d\tau_3. \quad (63)$$

Out of (61) we take the corresponding term

$$J=\int\exp[\pi i\{\mathbf{K}'\cdot(\mathbf{r}_1+\mathbf{r}_3)-\mathbf{K}\cdot(\mathbf{r}_1+\mathbf{r}_2)\}]\varphi_{nlm}^*(\mathbf{r}_1-\mathbf{r}_2) \times\varphi_{n'l'm'}(\mathbf{r}_1-\mathbf{r}_3)\chi(\mathbf{r}_3)\chi(\mathbf{r}_2)d\tau. \quad (64)$$

We can, by omitting the exponentials in (64), write

$$|J|\leqslant\int\varphi_{nlm}^*(\mathbf{r}_1-\mathbf{r}_2)\varphi_{n'l'm'}(\mathbf{r}_1-\mathbf{r}_3) \times\chi^*(\mathbf{r}_3)\chi(\mathbf{r}_2)\frac{1}{r_{23}}d\tau. \quad (65)$$

Because of the nature of the positronium functions φ the integral (65) converges, in spite of χ not being quadratically integrable. By contrast, the third integral in (63) diverges. Thus, a suitable box normalization to ensure the convergence of the direct interaction term I causes the exchange term J to vanish.

Oscillatory Magnetoresistance in Gray Tin*

E. D. Hinkley† and A. W. Ewald
Department of Physics, Northwestern University, Evanston, Illinois
(Received 10 January 1964)

The oscillatory component of magnetoresistance has been measured for single crystals of n-type gray tin at liquid-helium temperatures. The period of oscillation is independent of magnetic field direction, confirming an isotropic effective mass and, therefore, a conduction-band edge at the center of the Brillouin zone. Oscillations were also observed in a polycrystalline specimen. Carrier concentrations deduced from the oscillatory period are in reasonably good agreement with values obtained from the Hall coefficient over a range of almost two orders of magnitude in this parameter. An electron effective mass of 0.024 m_0 was obtained from the field and temperature dependence of the oscillatory amplitude for samples having carrier concentrations on the order of 10^{16} cm^{-3}. Nonthermal damping of the oscillations is attributed mainly to inhomogeneities in the impurity distribution. The experimental results are compared with theory.

I. INTRODUCTION

In recent years oscillatory magnetoresistance measurements have provided band-structure information for several of the compound semiconductors.[1–3] The results are in agreement with those obtained from cyclotron resonance[4–6] and de Haas–van Alphen[7] experiments. Of the *elemental* semiconductors, only germanium[8] and gray tin[9] have shown an oscillatory component of the magnetoresistance. The band structure of germanium had already been established through cyclotron resonance and other measurements before the magnetoresistance oscillations were observed, and therefore, this phenomenon was not exploited. In the case of gray tin, where cyclotron resonance has not been observed, low-temperature band-structure information was lacking. Previous magnetoresistance measurements at liquid-nitrogen temperature and above had indicated a change in symmetry type from that characteristic of [111] valleys at 273°K to the spherical symmetry of a central conduction-band minimum at 77°K (see Ref. 10). The present work indicates that at lower temperatures the electrons remain in the central minimum. It also yields a value for the effective mass of electrons in this band.

This paper describes the oscillatory magnetoresistance measurements made on single crystals (and on one polycrystalline specimen) of n-type gray tin. The experimental data are compared with magnetoresistance theories in terms of oscillatory period, phase, and amplitude. The value of electron effective mass and the shape of the constant energy surfaces for gray tin as deduced from the data are also compared with the theoretical predictions.

II. THEORY

When a magnetic field is applied to a system of charge carriers, the quasicontinuous distribution of states in momentum space collapses into a set of highly degenerate one-dimensional Landau subbands. Consequently, under certain conditions, the electrical resistance of a degenerate ($E_F > kT$) semiconductor is found to have an oscillatory dependence on magnetic field, periodic in reciprocal field. The oscillatory period is inversely proportional to the extremal cross-sectional area of the Fermi surface in a plane perpendicular to the magnetic field direction, and is generally a function of field orientation. For the special case of a spherical Fermi surface, however, the oscillatory period is a function only of carrier concentration.

$$P = (2e/\hbar c)(3\pi^2 n)^{-2/3} = 3.18 \times 10^6 n^{-2/3}, \qquad (1)$$

where n is measured in cm^{-3} and P in reciprocal gauss.

The usual semiquantitative conditions for the occurrence of quantum oscillations require that the separation $\hbar\omega$ between Landau levels be greater than the energy spread associated with the Fermi surface electrons. There are two major causes of this energy spread: First, a thermal "fuzzing" occurs at any non-

zero temperature since the electrons may deviate from the Fermi surface by a few kT; second, collisions limit the lifetime τ of a quantum state, with concomitant uncertainty $\hbar/\tau$ in electron energy leading to the cyclotron condition $\omega\tau>1$. This condition may be written more conveniently as $\mu B>10^8$, where μ is the Hall mobility in cm^2/V sec and B is the magnetic field in gauss.

In addition to the thermal and collision broadening of the electron energy levels described above, the Fermi level itself may vary throughout the specimen as a result of an inhomogeneous distribution of impurities. It is clear from Eq. (1) that such an effect would be manifested as a spatial variation of the oscillatory period, and partial cancellation of oscillations would occur.

The above conditions, together with their implications concerning the observation of quantum oscillations at readily obtained steady magnetic fields, are summarized below:

(1) $\hbar\omega>kT$. Low carrier effective mass, low ambient temperature.
(2) $\mu B>10^8$. High carrier mobility.
(3) $\hbar\omega>\Delta E_F$. Homogeneous specimen.

A recent theory for transverse ($B\perp I$) oscillatory magnetoresistance proposed by Adams and Holstein[11] embodies all the above conditions, except for inhomogeneity broadening. The latter is taken into account by defining a combined nonthermal broadening temperature T' as the sum of the collision (Dingle) and inhomogeneity broadening temperatures. The analysis of Adams and Holstein, while limited to materials with spherical Fermi surfaces, shows the oscillatory phenomenon to be essentially independent of the type of scattering. On the basis of their derivation, the oscillatory part of the transverse magnetoresistance of interest here may be written as

$$\frac{\Delta\rho_{0sc}}{\rho_0}=5\sqrt{2}\pi^2\frac{kT}{E_F^{1/2}(\hbar\omega)^{1/2}}\sum_{M=1}^{\infty}\frac{M^{1/2}(-1)^M e^{-2\pi^2M(kT'/\hbar\omega)}}{\sinh[2\pi^2M(kT/\hbar\omega)]}\times\cos\left[\frac{2\pi ME_F}{\hbar\omega}-\frac{\pi}{4}\right], \quad (2)$$

where ρ_0 is the zero-field resistivity and M is the harmonic of the oscillations. This expression may be simplified because only the fundamental ($M=1$) is usually significant. In addition, the hyperbolic sine may be replaced by its exponential approximation. Equation (2) then reduces to

$$\frac{\Delta\rho_{0sc}}{\rho_0}=-10\sqrt{2}\pi^2\frac{kT}{E_F^{1/2}(\hbar\omega)^{1/2}}\times\exp\left[-\left(\frac{2\pi^2k}{\beta_0}\right)\left(\frac{m^*}{m_0}\right)\left(\frac{T+T'}{B}\right)\right]\cos\left(\frac{2\pi}{PB}-\frac{\pi}{4}\right), \quad (3)$$

where the oscillatory period P, the effective mass m^*, and $\beta_0(=e\hbar/m_0c$, the double Bohr magneton) have been introduced.

Oscillations in the longitudinal ($B||I$) magnetoresistance have been treated by Argyres.[12] The corresponding equation is identical with Eq. (3) when the latter is reduced by a factor of 5.

III. EXPERIMENTAL DETAILS

A. Specimens

Gray tin crystals were grown from mercury solution by the procedure of Ewald and Tufte.[13] Crystals of various impurity concentrations were available as a result of different purification processes carried out on the commercial zone-refined tin. The different purities were reflected in different carrier concentrations at 4.2°K as determined by the Hall coefficient. The samples ranged in carrier concentration from 6.4×10^{14} cm^{-3} to 4.2×10^{16} cm^{-3} and on this basis were divided into four categories designated by a letter prefix to the sample number as shown in Table I. The donor impurity atoms are probably antimony which is not removed during the zone-refining process, and only partially removed during subsequent purification. Cutting of the crystals into rectangular parallelepipeds suitable for electrical measurements was performed with a sand-blast unit. Sample dimensions were approximately $0.2\times0.4\times3$ mm.

Samples were mounted on Bakelite holders at the end of long, thin-walled Monel tubes. Current electrodes, which also served as support for the sample, were of No. 36 copper wire and were attached to the ends of the

sample with gallium-indium (3 parts Ga to 1 part In) solder. To reduce adverse effects due to large area potential-probe contacts, the following soldering procedure was employed. Bare No. 56 (0.0127 mm) copper wires, which served as the potential probes, were first "tinned" and then brought into contact with the cooled sample at the desired locations. A 200 mA current pulse was then passed through the potential leads producing localized heating which melted the solder. By this means the solder contact area was held to less than that of the wires. The potential probes were usually attached to the side of the sample and (to eliminate "edge" effects) at a distance from the ends greater than the sample width. In some instances, however, the potential probes were mounted at the ends of the specimens with the current electrodes.

B. Apparatus and Procedure

The sample was immersed directly in liquid helium. Temperatures below 4.2°K were obtained by pumping on the helium vapor, and were measured by the vapor pressure. The lower tip of the helium Dewar was located between the pole pieces of a magnet which could be rotated in the horizontal plane. Magnet current was supplied by a bank of storage batteries, and regulated by water-cooled rheostats.

A constant current of up to 10 mA was supplied to the sample by a high-impedance transistorized current source. Maximum sample current was determined by the condition that the rise in sample temperature as a result of joule heating should not be excessive. Analysis of the oscillatory amplitudes for a sample under varying conditions of power dissipation showed that if the input power was less than 100 μW, sample temperature rose by less than 0.1°K.

The amplified voltage from the potential probes was applied to the Y axis of an X-Y recorder, the X axis of which was driven by a signal proportional to the current through the magnet. Magnetic field values corresponding to various positions along the X axis were obtained from a calibration curve made with a rotating-coil fluxmeter. In those cases in which the nonoscillatory part of the magnetoresistance was approximately linear with field, a bucking voltage proportional to magnet current was used to permit greater amplification of the oscillations. For precise measurements, e.g., to determine Hall voltage or zero-field resistance, the electrometer amplifier was replaced by a potentiometer.

IV. DATA REDUCTION TECHNIQUE

A. Oscillatory Period and Phase

The period and phase of the magnetoresistance oscillations were usually obtained from a direct analysis of the X-Y recorder curves. (In order to determine the nonoscillatory magnetoresistance, however, the data had to be averaged over positive and negative field directions to cancel Hall voltage contributions resulting from misalignment of the potential probes.) Envelope curves were constructed tangent to the oscillations with a nodal line drawn halfway between. The intersections of the nodal line with the recorder curve located the nodes of the oscillations which were used to determine the period and phase.

Equation (3) may be expressed in terms of an amplitude A, period P, and phase ϕ as

$$\Delta\rho_{0sc}/\rho_0 = A(B,T)\cos[(2\pi/PB+\phi+\pi], \quad (4)$$

where the minus sign has been absorbed into the argument of the cosine. A node occurs whenever the argument of the cosine is an odd integer multiple of $\pi/2$. This condition may be stated as

$$(2\pi/PB_n)+\phi+\pi=(2n+\tfrac{1}{2})\pi, \quad (5)$$

where n takes on both integer and half-integer values corresponding to the two nodes per oscillation. Ambiguity in the assignment of integers and half-integers to the experimentally observed nodes is removed by noting that, according to Eqs. (4) and (5), the oscillatory curve (as a function of B) has positive slope at the integer nodes and negative slope at the half-integer nodes. This point is very important to an experimental determination of phase. A plot of reciprocal magnetic field values at which the nodes occur versus integers and half-integers represents a straight line of slope P. The intercept n_0 with the $1/B=0$ axis is related to the phase. These relationships become clear upon rearranging Eq. (5) into the following form:

$$1/B_n = Pn-[(\phi/2\pi)+\tfrac{1}{4}]P. \quad (6)$$

The phase can be deduced from n_0 by the expression

$$\phi=(2n_0-\tfrac{1}{2})\pi. \quad (7)$$

If the measured phase agrees with the predicted value of $-\frac{1}{4}\pi$, then $n_0=\frac{1}{8}$. For future reference, an intercept $n_0=0$ implies a phase of $-\frac{1}{2}\pi$. Since integral multiples of 2π may be added algebraically to ϕ without altering the situation, n_0 is likewise arbitrarily defined with respect to the integers.

B. Effective Mass

Equation (1) shows that, for a semiconductor having spherical constant-energy surfaces, the oscillatory period is a function only of carrier concentration, and is, therefore, independent of the effective mass. The effective mass parameter is, however, contained in the oscillatory amplitude expression,

$$A(B,T)\propto B^{-1/2}\exp[-\gamma(m^*/m_0)(T+T')/B], \quad (8)$$

where $\gamma\equiv 2\pi^2k/\beta_0=14.68\times10^4$ gauss/deg If the above equation is multiplied by $B^{1/2}$, and the logarithm of the resulting expression differentiated with respect to $1/B$,

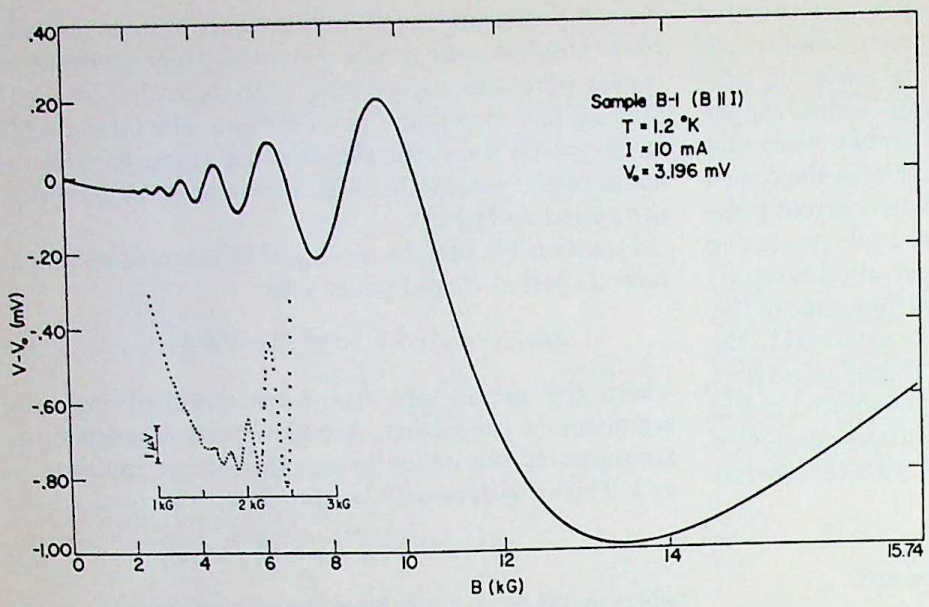

FIG. 1. Recorder traces of magnetoresistance voltage versus magnet current for gray tin single-crystal sample B-1 at 1.2°K. Data in the low-field region (inset) were recorded point-by-point because the signal was comparable to induced voltages occurring when the magnetic field was changed. Magnetic field is parallel to sample current.

the following is obtained:

$$d\ln(AB^{1/2})/d(1/B) = -\gamma(m^*/m_0)(T+T'). \quad (9)$$

Therefore, a logarithmic plot of $AB^{1/2}$ versus $1/B$ yields a straight line, the slope of which is proportional to the product $m^*(T+T')$. The unknown quantities m^* and T' may be evaluated by analyzing the field dependence of the oscillatory amplitude for at least two different ambient temperatures. For some of the samples tested *several* ambient temperatures were used in an attempt to overdetermine the effective mass value and (hopefully) increase its accuracy. We found it convenient to define a slope function $S(T)$ equal to the negative of Eq. (9). The points of an S versus T plot represent a straight line having slope $\gamma(m^*/m_0)$ and an intercept (at the $T=0$ axis) of $\gamma(m^*/m_0)T'$.

V. RESULTS AND DISCUSSION

A. Oscillatory Parameters

Figure 1 shows actual recorder traces of voltage across the potential probes of sample B-1 as a function of magnet current. The continuous curve exhibits oscillations starting somewhat above 2 kG. Oscillations at still lower fields are apparent in the inset curve which was taken with one hundred times greater amplification. The latter curve was recorded point-by-point to eliminate traces of induced voltages due to the quasi-continuous change in magnetic field.

Since sample B-1 exhibited the largest number of detectable oscillations of all those tested, it was of special interest to our investigation. Figures 2 and 3 show the transverse and longitudinal magnetoresistance field dependences, respectively, for this sample. It is noteworthy that the oscillatory amplitudes for the two modes are approximately the same, although an order of magnitude smaller than predicted by Eq. (3). The nonoscillatory magnetoresistance components differ

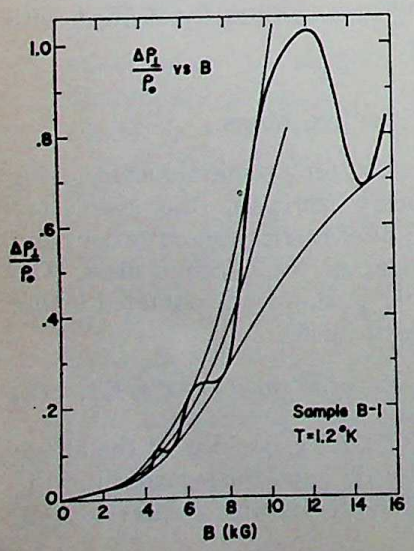

FIG. 2. Field dependence of transverse magnetoresistance for sample B-1 at 1.2°K. This curve was obtained by averaging data for positive and negative field directions. A line of nodes has been constructed midway between envelope lines, and was used to determine the oscillatory period and phase.

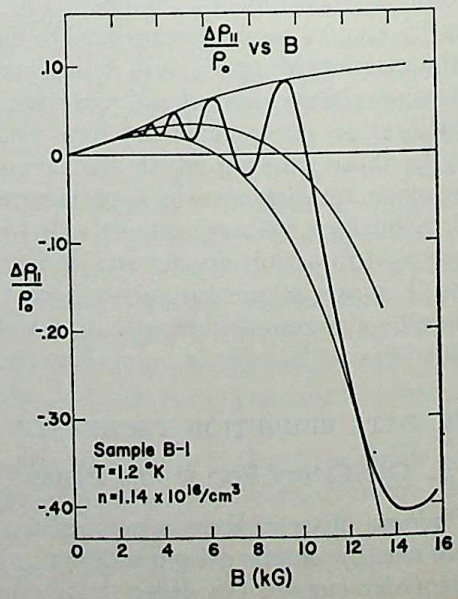

FIG. 3. Field dependence of longitudinal magnetoresistance for sample B-1 at 1.2°K. Negative longitudinal magnetoresistance was observed for all samples in the high-field region.

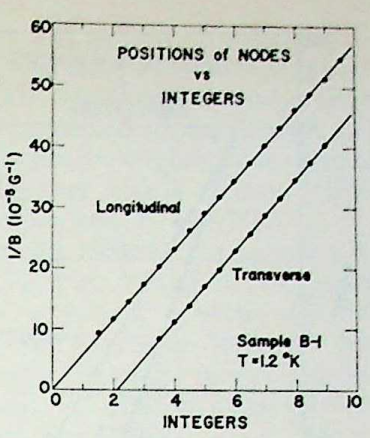

FIG. 4. Nodal positions of transverse and longitudinal magnetoresistance oscillations for sample B-1 are plotted versus integers and half-integers. The oscillatory periods and phases were obtained from the slopes and intercepts, respectively, of the straight lines.

markedly between the transverse and longitudinal modes, and the *negative* longitudinal magnetoresistance apparent at high fields was observed at liquid-helium temperatures for all samples. Node-integer plots for both orientations of magnetic field are shown in Fig. 4. The oscillatory periods deduced from the slopes in accordance with Eq. (6) are 5.84×10^{-5} G^{-1} for the transverse mode and 5.72×10^{-5} G^{-1} for the longitudinal mode. Since this sample was mounted so that the magnetic field for both modes was [110] oriented, this agreement is expected.

A detailed study of the dependence of oscillatory period on crystal orientation was made using sample B-6. Figure 5 shows the oscillatory period for this sample as a function of magnetic field direction. If we attribute the 3% scatter of points to errors in the data reduction, we conclude that the period is independent of crystal orientation. This *indifference* of oscillatory period to magnetic field direction relative to the crystal axes was found on all samples and is the basis for concluding that, at liquid helium temperatures, the electrons occupy a spherically symmetric band.

The absence of a crystal orientation dependence of the oscillatory period was also verified by the method

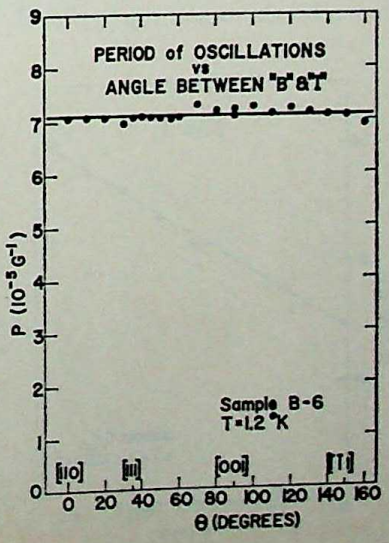

FIG. 5. Angular dependence of oscillatory period for sample B-6. Sample current is in the [110] direction, with magnetic field in the (1$\bar{1}$0) plane. The 3% scatter of points from the average value is attributed to errors in the graphical data reduction procedure.

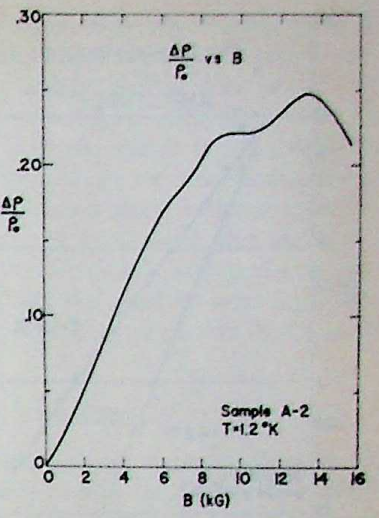

FIG. 6. Field dependence of magnetoresistance for polycrystalline sample A-2. The presence of oscillations confirms the orientation-independence of oscillatory period.

of Sladek[2] which utilizes a polycrystalline specimen. A sample was prepared by transforming a thin white-tin foil to the gray phase. (X-ray analysis has shown that samples prepared in this manner are highly polycrystalline.) The magnetoresistance field dependence for this sample is shown in Fig. 6, where the presence of oscillations confirms sphericity of the constant energy surfaces.

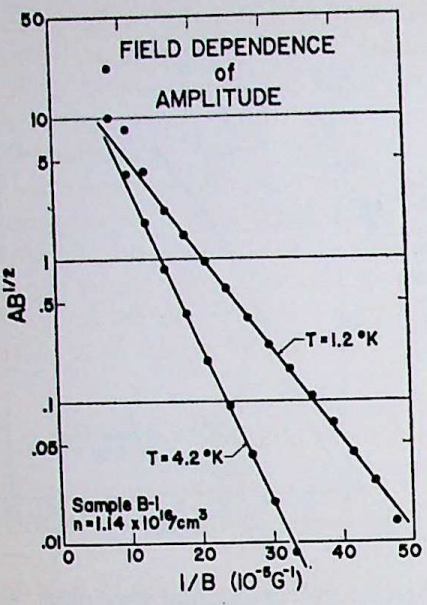

FIG. 8. Field dependence of oscillatory amplitude for sample B-1 at ambient temperatures of 4.2 and 1.2°K. Slopes are proportional to the product $m^*(T+T')$.

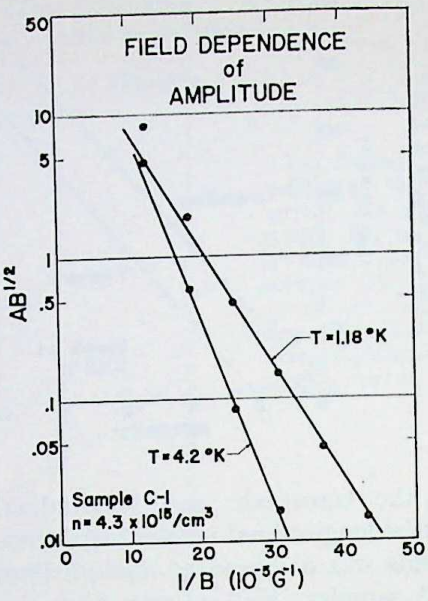

FIG. 10. Field dependence of oscillatory amplitude for sample C-1 at ambient temperatures of 4.2 and 1.18°K. Smaller number of data points (cf. Fig. 8) reflects longer period of this higher purity specimen.

with that given by the Hall coefficient. For sample B-1, $n_P=1.30\times10^{16}$ cm^{-3}, whereas $n_H=1.14\times10^{16}$ cm^{-3}. Similar comparisons for other samples are shown in Table II. It should be noted that the n_H value for any particular sample is probably somewhat dependent on the location of the Hall probes because of inhomogeneity in the impurity distribution.

Small magnetoresistance oscillations were detected in the very pure sample D-2 at 4.2°K. The large decrease in conductivity for this sample from 4.2 to 1.2°K (cf. Table I) led to a search for a temperature dependence of the oscillatory period, indicative of carrier freeze-out. Figure 7 illustrates the magnetoresistance field dependence for sample D-2 at three different ambient temperatures. The period is very long (corresponding to a carrier concentration of only 6.4×10^{14} cm^{-3}), but a change of period with temperature is quite apparent. A shifting of the extrema toward smaller magnetic field values with decreasing temperature indicates an increasing period, in qualitative agreement with Eq. (1).

For a discussion of oscillatory phase, we return to Fig. 4. The intercepts n_0 for the transverse and longitudinal modes are $\frac{1}{8}$ and 0, respectively, which correspond to phases of $-\frac{1}{4}\pi$ and $-\frac{1}{2}\pi$. Thus, the measured *transverse* phase agrees with theory, but a significant discrepancy exists for the *longitudinal* mode (predicted to be $-\frac{1}{4}\pi$ also). Several further measurements were made on this particular sample over a period of a few months (between which the sample was removed from its holder), and the above phases were consistently obtained. Moreover, a transverse phase of $-\frac{1}{4}\pi$ was observed on all other samples as well.

B. Electron Effective Mass Determination

The magnetic field dependence of the oscillatory amplitudes for sample B-1 at ambient temperatures of 1.2 and 4.2°K is shown in Fig. 8. [Deviations from linearity at the high-field region stem, at least in part, from a breakdown of the hyperbolic sine approximation

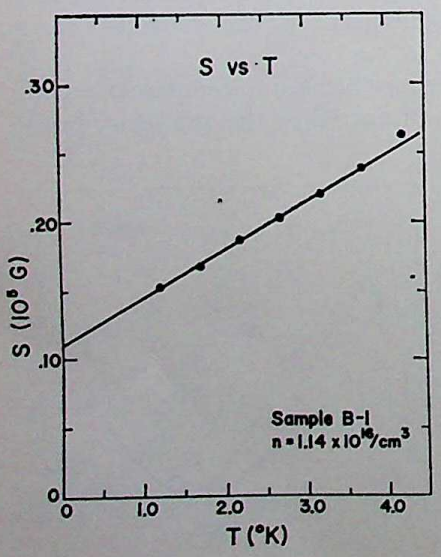

FIG. 9. Temperature dependence of slope function for sample B-1. Slope of line through points equals $\gamma(m^*/m_0)$. Intercept with ordinate equals $\gamma(m^*/m_0)T'$.

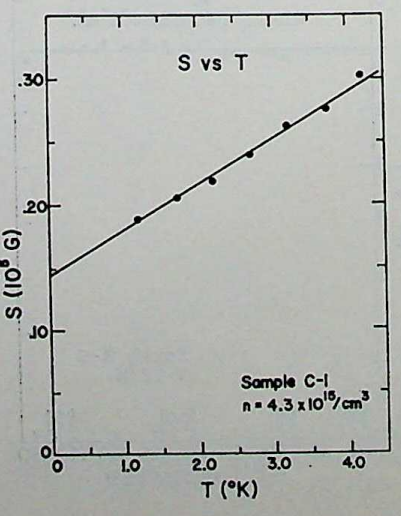

FIG. 11. Temperature dependence of slope function for sample C-1.

of Eq. (3).] Five other intermediate temperatures at half-degree intervals were also used, but these data were omitted for clarity. In Fig. 9 are shown the slopes $S(T)$ for all seven ambient temperatures. From the slope and intercept of this straight line an effective mass value of $0.024m_0$ was found, together with a combined nonthermal broadening temperature, T', of 3.2°K.

A similar procedure was followed for sample C-1, with the results shown in Figs. 10 and 11. Because of the fewer detectable oscillations exhibited by this higher purity sample, the results are somewhat less accurate, as is evidenced by the larger spread of points in Fig. 11. Nevertheless, an effective mass value of $0.025m_0$ was found, with $T'=3.9$°K.

In Table II are listed the experimentally obtained values for the electron effective mass in gray tin. Although T' varies from 3.2° to 9.3°K, the mass values themselves are fairly consistent. As mentioned previously, T' is the sum of the Dingle and inhomogeneity broadening temperatures. Because of the high mobility of these specimens, the Dingle temperature is less than 1°K (cf. Ref. 2). Consequently, we conclude that the major contribution to T' is from inhomogeneities in the specimens.

The spherical symmetry of the conduction band observed experimentally and discussed in the previous section was predicted by Herman,[14] and Liu and Bassani.[15] However, the calculated effective mass value of $0.0036m_0$ (see Ref. 16) which is based in part on the experimental band gap, is almost an order of magnitude smaller than our most accurate value of $0.024m_0$. Correction of the experimental value for nonparabolicity of the band[17] reduces it only slightly, to $0.020m_0$. To account for the relatively large observed mass as well as the pressure behavior of the conductivity at temperatures below 160°K, Groves and Paul[18] have recently proposed a new model for the band structure of gray tin. In this the direct gap is fixed at zero at all temperatures, and the temperature dependence of the conductivity in the intrinsic range is attributed to transitions from the uppermost valence band edge to [111] valleys. While a detailed quantitative comparison between the predictions of this model and all experimental data has not yet been made, the model appears to be more successful than the usual nonzero gap model in accounting for the experimental results in the lower temperature range.

VI. CONCLUSION

An oscillatory component of magnetoresistance has been observed at liquid-helium temperatures in single crystals of n-type gray tin. Exceptions to the general agreement between the experimental results and the theories of Adams and Holstein, and Argyres are the smaller observed amplitude and a measured longitudinal phase of $-\frac{1}{2}\pi$.

The *indifference* of oscillatory period to magnetic-field orientation relative to the crystal axes indicates that the minimum of the conduction band is at the center of the Brillouin zone, in agreement with the theoretical predictions of Herman, and Liu and Bassani. This was also confirmed by detecting oscillations in a polycrystalline specimen. A dependence of the oscillatory period on temperature observed in a very pure specimen was attributed to carrier freeze-out.

On the basis of the field and temperature dependence of the oscillatory amplitude we have obtained an electron effective mass value of $0.024m_0$, which does not appear to depend on carrier concentration. This is much larger than the value $0.0036m_0$ calculated by Bassani and Liu, and suggests that a major revision of the band structure model, such as that recently proposed by Groves and Paul, is required.

$FeAl_2O_4$–$MgAl_2O_4$: Growth and Some Thermal, Optical, and Magnetic Properties of Mixed Single Crystals

GLEN A. SLACK
General Electric Research Laboratory, Schenectady, New York

(Received 30 December 1963)

Synthetic single crystals of $FeAl_2O_4$ have been grown from the melt. Measurements of the thermal conductivity K and optical absorption coefficient α have been made on a combination of synthetic and natural single crystals of $Mg_{1-x}Fe_xAl_2O_4$ for $0 \leq x \leq 1$. The α measurements at 300°K in the absorption band of tetrahedral Fe^{2+} between 0.4 and 0.6 eV have been calibrated and then used to measure x. The thermal conductivity results between 3 and 300°K show that the heat is conducted by phonons and that tetrahedral Fe^{2+} is a very effective phonon scatterer at all temperatures because it possesses a series of low-lying energy levels in the $3d$ shell. This type of scattering is absent in $CoAl_2O_4$. The phonon scattering by Fe^{2+} is dominant for $x > 0.1$, and for these crystals $K \sim T/\sqrt{x}$. The magnetic susceptibility χ of a single crystal of $FeAl_2O_4$, measured between 2 and 290°K, shows a peak at 9.5±0.5°K. The analysis of the χ and K measurements suggests that the ~10°K transition is caused by the individual Fe^{2+} ions, and is not associated with a long-range, antiferromagnetic ordering of the $FeAl_2O_4$.

INTRODUCTION

THE simplest magnetic analog of the basic diamagnetic spinel $MgAl_2O_4$ is one in which all or part of the Mg is replaced by a transition-metal ion M. The present series of studies concerns crystals in which M is divalent Fe. The compound $FeAl_2O_4$ is a normal spinel[1,2] as is[3,4] $MgAl_2O_4$ in which almost all of the Fe (or Mg) ions are in the tetrahedral (or A) lattice sites. The magnetic properties in a completely normal spinel are thus determined by the magnetic A-A interaction. Since the A-A separation is 3.52 Å in $FeAl_2O_4$, this interaction is very weak.[5] Thus, it is not possible for $FeAl_2O_4$ to become magnetically ordered until very low temperatures (~ 4°K) are reached. The following measurements at and below 300°K of the thermal conductivity, optical absorption, and magnetic susceptibility of synthetic single crystals of $FeAl_2O_4$ and of natural mixed crystals of $Mg_{1-x}Fe_xAl_2O_4$ give some information on the behavior of the individual Fe ions and some on the nature of the A-A interaction.

SINGLE CRYSTALS

The samples used in the present study were a combination of synthetic and natural crystals. See Table I. High-purity oligocrystalline $MgAl_2O_4$ prepared[6] by Navias by the vapor reaction of MgO with Al_2O_3 was used as a comparison standard. A large sample 1.2×0.3×0.3 cm composed of about five single crystals was obtained, and was used for the thermal conductivity and optical absorption measurements. A combination of chemical and x-ray analyses indicated this sample, R68, was a nearly stoichiometric spinel with a composition, 1 MgO+1.02 Al_2O_3, slightly rich in Al_2O_3. The crystallite diameter of 0.3 cm is sufficiently large so that these results should be representative of single-crystal values.

Natural crystals of $Mg_{1-x}Fe_xAl_2O_4$, where $0.0005 \leq x \leq 0.3$ were obtained through various sources. They originated in Australia (Queensland), Burma, and Ceylon. For the lowest values of x they were light pink in color. This color is caused by the presence of Cr in these, as in almost all natural spinel samples. For $x = 0.3$, the crystals were opaque black in the massive state, but in thin, polished sections were a yellowish-brown color.

No good natural crystals of hercynite, $FeAl_2O_4$, were available. Therefore synthetic single crystals of $FeAl_2O_4$ were grown from the melt in an iridium crucible under a controlled partial pressure of oxygen.

$FeAl_2O_4$ Crystals

Since single crystals of $FeAl_2O_4$ do not appear to have been grown before, it seems worthwhile to describe their preparation. The FeO-Al_2O_3 phase diagram at high temperatures has been worked out by Fischer and

Hoffmann[7] and by Galakhov.[8] They show that $FeAl_2O_4$ is the only ternary compound in the system, and it has a congruent melting point between 1780 and 1800°C. The partial pressure of oxygen at the phase boundary where $FeAl_2O_4$ dissociates into Fe, Al_2O_3, and O_2 has been measured[9–12] between 900 and 1100°C. When these data are extrapolated to the melting point at 1780°C, the predicted dissociation pressure is 10^{-7} atm of oxygen. A gas mixture of carbon monoxide to carbon dioxide in a molecular ratio of 8 to 1 at a total pressure in the vicinity of 1 atm will possess[13] this partial pressure of oxygen at 1780°C. Such an 8 to 1 mixture will provide an oxygen pressure about 5 times the dissociation pressure at 1000°C. Thus, a CO/CO_2 gas mixture of constant composition is a nearly ideal medium to use for growing $FeAl_2O_4$ since it will supply an oxygen partial pressure very close to the one needed. If the oxygen partial pressure becomes too high, much of the Fe^{2+} will be converted to the unwanted Fe^{3+}. The major problem in making $FeAl_2O_4$ is to keep as much of the iron as possible in the divalent Fe^{2+} state. In analogy with wüstite, "FeO," it may never be possible to have all of the iron in the divalent state.[14]

The $FeAl_2O_4$ crystals were therefore grown in a CO/CO_2 atmosphere with a molecular ratio of 1 part CO to 1 part CO_2. This is slightly more oxidizing than necessary in order to provide a margin of safety. Following the work of Horn[15] on ferrites, crucibles of pure iridium were used. These were in the shape of a tapered cylinder with a conical end to facilitate growth of only a few nuclei. The crystal growing furnace is shown in Fig. 1. The iridium crucible is placed inside of an iridium cylinder with a 0.05 cm wall thickness which acts as an rf susceptor. The heat is supplied by a 0.5-Mc, 25-kW radiofrequency oscillator. The rf coil, 20 cm long, is wound with a change in diameter and pitch at its midpoint, as shown in Fig. 1. The operating power level is adjusted so that the $FeAl_2O_4$ in the crucible is liquid when the crucible is in the upper part of the rf coil, and is solid when in the lower part. The temperature difference between the two parts of the coil is approximately 300°C. The motion of the temperature gradient in this modified Bridgman technique is produced by moving the rf coil upward past the crucible at a rate of 1 cm/h. After the melt has solidified, the power level of the rf oscillator is slowly reduced to zero over a period of hours. The thermal insulation around the iridium susceptor was composed of zirconia ceramic, Pt-40% Rh radiation shields, alumina ceramic, and quartz. Most of this detail has been omitted from Fig. 1. for clarity.

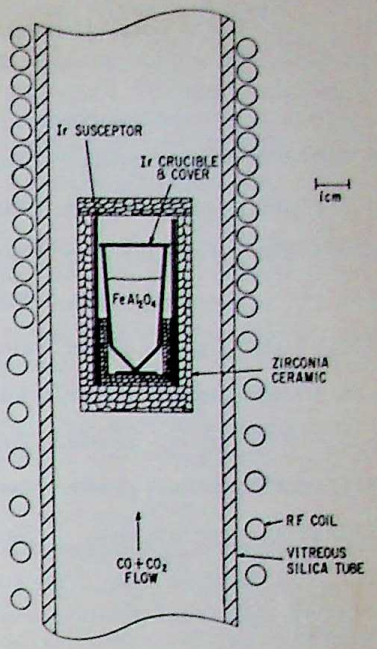

FIG. 1. A schematic of the apparatus used for growing single crystals of $FeAl_2O_4$ by a modified Bridgman technique. The rf coil is moved upward past the stationary crucible.

Large, sound single crystals of the order of 1 cm^3 in volume were produced by this technique. Metallographic and x-ray analyses indicated a single-phase material with the spinel-crystal structure and a lattice parameter a_0 of 8.138±0.001 Å for the as-grown sample R67. This value for a_0 is in reasonable agreement with the literature values[5,16–22] listed in Table II. It appears to be somewhat smaller than the most recent values on samples equilibrated at 1000°C, which cluster around 8.151 Å. If the results of Holgersson[16] on a natural crystal are corrected for the small concentration of $MgAl_2O_4$ in his sample, one obtains 8.155±0.004 Å. The variation in a_0 of a nominally pure $FeAl_2O_4$ sample can be caused[20,22] by the formation of mixed crystals with Al_2O_3, which reduces a_0, or with Fe_3O_4, which increases a_0. It can also be caused by a partial inversion[5,22] of the spinel from its ideal normal structure, or by oxidation of some Fe^{2+} to Fe^{3+}.

A chemical analysis of the as-grown crystal R67

[a] 8.155±0.004 Å for pure $FeAl_2O_4$ when corrected for slight amount of $MgAl_2O_4$.

gave an atomic ratio of aluminum to iron of 2.00±0.04. Even though the Al to Fe ratio is exactly 2.00, some of the Fe is probably in the Fe^{3+} state. Such oxidation of the Fe will increase the O to Fe ratio above the ideal value of 4. The chemical analysis of R67 gave this ratio as 4.1±0.1, indicating that some of the Fe was in the Fe^{3+} state. If the O to Fe ratio is actually 4.1, then 20% of the Fe occurs as Fe^{3+}. Except for the possibility that some of the Fe is in the Fe^{3+} state, the present synthetic crystals are close to being ideal $FeAl_2O_4$. A heat treatment of the as-grown crystals is needed in order to reduce the Fe^{3+} concentration to its lowest possible value. Crystal R75 was prepared by taking an as-grown sample of $FeAl_2O_4$, surrounding it with high-purity Al_2O_3 powder, and sealing it inside a capsule of high-purity iron. This capsule was then annealed at 1200°C for 21 h in an effort to bring the volume of the crystal to equilibrium with the reaction[12,21]:

$$FeAl_2O_4 \rightleftarrows Fe + Al_2O_3 + \tfrac{1}{2}O_2.$$

This equilibration produced a slight increase in a_0 to 8.140 ±0.002 Å and, as will be shown later, a noticeable decrease in the optical absorption, and a sharpening of the kink in the thermal conductivity curve at 10°K. Since the equilibration is a diffusion process, annealing times even longer than 21 h may be necessary to bring the bulk of the crystal to equilibrium with the oxygen atmosphere. A thin sample of $FeAl_2O_4$ which was given a longer anneal had a lattice constant of 8.144 Å, which is approaching the ideal value of 8.151 Å. The fact that the a_0 of the synthetic $FeAl_2O_4$ is less than 8.151 Å is attributed to the presence of Fe^{3+}.

Chemical Purity

The chemical purity of the various samples has been measured in order to determine what foreign elements were present. This is especially necessary since many of the samples were natural crystals. The impurity content of samples R42, R54, R56, and R62 has previously been published.[23] The major impurities in the other four samples are listed in Table III. These have been determined by spectrographic analysis in all cases except for the Fe and Cr of R97. These two impurities were determined by aqueous solution colorimetry to ±10%. These results show that Fe is the dominant impurity in R97. Crystal R97 was in fact chosen from a group of several natural spinel crystals just for this reason.

The synthetic $FeAl_2O_4$ is reasonably pure. Most of the impurities appear to have been introduced during the growing process since Johnson-Matthey "Specpure" oxides were used as the starting material. With more care purer samples could be made.

THERMAL CONDUCTIVITY

The physical properties that were measured were the lattice constants a_0 (see Table I), the thermal conductivity, the optical absorption, and the magnetic susceptibility. The interpretation of and the interrelationships between these parameters will be discussed.

Extensive measurements of the thermal conductivity K have been made between 3 and 300°K by techniques previously described.[24] The K versus T curves for R42, R54, R56, and R62 have already been published.[23] They are reproduced again in Fig. 2 along with the new data for the other crystals. The main features to notice in Fig. 2 are the monotonic decrease in K at any and all temperatures with the increasing content of Fe. The pure $FeAl_2O_4$ has the lowest K of all. This crystal is a rare example of a good single crystal with no (or very little) atomic disorder in which the K decreases continuously with decreasing T for all temperatures below 300°K. The other important feature to notice is the "kink" in several of the K versus T curves at 10°K.

TABLE III. Major metallic impurities in several spinel samples in units of 10^{18} atoms/cm^3.

Impurity	Sample R68	Sample R67, R75	Sample R97
Ca	8	<0.7	<5
Cr	<0.2	3	35
Fe	0.4	m[a]	360
Mg	m	0.3	m
Si	2	7	4
Ti	0.5	1	5
V	<0.4	0.3	8
Zn	<0.7	<0.8	20

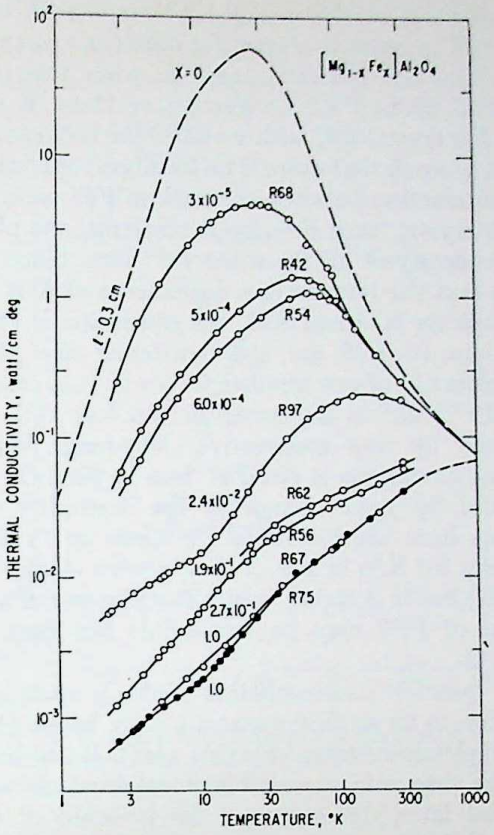

FIG. 2. The thermal conductivity K versus temperature for several mixed crystals of $Mg_{1-x}Fe_xAl_2O_4$. The value of x for each crystal is given. Note the continuous decrease in K with increasing x.

The heat transport in all of these crystals is believed to be caused by phonons. It does not appear that the magnetic moments in any of the crystals become well ordered between 3 and 300°K, so that a magnon heat transport is not at all likely. This lack of ordering will be discussed later. The phonons in the pure $MgAl_2O_4$ with $x=0$ are scattered by[23] the crystal boundaries, the isotopes, and the other phonons for $3°K \leq T \leq 300°K$. The relative strengths of these scattering processes vary with temperature, and their combined effect gives an upper bound to the K given by the dashed curve labeled $x=0$ in Fig. 2. This curve is computed for a specimen diameter of 0.3 cm, which is just the average crystallite size in the purest sample R68. The other crystals ranged in diameter from 0.2 to 0.4 cm, and in length from 0.3 to 1.2 cm. Thus, 0.3 cm is a reasonable average diameter for all of the crystals. Only the purest sample R68 comes close to the K limit imposed by boundary scattering at 3°K.

The failure of sample R68 to have a K as high as the dashed curve in Fig. 2 may be caused by some disorder in the Mg and Al distribution on the A and B sites that has been seen in other synthetic spinels.[4] It may also be caused by the presence of the various chemical impurities listed in Table III. The Fe and Ti are the dominant transition-metal impurities, and are the most likely source of any phonon scattering by the impurities.

In these crystals containing tetrahedral Fe^{2+} it is suggested in this paper that the isolated Fe^{2+} ions are very effective phonon scatterers. The scattering mechanism is believed to be the same as that postulated for Fe^{2+} in the tetrahedral sites in CdTe,[25] and is caused by phonon assisted transition between the several low-lying energy levels of the $3d^6$ configuration. Thus, the phonon scattering and hence the thermal resistivity $W=K^{-1}$ should depend on the Fe^{2+} concentration. Notice that in Fig. 2 for a crystal with $x=0.1$, i.e., somewhere between R97 and R62, the K would decrease monotonically with decreasing T for $T \leq 300°K$. This means that for $x>0.1$, the phonon scattering by the Fe^{2+} predominates over the normal phonon-phonon scattering for all $T \leq 300°K$. In order to characterize the Fe^{2+} scattering mechanism, we are interested in the K as a function of T and of x.

Values of x for the concentration of tetrahedral Fe^{2+} in the various crystals have been obtained from the strength of the optical absorption at 0.60 eV. The details are described later. These x values are given in Table I. The x values for R67 and R75 will change slightly with heat treatment and the residual concentration of Fe^{3+}, however, they are probably between 0.9 and 1.0. Figure 3 shows a plot of the thermal resistivity W versus x at 3, 10, 30, 100, and 300°K for the crystals studied. The straight lines in Fig. 3 are drawn to weight the points for R97 and R75 most heavily since in these two crystals Fe^{2+} is by far the most prevalent impurity. Crystals R62 and R56 have substantial concentrations of Fe^{3+}, as found in the optical absorption studies. Crystals R54 and R68 both have several other impurities whose concentrations are equal to or greater than that of the Fe. Figure 3 indicates, however, that Fe^{2+} is responsible for a major part of the W in these two crystals between 3 and 30°K. The lines in Fig. 3

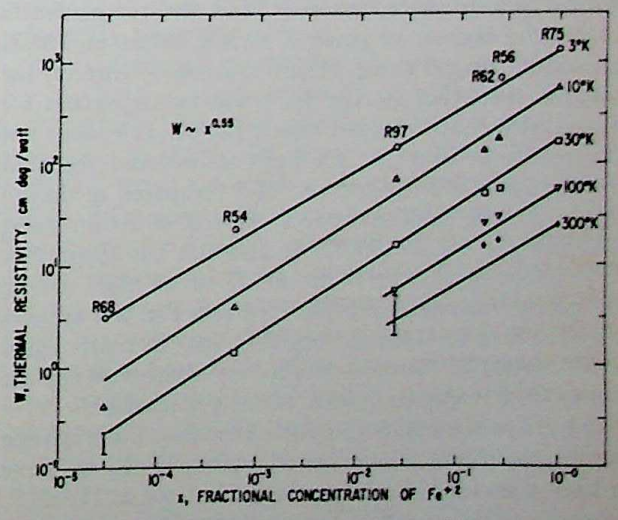

FIG. 3. The thermal resistivity W versus the Fe^{2+} concentration x for several temperatures. For any given temperature, w varies approximately as $x^{0.55}$.

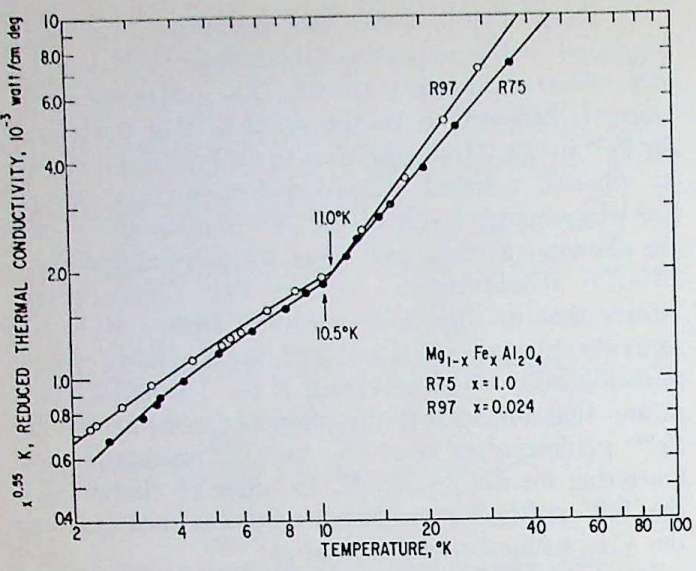

FIG. 4. The reduced thermal conductivity versus temperature in the region of 10°K. The similarity of the "kink" at 11°K for R75 and R97 is quite plain.

show that when the Fe^{2+} is the dominant phonon scatterer, W varies approximately as $x^{0.55\pm0.05}$, or K as $x^{-0.55}$ for all temperatures between 3 and 300°K. The K versus T curves in Fig. 2 show that in the temperature range where Fe^{2+} is the dominant phonon scatterer, K varies roughly as T^{1+}. A detailed calculation of the magnitude, temperature, and Fe^{2+} concentration dependence of K for the crystals shown in Fig. 2 could be made using Callaway's[26] approach if one had a good idea of the relaxation times for phonon scattering by the Fe^{2+} ions and by the normal phonon processes. However, neither is very well known at present. The scattering from the Fe^{2+}, $3d^6$ configuration in tetrahedral sites involves a series of five equally-spaced magnetic levels, and is similar to the case of Fe^{2+} in CdTe.[25] Some recent, preliminary measurements by the author on the optical absorption of crystal R97 at low temperatures places the highest of these 4 excited levels at 120°K above the ground state. If this estimate is correct, the phonon scattering by the Fe^{2+} will be important for temperatures up to a few times 120°K. It is thus not difficult to believe that the Fe^{2+} has reduced the K of $FeAl_2O_4$ at 300°K by a factor of 5 compared to that of $MgAl_2O_4$. The continuous decrease in K with decreasing temperature for $T<300$°K is also not too surprising. The effect of the Fe^{2+} on the K of $FeAl_2O_4$ should disappear only when $T\gg120$°K. From Fig. 2 it appears that the K of $FeAl_2O_4$ and $MgAl_2O_4$ may be nearly equal for $T>1000$°K. A more detailed calculation to explain the $x^{-0.5}$, T^{1+} variation of K is not yet feasible.

The curves for R75 and R97 show that there is some structure in the K versus T curves. Both of these exhibit a decided "kink" or change in slope at 11±1°K. In order to demonstrate the similarity between the two curves, reduced K values for both of them have been replotted side-by-side in Fig. 4. The reduced K is taken as $x^{0.55}$ K in order to correct for different x values. The "kink" for R97 comes at 11±1°K, while that for R75 comes at 10.5±1°K. An average of 11±1°K will be used. For crystal R97 with $x=0.024$ the Fe^{2+} concentration is so small that there is no likelihood of a magnetic A-A interaction between the various Fe^{2+} ions. Thus, in this crystal, each Fe^{2+} ion is scattering the phonons independently of all the other Fe^{2+} ions. Since Fig. 4 shows that the temperature dependence of K is nearly the same for R75 and R97, the conclusion is that the Fe^{2+} ions in R75 are also scattering the phonons independently of one another for $x=1$. It is concluded that the "kink" in the curves in Fig. 4 at 11°K is not produced by any cooperative, long-range magnetic ordering among the A site Fe^{2+} ions in $FeAl_2O_4$, but is produced by some change in the scattering of the phonons from the individual Fe^{2+} ions at 11°K. The K results for R56 in Fig. 3 show a very small "kink" at 11°K, but it is rather weak. The presence of a large amount of Fe^{3+} may be responsible for suppressing the effect.

The question as to whether $FeAl_2O_4$ undergoes a transition to an antiferromagnetic state below 11°K is not completely answered by this result. Roth[5] believes that the magnetic susceptibility data, which will be discussed later, demonstrates the presence of short-range antiferromagnetic ordering below 8 to 10°K. His neutron results, however, fail to show any long-range ordering at these temperatures. The present K results show that if a transition to an antiferromagnetic state does take place in $FeAl_2O_4$, such a transition does not affect the K. This would be surprising in view of the results[24,27,28] on MnO, CoO, MnF_2, and CoF_2; on[29] $CuCl_2\cdot2H_2O$ and $CoCl_2\cdot6H_2O$, and on[30] UO_2, where there was a noticeable break in the K versus T curve on passing through the Néel temperature. More work will be necessary before the 11°K transition in $FeAl_2O_4$ is understood.

As a check on the hypothesis that the Fe^{2+} in the $FeAl_2O_4$ is the cause of the anomalously low thermal conductivity, some measurements of K were made on a single crystal of $CoAl_2O_4$. This crystal R106 is a normal spinel[5] and was grown by E. M. Clausen of this laboratory using a flame-fusion technique. The K results for a crystal 0.83 cm×0.20 cm×0.18 cm annealed in air for 100 h at 1000°C are shown in Fig. 5 together with the curves for $MgAl_2O_4$ (R68) and $FeAl_2O_4$ (R75). The K results for the as-grown $CoAl_2O_4$ sample were identical to those for the annealed sample. Notice that the K values lie between the other two curves except at the

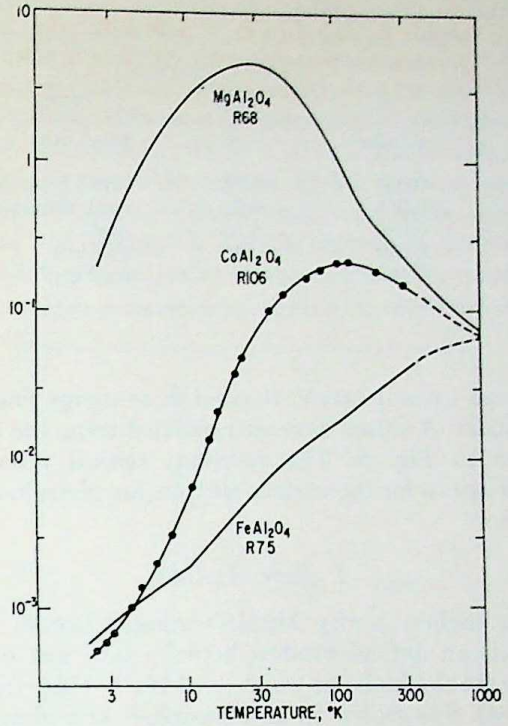

FIG. 5. The thermal conductivity of a single crystal of $CoAl_2O_4$ versus temperature. The results lie between those for $MgAl_2O_4$ and $FeAl_2O_4$, which are also shown.

very lowest temperatures. The K of $CoAl_2O_4$ does not decrease monotonically with decreasing T. All three crystals appear to have nearly identical K for $T \geq 1000$°K. The tetrahedral Co^{2+} has a $3d^7$ configuration, and does not possess[25] any low-lying energy levels in the 1 to 1000°K energy range. Thus it should not scatter phonons with anywhere near the same effectiveness as does the tetrahedral Fe^{2+}. This conclusion is demonstrated by the results in Fig. 5, at least for temperatures between 4 and 300°K. Solely on the basis of the magnetic scattering by the tetrahedral Co^{2+}, the K of $CoAl_2O_4$ should be nearly as high as that of $MgAl_2O_4$. The failure of the $CoAl_2O_4$ to exhibit such a high K may be caused by a partial inversion of the $CoAl_2O_4$, or by other crystal imperfections.

From the differences in K of the spinels $MgAl_2O_4$, $FeAl_2O_4$, and $CoAl_2O_4$, one concludes that the phonon scattering is very sensitive to the details of the magnetic nature of the A-site ions.

OPTICAL PROPERTIES

Optical absorption measurements on most of the samples listed in Table I and on a sample of commercial $MgO \cdot 3.5\ Al_2O_3$ spinel have been made at 300°K over the photon-energy range from 0.1 to 7.0 eV (12- to 0.18-μ wavelength). These measurements were made using three different recording spectrophotometers. A Perkin-Elmer[31] model-421 grating instrument was used from 0.1 to 0.5 eV, and a Beckman[32] DK-2A and a Cary[33] model-14 were used from 0.5 to 7.0 eV. These instruments operated well down to about 1% sample transmission. The sample thickness ranged from 5×10^{-1} to 3×10^{-3} cm. Samples thinner than 3×10^{-3} cm were difficult to prepare because they often broke during the polishing process. This combination of instruments and samples allowed one to measure values of the optical absorption coefficient α from 10^{-1} to 10^{+3} cm^{-1}. The coefficient α is defined by

$$I = I_0(1-R)^2 e^{-\alpha t}, \quad (1)$$

where I_0 = incident light intensity, I = transmitted light intensity, R = reflection loss for a single surface at normal incidence, t = sample thickness in cm.

The two main purposes of these measurements are to determine the site symmetry of the Fe^{2+} in the spinel crystals and to determine the concentration of the Fe^{2+}. The Fe^{2+} in the tetrahedral sites produces a strong absorption in the infrared over a broad band between 0.4 and 0.8 eV. The α-versus-photon energy $h\nu$ curves allow one to make some estimate of the Fe^{2+} and the Cr^{3+} concentration in the crystal.

Reflectivity

Some optical reflectivity measurements were made on $MgAl_2O_4$ and $FeAl_2O_4$ from 0.03 to 2.0 eV in order to identify the regions of strong lattice absorption and to measure the reflection loss R. These measurements were made at 300°K with a Perkin-Elmer[31] model-83 monochromator at nearly normal incidence. The strong lattice peaks were all found in the energy range between 0.03 and 0.11 eV. The samples used were a natural spinel crystal from Burma which was medium-pink in color, and a synthetic crystal of $FeAl_2O_4$ in the as-grown, unannealed condition. The surfaces of the crystals were polished so that they were optically flat before the reflectivity was measured.

The reflectivity results for $MgAl_2O_4$ are shown in Fig. 6. The main lattice absorption peaks are at 0.066 and 0.091 eV. The other smaller peaks that were found are listed in Table IV along with those found for $FeAl_2O_4$. The reflectivity values for $MgAl_2O_4$ in Table IV for normal incidence are reasonably accurate. The values for $FeAl_2O_4$ taken at about 30° from the normal are only approximate, but do indicate the relative strengths of the various peaks. Table V also gives the positions for the absorption maxima by transmission found by other authors[4,24,35] using powdered samples compressed in KBr pellets. The Greek letters serve to identify the various peaks. Even though the peaks in the reflectivity and absorption are not at

[a] These Greek letters serve only to identify the various peaks.

identical energies, the energies are nearly equal. The strong reflectivity peaks are associated with the strong absorption ones. There is a close similarity between these lattice vibration peaks for $MgAl_2O_4$ and $FeAl_2O_4$ since they both have the spinel crystal structure, and nearly the same lattice constants. The Fe is a heavier atom than the Mg and the reflectivity peaks for $FeAl_2O_4$ occur at an energy about 5% less than those for $MgAl_2O_4$. In the energy range between 0.12 and 3.0 eV (and up to 4 eV actually) the reflectivity R of $MgAl_2O_4$ is quite small (2 to 8%), and there is no structure in the R versus $h\nu$ curve in Fig. 6. The same general statement can be made for $FeAl_2O_4$. Thus, any structure found in the optical transmission curves of the single crystals in this energy range is caused by variations in the absorption coefficient α and the reflection correction is small, see Eq. (1).

Absorption Coefficient

The % transmission curves that were taken were corrected for reflection losses using R values calculated from the refractive index[36,37] n for $MgAl_2O_4$ in the range between 1.6 and 3.0 eV. Beyond these energy limits the calculated R values were extrapolated using the results shown in Fig. 5. The resultant optical absorption coefficients α for the various samples are given in Figs. 7 and 8.

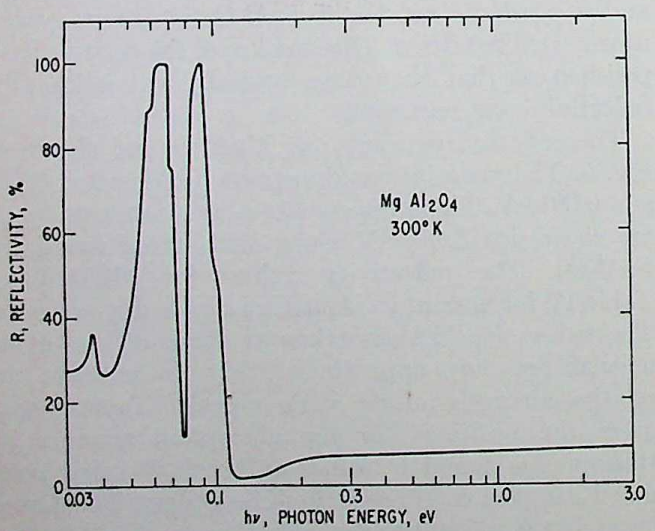

FIG. 6. The optical reflectivity R versus photon energy. These results for a natural single crystal of $MgAl_2O_4$ at 300°K were taken at nearly normal incidence.

1. Pure $MgAl_2O_4$

The highest purity $MgAl_2O_4$ sample R68 in Fig. 7 exhibits an optical window between 0.23 and 6.0 eV. These are the limits at which $\alpha = 1$ cm^{-1}. This synthetic $MgAl_2O_4$ was grown[6] in an atmosphere of hydrogen by diffusing MgO into Al_2O_3. It does not show any signs of the OH or H_2O band at 0.4 eV (3 μ) that has been seen[34,38] in synthetic spinels grown by the flame-fusion process. As a check on the presence of this band a synthetic crystal of $MgO+3.5\,Al_2O_3$ from Linde[39] (crystal R53 of Ref. 23) was measured in this region. It showed a double-peaked band with peaks at 0.415 and 0.436 eV with absorption coefficients of 6 cm^{-1} and 3 cm^{-1}, respectively. For contrast, the R68 crystal had an $\alpha < 0.05$ cm^{-1} in this same energy region. Thus, the 0.4-eV band is not an intrinsic feature of $MgAl_2O_4$, but shows up only in the flame-fusion grown crystals. It has not been seen in any of the natural $MgAl_2O_4$ crystals. It is necessary to understand the source of this band, since the absorption peak for Fe^{2+} ions in the A sites occurs at about this same energy.

2. *Tetrahedral* Fe^{2+}

The main feature in all of the α versus $h\nu$ curves in Figs. 7 and 8 is the very strong absorption band between 0.4 and 0.8 eV. This band is assigned to the tetrahedral Fe^{2+}, $3d^6$ transition $^5E(^5D) \rightarrow {}^5T_2(^5D)$. This same transition has been seen in several II–VI semiconducting compounds doped with Fe. Probably the earliest report of it was by Coblentz[40] in natural crystals of zincblende (cubic ZnS), which almost always contain Fe, where he found a broad single absorption peak at 0.41 eV. Low and Weger[41] have also found this peak in natural zincblende, Pappalardo and Dietz[42] have seen it in Fe-doped synthetic CdS, and the present author[43] has seen it in Fe-doped synthetic CdTe. The energies of the two peaks in this double peak are listed in Table VI. In some cases only a single, broad peak is seen. This absorption peak shifts toward higher energies as the Fe-anion distance decreases, see Table VI.

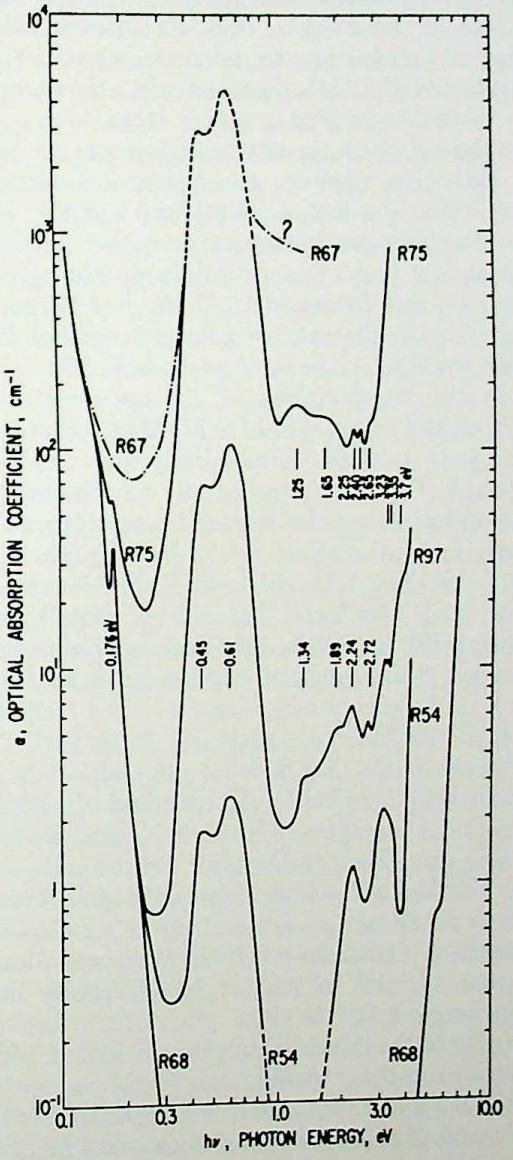

FIG. 7. The optical absorption coefficient α versus the photon energy $h\nu$ for several different single-crystal spinels. Corrections for reflection losses have been made. The energies of various absorption peaks have been labeled in electron volts. The dashed curve for R75 indicates that the absorption between 0.4 and 0.8 eV was too large to be measured. However, the estimated behavior is shown. Similarly the ? for R67 indicates that above 0.8 eV, α was too large to be measured. The main absorption peaks at 0.45 and 0.61 eV are caused by tetrahedral Fe^{2+}.

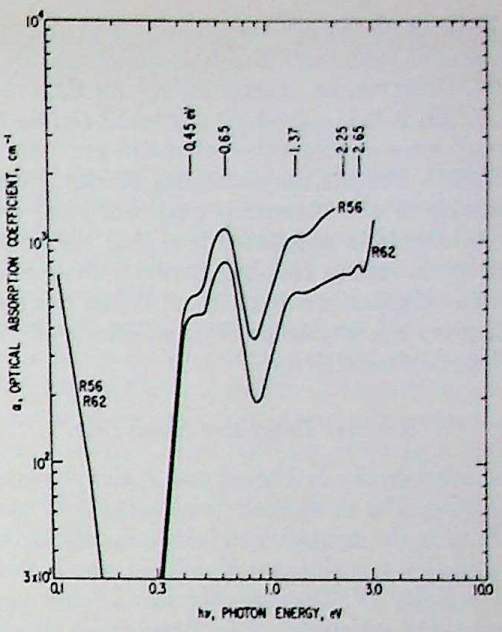

FIG. 8. The optical absorption coefficient α versus the photon energy $h\nu$ for two pleonaste spinels which contain large amounts of both Fe^{2+} and Fe^{3+}. Corrections for reflection losses have been made. The main peaks are labeled in electron volts.

The strength of the electrostatic crystalline field at the Fe^{2+} ion produced by the other surrounding ions is given[44] by the parameter Dq. The energy $h\nu$, at the peak in the α versus $h\nu$ curve is approximately equal to 10 Dq.

TABLE VI. Peak energies for the double-peak, infrared optical absorption band of tetrahedral Fe^{2+} at 300°K.

Crystal	Peaks $h\nu$, eV	Reference	Fe-anion distance, Å
$MgAl_2O_4$, cubic	0.45, 0.61	present work	1.81
ZnS, cubic	0.41	Coblentz[b]	2.34

The breadth of the absorption band and the presence of the double peak make the determination of Dq rather inexact. However, an average energy for the two peaks in $MgAl_2O_4$ is 0.53 eV = 4300 cm^{-1} = 10 Dq. So Dq has the not unreasonable value of +430 cm^{-1} for tetrahedral Fe^{2+}. Further understanding of what causes the broadening of the absorption peak will yield a better value of Dq. It is postulated here that the breadth is caused by a strong coupling between these magnetic levels and the lattice vibrations. It is just this coupling which gives rise to the pronounced effects of Fe^{2+} on the thermal conductivity.

3. *Other Transition Metal Ions*

The other peaks in Figs. 7 and 8 also require some explanation. The small, sharp peak at 0.176 eV has been seen in all of the crystals, and is independent of doping. It is probably a lattice vibration band, and is therefore listed in Table IV. There are numerous peaks between 1.0 and 4.0 eV which vary from sample to sample. Since pure $MgAl_2O_4$, sample R68 has no absorption bands between 0.23 and 6.0 eV, these bands are caused by various transition-metal impurities. So far none of these other bands in Figs. 7 and 8 has been definitely associated with transitions in the tetrahedral Fe^{2+} ion. They all appear to be caused either by octahedral Cr^{3+} in the natural crystals (R54 and R97), by Fe^{3+}, or by octahedral Fe^{2+} in the other crystals. The various Cr^{3+} peaks in R54 and R97 are dealt with in the Appendix. The conclusion is that except for the 1.34-eV peak in R97 all the other peaks above 1.0 eV in these two crystals are due to Cr^{3+}. Crystal R54 shows the two peaks at 2.24 and 3.23 eV characteristic of octahedral Cr^{3+}. In R97 the simple octahedral Cr^{3+} spectrum has been modified by the presence of the much larger concentration of tetrahedral Fe^{2+}.

4. *Other Fe Ions*

Let us now consider the possibilities involved in the absorption spectra of Fe^{3+}, both octahedral and tetrahedral, and of octahedral Fe^{2+}. If $FeAl_2O_4$ were a perfectly stoichiometric, normal spinel, then only tetrahedral Fe^{2+} would exist. The x-ray data have shown[1,2] that $FeAl_2O_4$ is a normal spinel. The recent work of Schmalzried[45] on other aluminates has shown that $CoAl_2O_4$ is nominally a normal spinel, but when equilibrated at 1000°C is partially inverse. In view of the similarity of the octahedral preference energies of $CoAl_2O_4$ and $FeAl_2O_4$ calculated by Miller,[46] $FeAl_2O_4$ can be expected to be slightly inverse in the 1000 to 1500°C range. From neutron scattering data, Roth[5] has found that in his powder sample of synthetic $FeAl_2O_4$, annealed at 1200°C, about 15% of the iron was in the octahedral sites. Thus there will probably be some small amount (i.e., 1 to 20%) of octahedral Fe^{2+} in the present single crystals annealed at 1200°C. The presence of Fe^{3+} in the $FeAl_2O_4$ is less certain. It is well known[14] that the iron in wüstite or "FeO" cannot be reduced to the point where all of the iron is divalent. Thus, one might expect some Fe^{3+} in the $FeAl_2O_4$ even when it is at the low-oxygen pressure dissociation limit of decomposing into Fe, Al_2O_3, and O_2. From Miller's[46] calculations one would predict that this Fe^{3+} would be on the tetrahedral sites. Notice that any octahedral Fe^{3+} that is present requires only that one of the many tetrahedral Fe^{2+} ions in the $FeAl_2O_4$ transfers an electron to the octahedral Fe^{3+} in order to yield an octahedral Fe^{2+} and a tetrahedral Fe^{3+} ion. For example, this exchange is quite favorable in Fe_3O_4, which is an inverse spinel where the Fe^{3+} is on the tetrahedral sites in competition with Fe^{2+}. The opposite conclusion of Hoffman and Fischer[20] that the first small additions of Fe^{3+} go into the octahedral sites is suspect since their lattice constants at low Fe_3O_4 concentrations do not agree with the later ones of Atlas and Sumida[21] or of Turnock.[22] It seems probable that at low concentrations of Fe^{3+} in $FeAl_2O_4$ the Fe^{3+} occurs on the tetrahedral sites. Therefore, in the interpretation of the optical absorption spectra of the mixed $FeAl_2O_4$–$MgAl_2O_4$ crystals, it is necessary to consider tetrahedrally and octahedrally coordinated Fe^{2+}, and tetrahedrally coordinated Fe^{3+}.

The optical absorption caused by octahedral Fe^{2+} is believed to be the cause of the broad peaks seen in Fig. 6 for R75 at 1.23 and 1.65 eV. Previous work by Holmes and McClure[47] has shown that hydrated, octahedral Fe^{2+} in $FeSO_4 \cdot 7H_2O$ crystals possesses only two rather weak, broad absorption bands at 1.04 and 1.34 eV in the energy range from 0.75 to 4.7 eV, with a combined oscillator strength of $f \simeq 4 \times 10^{-5}$. These authors also found that the absorption of Fe^{2+} in water solution was very similar. The method of calculating the oscillator strengths f from the optical absorption curves is that given by Dexter.[48] Octahedrally coordinated Fe^{2+} is a well-known colorant in glass,[49] where it produces an absorption band at about 1.2 eV (1 μ) in the infrared. Octahedral Fe^{2+} in MgO was found by Low and Weger[41] to have a broad, poorly defined absorption peak at 1.24 eV.

A study of the optical absorption of Fe^{2+} in MgO by the present author[43] shows, that in the energy range between 0.5 and 3.0 eV, there is a broad, rather weak, double-peaked absorption band with peaks at 1.21 and 1.46 eV. The derived oscillator strength is $f \simeq 6 \times 10^{-5}$ for each peak,[6] close to the value for the hydrated Fe^{2+}. The energies for these absorption bands of Fe^{2+} in MgO and $FeSO_4 \cdot 7H_2O$ are in reasonable agreement with the

1.23- and 1.65-eV bands seen in $FeAl_2O_4$ in Fig. 6. This is the reason for the assignment of these two bands to octahedral Fe^{2+}. If one makes the assumption that 15% of all the Fe^{2+} in the R75 sample of $FeAl_2O_4$ is on the octahedral sites, and is producing the 1.23-eV band, Fig. 6, the calculated oscillator strength for this 0.7-eV wide band is $f \simeq 3\times10^{-4}$. This is five times higher than that found for MgO. Since the actual concentration of octahedral Fe^{2+} in R75 may be higher or lower than the 15% found by Roth, the f value is only approximate. If anything, the octahedral Fe^{2+} concentration in R75 is probably less than 15% of the total, thus making $f > 3\times10^{-4}$. The optical transition responsible for this broad, double-peaked band is believed to be the lowest energy one possible,[44] that is ${}^5T_2({}^5D) \rightarrow {}^5E({}^5D)$. The intensity of this optical transition and hence its f value is enhanced by distortion of the local cubic symmetry around the Fe^{2+} ion. The f value is small in highly symmetric environments such as at a Mg site in MgO. In $FeAl_2O_4$ the oxygen ions surrounding the octahedral site form a distorted octahedron. The site symmetry may be further reduced by the presence or absence of an Al^{3+} ion in one or more of the surrounding tetrahedral sites in the real crystal. These sites would, of course, be occupied only by Fe^{2+} in the pure, normal spinel. These effects will all serve to make the oscillator strength f of octahedral Fe^{2+} in $FeAl_2O_4$ greater than it is in MgO. Therefore, the optical absorption data is not yet of much help in determining the absolute concentration of octahedral Fe^{2+}, and hence the fractional inversion in $FeAl_2O_4$. However, it seems clear that the 1.23- and 1.65-eV bands are caused by octahedral Fe^{2+}, and may be useful in determining changes in the fractional inversion.

The other absorption peaks seen for R56 and R62 in Fig. 7 above 1 eV and for R75 in Fig. 6 above 2 eV are probably associated with the Fe^{3+} ions. Just what the assignments should be are rather uncertain. The lowest energy peak for Fe^{3+} in octahedral coordination with oxygen in α-Fe_2O_3 has been found by Bailey[50] at 1.49 eV. A similar peak at the same energy in $Y_3Fe_5O_{12}$(YIG) has been found by Dillon.[51] This is probably the ${}^6A_1({}^6S) \rightarrow {}^4T_1({}^4G)$ transition. The first transition for tetrahedral Fe^{3+} should be at an even higher energy since Fe^{3+} has a ${}^6S$ ground state and the crystalline field at a tetrahedral site is about half of that at an octahedral site. Therefore, the optical absorption characteristic of tetrahedral Fe^{3+} should occur for $h\nu > 1.5$ eV in these oxide spinels. The optical absorption of Fe^{3+} tetrahedrally coordinated by Cl^{-1} ions has been studied by Friedman.[52] He found a number of peaks starting at 1.7 eV and extending toward higher energies. It seems reasonable to suppose that the 2.25-, 2.40,- and 2.65-eV peaks in R56, R62, and R75 may be caused by tetrahedral Fe^{2+}. More work is clearly necessary before such an assignment is convincing.

5. Charge Transfer

The last feature of Figs. 7 and 8 that remains unexplained is the hump in the curves for samples R56, R62, and R97 at 1.35 eV. Samples R56 and R62 have fairly large concentrations of Fe^{3+} ions in them, as will be shown later. These Fe^{3+} ions are probably on tetrahedral sites, as are the more numerous Fe^{2+} ions. When the same cation in two different charge states exists on the same lattice site in a crystal, it is relatively easy for a photon to cause an electron transfer between the two differently charged ions. Such a process is believed to be the source of a rather broad, structureless absorption in NiO,[53] $Y_3Fe_5O_{12}$,[54] and Fe_3O_4.[55] It is suggested here that this charge transfer absorption commences at about 1.35 eV in the present spinel crystals, and accounts for the hump in the curves. It would then be responsible for the dull, yellowish-brown appearance of the pleonaste spinels, R56 and R62, by transmitted light. See Table I.

CONCENTRATION OF TETRAHEDRAL Fe^{2+}

The shape of all of the absorption curves in Figs. 7 and 8 between 0.3 and 0.9 eV is nearly the same. The absorption in this portion of the curve is caused by the presence of tetrahedral Fe^{2+}. Since the shapes are all similar, the value of α at, say, the 0.61-eV peak should be proportional to the concentration of tetrahedral Fe^{2+}. The Fe concentration in R97 has been carefully measured as $3.6\pm0.4\times10^{20}$ atoms/cm^3. Since there is no sign of any optical absorption due to octahedral Fe^{2+}, and since the 1.34-eV peak, which is the only peak that might be associated with the presence of Fe^{3+}, is very weak, it is concluded that tetrahedral Fe^{2+} is by far the dominant species of Fe in crystal R97. The peak absorption cross section σ_p is defined by

$$\sigma_p = \alpha_p N^{-1}, \qquad (2)$$

where α_p = absorption coefficient at the peak, and N = concentration of the absorbing ions. The computed value is $\sigma_p = 2.9\times10^{-19}$ cm^2 for the 0.6-eV peak in R97. From Fig. 7 the full width of the 0.6-eV peak at $\alpha = 0.5\alpha_p$ is 0.22 eV. This width and the value of σ_p of 2.9×10^{-19} cm^2 yields[48] an oscillator strength of $f = 4\times10^{-4}$. The 0.45-eV peak gives a somewhat smaller calculated value of $f = 1\times10^{-4}$.

The concentration of tetrahedral Fe^{2+} in the other crystals in Figs. 7 and 8 has been calculated on the assumption that tetrahedral Fe^{2+} concentration is proportional to α_p at 0.6 eV. The results are given in Table VII along with the total concentration of Fe

TABLE VII. A comparison of the concentration of tetrahedral Fe^{2+} ions (optical) with the concentration of total Fe (chemical).[a]

Sample	Conc. tetra. Fe^{2+} atoms/cm³	Conc. Fe total atoms/cm³	x
R68	$<5\times10^{17}$	4×10^{17} *s*	3×10^{-5}
R54	0.9×10^{19}	2×10^{19} *s*	6.0×10^{-4}
R97	3.6×10^{20} *a*	3.6×10^{20} *w*	2.4×10^{-2}
R62	2.7×10^{21}	5.0×10^{21} *w*	1.9×10^{-1}
R56	4.0×10^{21}	6.2×10^{21} *w*	2.7×10^{-1}
R67, R75		1.5×10^{22} *w*	~1

[a] *a* = assumed to be identical to concentration of total iron. *s* = determined from an emission spectrograph to within a factor of two. *w* = determined from a wet chemical analysis to ±10%. *x* = fraction of tetrahedral sites occupied by Fe^{2+}.

determined chemically. For the $FeAl_2O_4$ crystal the absorption was too large to be measured, and the expected curve, shown dashed in Fig. 7 between 0.4 and 0.8 eV, has been estimated from the chemical determination. The agreement with the known portion of the curve is quite good, showing that the proportionality assumption is not too bad. In Table VII the agreement between the optical and chemical values for R68 and R54 is again satisfactory. However, for samples R62 and R56 the chemical concentration is higher than the concentration of tetrahedral Fe^{2+}. Judging from the chemical analyses of these samples in Ref. 23 and the optical absorption curves in Fig. 8, the remaining 40% of the Fe probably occurs as Fe^{3+}.

MAGNETIC SUSCEPTIBILITY

The magnetic sysceptibility χ of an as-grown single crystal of $FeAl_2O_4$ quite similar to sample R67 was measured from 1.9 to 290°K. The measurements were made by Kouvel and Hartelius with an apparatus[56] described previously. The susceptibility was independent of applied field for values of the magnetic field H, between 1.5×10^5 to 8×10^5 A/m. (2000 to 10 000 Oe.) The susceptibility in rationalized mks units is shown in Fig. 9. The susceptibility is defined as the ratio of the induced magnetic moment per unit volume (A/m) to the applied magnetic field (A/m), and is dimensionless. These χ values can, if desired, be converted to emu/cm³ by dividing by 4π. The x-ray density of $FeAl_2O_4$ is 4.26 g/cm³. There is a very sharp peak in the χ versus T curve at 9.5±0.5°K. The χ^{-1} curve for the single crystal above 9.5°K is also shown in Fig. 9 compared with the recent data of Roth[5] and Lotgering[57] on powder samples. The present results lie between these two previous curves, and indicate that the χ is somewhat dependent on the exact nature of the sample. Small changes in the fractional inversion and the Fe^{3+} content are probably responsible for the variability in χ above 10°K. They are presumably responsible for slight shifts in the peak temperature. Roth[5] found a peak at 8°K. These measurements have not yet been made on annealed single crystals similar to R75.

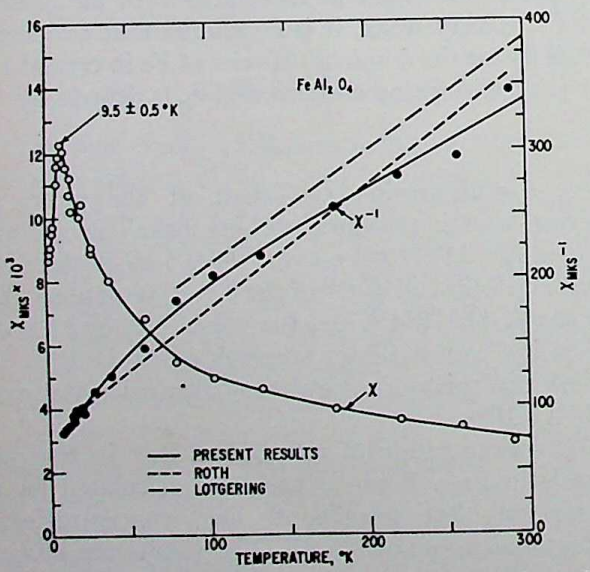

FIG. 9. The magnetic susceptibility χ and its reciprocal χ^{-1} versus temperature for a single crystal of $FeAl_2O_4$ similar to R67. The χ^{-1} curves obtained by other authors for powder samples are also shown.

The 9.5°K temperature for the peak in the χ versus T curve closely matches the "kink" in the K versus T curve at 11±1°K. It would seem that these two features are closely related. Since the "kink" in the K curve appears to be independent of the Fe^{2+} concentration, it is postulated here that the position of the peak may also be nearly independent of the Fe^{2+} concentration. Thus the behavior of the χ versus T curve may be a function of the individual Fe^{2+} ions, and may not be associated with a long-range ordering of the magnetic moment of the Fe^{2+}. A localized Jahn-Teller distortion of the Fe^{2+} ions at 11°K could, perhaps, account for much of the observed behavior. It is known that the normal spinel $FeCr_2O_4$ undergoes[58–60] such a distortion at 135°K, which is rather higher than its Curie temperature[58,61] of about 85°K. Even though Roth[5] found no evidence for a crystallographic distortion in the cubic $FeAl_2O_4$ at 4°K, it is possible that there is a small, local distortion around each Fe^{2+} site. This local distortion, however, may not be large enough to produce a long-range, cooperative, crystallographic distortion. The neutron scattering results of Roth also failed to show any evidence of long-range ordering in $FeAl_2O_4$ at 4°K. This rather unusual behavior of tetrahedral Fe^{2+} may be associated with the four low-lying energy levels, the closest of which is about 30°K above the singlet ground state. Since the ground state is a singlet with no orbital or spin degeneracy, the Fe^{2+} should have no magnetic moment in zero magnetic fields at temperatures well below 30°K. Thus, one might

expect that signs of a magnetic ordering at these temperatures would not occur. It would appear desirable to make χ measurements on mixed crystals of $FeAl_2O_4$–$MgAl_2O_4$ in order to test some of these speculations. This has not yet been done.

CONCLUSIONS

(1) A method of growing good single crystals of $FeAl_2O_4$ has been devised. A post-growth heat treatment in the appropriate atmosphere permits some control of the concentration of the residual Fe^{3+} and the fractional inversion.

(2) The thermal conductivity K of synthetic crystals of $FeAl_2O_4$ and $MgAl_2O_4$ and natural crystals of $Mg_{1-x}Fe_xAl_2O_4$ has been measured from 3 to 300°K. At all temperatures, the K decreases with increasing Fe^{2+} concentration x for $0 \leq x \leq 1$. For $x=1$, the K exhibits the unusual behavior of decreasing continuously with decreasing temperature for $T \leq 300$°K. In all of the crystals the heat is transported by phonons.

(3) The phonon scattering from the tetrahedral Fe^{2+} is quite strong. This scattering produces a change in the slope of the K versus T curve at 11 ± 1°K, independent of the Fe^{2+} concentration. These results suggest that the anomaly at 11°K is associated with the individual Fe^{2+} ions, and is not caused by the occurrence of an antiferromagnetic state.

(4) The magnetic susceptibility χ of a single crystal of $FeAl_2O_4$ has been measured from 1.9 to 290°K. The χ versus T curve shows a peak at 9.5 ± 0.5°K, in reasonable agreement with the 11°K peak found from the K measurements. It is suggested that this behavior may be characteristic of tetrahedral Fe^{2+}, and is not to be associated with the onset of an antiferromagnetic state.

(5) Thermal conductivity measurements on $CoAl_2O_4$ show that tetrahedral Co^{2+} is not as effective a scatterer of phonons as is tetrahedral Fe^{2+} in the range from 4 to 300°K.

(6) The optical absorption coefficients of crystals of $Mg_{1-x}Fe_xAl_2O_4$ for $0 \leq x \leq 1$ have been measured at 300°K for photon energies between 0.1 and 7.0 eV. The tetrahedral Fe^{2+} produces a broad, double-peaked absorption band between 0.4 and 0.6 eV. This absorption band has been used to measure the value of x.

Additional optical absorption bands have been seen which are due to octahedral Fe^{2+} and octahedral Cr^{3+}.

ACKNOWLEDGMENTS

I wish to thank J. H. McTaggart for his aid in growing the crystals and in making many of the measurements, R. M. Chrenko for his assistance with the optical absorption and reflectivity measurements, and Dr. J. S. Kouvel and C. C. Hartelius for measuring the magnetic susceptibility. I also thank E. M. Clausen for the $CoAl_2O_4$ crystal. My thanks are extended to W. Roth and F. S. Ham for several fruitful discussions concerning the nature of $FeAl_2O_4$.

APPENDIX: THE OPTICAL ABSORPTION OF Cr^{3+} IN $MgAl_2O_4$ SPINELS

Almost all natural crystals of $MgAl_2O_4$ contain traces of Cr. The chemical analyses in Table III and Ref. 23 show that Cr is indeed present in the natural crystals R54, R56, and R97. The Cr^{3+} ion has a very strong preference[46] for the octahedral sites in the spinel, and thus occurs only in these sites in $MgAl_2O_4$. The optical absorption of Cr^{3+} in spinel has been studied by many people,[62–71] and at low concentrations in natural crystals of reasonably pure $MgAl_2O_4$ it gives rise to two broad, intense absorption bands at 2.25 and 3.21 eV. Crystal R54 in Fig. 7 shows these two bands with the peaks at 2.30 and 3.18 eV, in good agreement with the previous literature. The emission spectrographic analysis of this sample showed a Cr content of 2×10^{19} cm^{-3} to within a factor of, say, 2. The calculated oscillator strengths[48] are, to within a factor of 2, $f = 2 \times 10^{-4}$ and 5×10^{-4} for the 2.30- and 3.18-eV peaks, respectively. If the synthetic crystal containing a nominal 0.5 weight % Cr studied by Schlossmacher is considered, the derived f value for his 2.21-eV peak is $f = 0.9 \times 10^{-4}$ to within a factor of 2. Thus the assignment of the 2.30-eV peak in R54 to Cr^{3+} is reasonable in terms of both the photon energy and the magnitude of the absorption coefficient. The optical absorption from a known amount of Cr^{3+} in α-Al_2O_3 has been measured by Maiman *et al.*[72] Their results for the 2.23- and 3.02-eV absorption bands averaged over the three directions in the crystal give f values of approximately 2×10^{-4} and 6×10^{-4}, respectively, for the two bands. These results for α-Al_2O_3 are in very good agreement with those for $MgAl_2O_4$. Of the other various references already cited for Cr^{3+} in $MgAl_2O_4$, none have enough data to enable a calculation of the oscillator strengths to be made.

Let us now consider the various bands found in R97 between 1.5 and 4.0 eV. The 2.24-eV band and the double-peaked band at 3.23 and 3.35 eV are believed to be the two Cr^{3+} bands that appear prominently in R54. The chemical analysis of R97 gave a Cr content of $3.5 \pm 0.3 \times 10^{19}$ cm^{-3}. From this value the calculated oscillator strengths are $f = 8 \times 10^{-4}$ for the 2.24 eV and $f = 16 \times 10^{-4}$ for the "3.29-eV" band. These f values are about 3 times larger than before. These two bands are

TABLE VIII. Comparison of the optical absorption transitions of Cr^{3+} in $MgAl_2O_4$ with those of $[Cr(H_2O)_6]^{3+}$.

Transition	Energy, $h\nu$, in eV R54	R97	$[Cr(H_2O)_6]^{3+}$
$^4A_2(^4F) \rightarrow {}^2E(^2G)$		1.89	1.85
$\rightarrow {}^2T_1(^2G)$			1.87
$\rightarrow {}^4T_2(^4F)$	2.30	2.24	2.23
$\rightarrow {}^2T_2(^2G)$		2.72	2.60
$\rightarrow {}^4T_1(^4F)$	3.18	3.23, 3.35	3.05
$\rightarrow {}^2A_1(^2G)$		3.7	
$\rightarrow {}^4T_1(^4P)$			4.64

also assigned to Cr^{3+}, and their f values, though larger, are reasonable. The somewhat larger f values are thought to be caused by the presence of the Fe^{2+} in the tetrahedral sites enhancing the transition probabilities of the Cr^{3+} in the octahedral sites. The chemically determined concentration of Fe in R97 is $(3.6\pm0.3)\times10^{20}$ cm^{-3}. Thus, 1 out of every 42 tetrahedral sites is occupied by Fe. Since each tetrahedral site in the spinel lattice has 12 nearest octahedral sites, there will be 4.3×10^{21} cm^{-3} octahedral sites, or 1/7 of the total which have an Fe atom as a next-nearest neighbor. If the Cr atoms are randomly distributed over the octahedral sites, then 1/7 of them will be affected by the presence of the tetrahedral Fe in R97. For low concentrations of Fe and Cr the fraction of the Cr sites that are paired with Fe is proportional to the Fe concentration. The fraction of the Cr sites in R54 that are paired is 0.004. The optical absorption spectrum of the Cr^{3+} in R54 is thus not influenced by the presence of the Fe^{2+}. In R97 the case is different. The absorption of the 2.24 and "3.29" eV bands is apparently enhanced. Also the "3.29" eV band has been split into two components, as mentioned previously. In addition there are 3 normally very weak octahedral Cr^{3+} peaks which show up in Fig. 7 as absorption bands at 1.89, 2.72, and a shoulder at 3.7 eV. The 1.89- and 2.72-eV bands have been seen before in blue or blue-green, natural spinel crystals[64,68] which are known[66] to contain Fe^{2+}. The 3.7-eV band has been seen before by Weigel[63] in synthetic $MgAl_2O_4$ containing Cr^{3+}. The assignment of these several bands to various known transitions in octahedral Cr^{3+} is given in Table VIII. The corresponding energies found for $[Cr(H_2O)_6]^{3+}$ are also shown.[73] The agreement is good, indicating that the several absorption bands in R97 between 1.5 and 4.0 eV are caused by the Cr^{3+}. None of them can be attributed directly to optical transitions within the d shell of the tetrahedral Fe^{2+}. This is in contrast to the suggestions of Schlossmacher[64–66] who believed that the absorption spectrum in the visible range of the Fe containing $MgAl_2O_4$ crystals was actually due to the Fe^{2+}. In his crystals as in R97, it is caused by the presence of Cr^{3+}. The Fe^{2+} has, however, strongly modified the Cr^{3+} absorption spectrum. The absorption band at 1.34 eV in R97 is at too low an energy to be caused by the octahedral Cr^{3+}. As explained before, it is believed to be associated with the presence of some tetrahedral Fe^{3+}.

Low-Temperature Galvanomagnetic Phenomena in an Intense Electric Field

HERBERT F. BUDD*
Laboratoire de Physique de l'Ecole Normale Superieure, Paris, France
(Received 2 December 1963; revised manuscript received 16 January 1964)

The electron distribution function is calculated for a many-valley semiconductor in an intense electric field for the case of anisotropic scattering by acoustical phonons at low temperatures.

I. INTRODUCTION

IN this paper we shall consider the low-temperature galvanomagnetic properties of a semiconductor in an intense electric field. In order to calculate the low-temperature anisotropic transport properties of semiconductors such as n-type germanium and silicon, it is necessary to abandon both the simple picture of spherical constant energy surfaces and the assumption of phonon equipartition.

Zylberstejn and Conwell[1] have studied the deviations of the phonon distribution from equilibrium in a semiconductor in an intense electric field at low temperatures. They show that the deviation is small for a sample of small dimensions and small carrier concentration. We shall treat this latter case and assume that the phonon distribution remains in equilibrium.

The predominant electron scattering mechanism in a pure semiconductor at low temperatures is by acoustical phonons and the equilibrium number of such phonons of crystal momentum $\mathbf{q}$ is given by

$$N_q = 1/(e^{qs/kT}-1), \quad (1)$$

where s is the velocity of sound, k is Boltzmann's constant, and T is the absolute temperature. The conservation of energy and crystal momentum require that the acoustical phonons with which an electron of energy ϵ can interact have a maximum energy of the order of $2(\epsilon ms^2)^{1/2}$ where m is the effective electron mass. At high temperatures the average electron energy $\bar{\epsilon}$, even in an intense electric field, is such that

$$2(\bar{\epsilon}ms^2)^{1/2} \ll kT \quad \text{and therefore} \quad qsN_q \approx kT. \quad (2)$$

This is the case of equipartition of energy.

At low temperatures, on the other hand, an intense electric field may result in the average electron energy $\bar{\epsilon}$ being sufficiently large such that

$$2(\bar{\epsilon}ms^2)^{1/2} > kT \quad \text{and} \quad N_q \sim \exp-\left(\frac{2(\bar{\epsilon}ms^2)^{1/2}}{kT}\right). \quad (3)$$

Since the probability of phonon emission and absorption are proportional to $1+N_q$ and N_q, respectively, we may in this case neglect N_q compared to one and consider only acoustical phonon emission; this is the case of zero-point scattering.

Stratton[2] has calculated the electron distribution function in the limit of zero-point scattering for the case of spherical constant energy surfaces and isotropic scattering, while Paranjape[3] has calculated the electron temperature for a Boltzmann distribution for the same case. Koenig, Brown, and Schillinger (K.B.S.)[4] have recently applied Shibuya's[5] theory of hot electrons in order to describe hot electron phenomena in n-type germanium at low temperatures. Shibuya's treatment is based on the assumption of phonon equipartition and is therefore not applicable under the condition for which K.B.S. have used it. We see in fact from Table II of their paper that the electron temperatures, or the corresponding mean electron energies, do not satisfy the equipartition condition (2).

Stratton's zero-point distribution function and Paranjape's calculation predict an electron mobility $\mu \sim E^{-0.8}$, where E is the electric field. This is in agreement with the low-temperature conductivity measurements of Bray and Brown.[6]

In this paper we shall extend the previous calculations[2,3] by considering a many-valley semiconductor with ellipsoidal constant energy surfaces in an intense electric field and a magnetic field. We treat the case of acoustical phonon scattering in the zero-point limit, and allow for anisotropic scattering in our calculation.

In Sec. II of this paper we set up the Boltzmann equation for a many-valley semiconductor, and in Sec. III we derive expressions for the energy and momentum relaxation in the case of anisotropic zero-point scattering. We solve the Boltzmann equation for the distribution function in Sec. IV.

II. BASIC EQUATIONS

In a previous publication,[7] the author has shown that the Boltzmann equation for the case of ellipsoidal constant energy surfaces can be expressed as two coupled equations for S and A, the isotropic and aniso-

tropic parts of the distribution function, respectively,

$$e\mathbf{E}'\cdot\nabla_{p'}S+\mathrm{An}\{e\mathbf{E}'\cdot\nabla_{p'}A\}+\frac{e}{m_0}\mathbf{p}'\times\mathbf{B}'\cdot\nabla_{p'}A=\hat{C}'A\,,$$

$$\mathrm{Is}\{e\mathbf{E}'\cdot\nabla_{p'}A\}=\hat{C}'S\,, \tag{4}$$

with $\mathbf{p}'=\alpha\mathbf{p}$, $\mathbf{E}'=\alpha\mathbf{E}$, $\mathbf{B}'=R\mathbf{B}$, $\epsilon=p'^2/2m_0$,

$$\alpha=\begin{bmatrix}\frac{m_0}{m_x} & 0 & 0\\ 0 & \frac{m_0}{m_y} & 0\\ 0 & 0 & \frac{m_0}{m_z}\end{bmatrix}^{1/2} \qquad R=\begin{bmatrix}m_x & 0 & 0\\ 0 & m_y & 0\\ 0 & 0 & m_z\end{bmatrix}^{1/2}\frac{m_0}{(m_xm_ym_z)^{1/2}}\,, \tag{5}$$

where $\mathbf{E}$ and $\mathbf{B}$ are the electric and magnetic field vectors, ϵ and $\mathbf{p}$ are the electron energy and momentum and m_x, m_y, m_z are the electron masses corresponding to the three principal axes of the ellipsoid.

An$\{x\}$ and Is$\{x\}$ represent the anisotropic and isotropic parts of x respectively, and $\hat{C}'$ represents the collision operator in $\mathbf{p}'$ space.

Assuming that $\hat{C}'A$ can be described by an energy-dependent tensor whose principal axes coincide with those of the ellipsoid:

$$\tau=\begin{bmatrix}\tau_x(\epsilon) & 0 & 0\\ 0 & \tau_y(\epsilon) & 0\\ 0 & 0 & \tau_z(\epsilon)\end{bmatrix}, \tag{6}$$

and neglecting the An$\{e\mathbf{E}'\cdot\nabla\rho'A\}$ term (see Appendix II), we obtain straightforwardly:

$$A=-\frac{dS}{d\epsilon}\mathbf{V}'\cdot\left[\frac{\tau(e\mathbf{E}'+\tau e\mathbf{E}'\times e\mathbf{B}'/m_0)+(e^2/m_0^2)\mathbf{B}'(\mathbf{B}'\cdot e\mathbf{E}')\bar{\tau}^3}{1+(e^2/m_0^2)\bar{\tau}^3[(B_x'^2/\tau_x)+(B_y'^2/\tau_y)+(B_z'^2/\tau_z)]}\right], \tag{7}$$

$$\hat{C}'S=-\frac{2}{3m_0\epsilon^{1/2}}\frac{d}{d\epsilon}\left[\frac{dS}{d\epsilon}\epsilon^{3/2}\left(\frac{e^2\mathbf{E}'\tau\mathbf{E}'+\bar{\tau}^3(e^2\mathbf{E}'\cdot\mathbf{B}'/m_0)^2}{1+(\bar{\tau}^3e^2/m_0^2)[(B_x'^2/\tau_x)+(B_y'^2/\tau_y)+(B_z'^2/\tau_z)]}\right)\right], \tag{8}$$

where $\mathbf{V}'=(\mathbf{p}'/m_0)$ and $\bar{\tau}^3=\tau_x\tau_y\tau_z$.

We shall consider the solution of this equation after having calculated the energy relaxation term $\hat{C}'S$, and the relaxation time tensor τ.

III. CALCULATION OF ENERGY RELAXATION TERM AND RELAXATION TIME TENSOR

In this section we shall derive expressions for τ and $\hat{C}'S$ for a many-valley semiconductor with anisotropic scattering by the zero-point acoustical phonons. Denoting by M_L^2, c_L and M_T^2, c_T, the matrix elements and elastic constants corresponding to the longitudinal and transverse modes respectively, we obtain

$$\hat{C}f(\mathbf{p})=\frac{2\pi}{\hbar(2\pi\hbar)^3}\left\{\int d\mathbf{q}[f(\mathbf{p}+\mathbf{q})(1+N_q)-f(\mathbf{p})N_q][X_L+X_T]+\int d\mathbf{q}[f(\mathbf{p}-\mathbf{q})N_q-f(\mathbf{p})(1+N_q)][Y_L+Y_T]\right\}; \tag{9}$$

$$X_{L,T}=(qs_{L,T}/2c_{L,T})M_{L,T}^2\delta(\epsilon(\mathbf{p}+\mathbf{q})-\epsilon(\mathbf{p})-qs_{L,T})\,,$$

where

$$Y_{L,T}=(qs_{L,T}/2c_{L,T})M_{L,T}^2\delta(\epsilon(\mathbf{p}-\mathbf{q})-\epsilon(\mathbf{p})+qs_{L,T})\,,$$

$\rho s_L^2=c_L$, $\rho s_T^2=c_T$ and where ρ is the density. The matrix elements have been calculated by Herring and Vogt,[8] and we see from Table V of their paper that M_L^2 and M_T^2 are simple polynomials in $\cos^2\theta$, where θ is the angle between the principal axis of the ellipsoid and $\mathbf{q}$.

Transforming the elliposidal constant energy surfaces to spheres (5) in both the electron and phonon space,

[8] C. Herring and E. Vogt, Phys. Rev. **101**, 944 (1956).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

we obtain

$$\hat{C}'f=\frac{2\pi m_T m_L^{1/2}}{\hbar(2\pi\hbar)^3 m_0^{3/2}}\Big\{\int d\mathbf{q}'[f(\mathbf{p}'+\mathbf{q}')(1+N_{q^*})-f(\mathbf{p}')N_{q^*}][X_L'+X_T'] + \int d\mathbf{q}'[f(\mathbf{p}'-\mathbf{q}')N_{q^*}-f(\mathbf{p}')(1+N_{q^*})][Y_L'+Y_T']\Big\}, \quad (10)$$

where

$$X_{L,T}'=(q^*s_{L,T}/2c_{L,T})M_{L,T}^2(\cos^2\theta^*) \times\delta(\epsilon(\mathbf{p}'+\mathbf{q}')-\epsilon(\mathbf{p}')-q^*s_{L,T}),$$

$$Y_{L,T}'=(q^*s_{L,T}/2c_{L,T})M_{L,T}^2(\cos^2\theta^*) \delta(\epsilon(\mathbf{p}'-\mathbf{q}')-\epsilon(\mathbf{p}')+q^*s_{L,T}).$$

The principal axis of the ellipsoid has been taken as the polar axis in $\mathbf{q}'$ space; and m_T and m_L are the transverse and longitudinal masses, respectively;

$$q^*=(m_T/m_0)^{1/2}q'[1+(K-1)\cos^2\theta']^{1/2},$$

$$\cos\theta^*=\frac{K^{1/2}\cos\theta'}{[1+(K-1)\cos^2\theta']^{1/2}}, \quad K=\frac{m_L}{m_T}, \quad (11)$$

where θ' is the cone angle in $\mathbf{q}'$ space.

We first calculate $\hat{C}'S$, where S is a function of energy only. If the scattering were isotropic the matrix elements would be angularly independent and $\hat{C}'S$ would depend only on energy. In our case, M_L^2 and M_T^2 are angularly dependent and $\hat{C}'S$ will therefore in general be a function of the direction of $\mathbf{p}'$. We shall calculate the average of $\hat{C}'S$ over all directions of $\mathbf{p}'$, i.e.,

$$\langle\hat{C}'S\rangle_{\text{av}}=\int\int\hat{C}'Sd\Omega_{p'}\Big/\int\int d\Omega_{p'}, \quad (12)$$

where $d\Omega_{p'}$ is the differential solid angle in $\mathbf{p}'$ space.

Assuming that:

(1) The distribution function varies slowly over an energy interval equal to the phonon energy:

$$S(\epsilon+qs)=S(\epsilon)+qs\frac{dS}{d\epsilon}+\frac{(qs)^2}{2}\frac{d^2S}{d\epsilon^2}. \quad (13a)$$

(2) The average electron energy $\bar{\epsilon}$ is sufficiently large such that N_q is negligible compared to one:

$$2(\bar{\epsilon}ms^2)^{1/2}>kT \quad (13b)$$

and carrying out the required integrations we obtain

$$\hat{C}'S=\frac{64\pi^3m_T^2m_L^{1/2}}{\sqrt{2}h^4\rho\epsilon^{1/2}}\Sigma^{2*}\frac{d}{d\epsilon}\left[\epsilon^2\left(S+\frac{4\sqrt{2}}{5}m_T^{1/2}\epsilon^{1/2}V^*\frac{dS}{d\epsilon}\right)\right], \quad (14)$$

where

$$\Sigma^{2*}=\int_0^1R^2\left[M_L^2\left(\frac{Kx^2}{R^2}\right)+M_T^2\left(\frac{Kx^2}{R_2}\right)\right]dx,$$

$$V^*=\int_0^1R^3\left[s_LM_L^2\left(\frac{Kx^2}{R^2}\right)+s_TM_T^2\left(\frac{Kx^2}{R^2}\right)\right]dx\Big/\Sigma^{2*},$$

and

$$R=[1+(K-1)X^2]^{1/2}.$$

A relaxation time does not generally exist when the matrix elements are angularly dependent; we follow the procedure of Herring and Vogt and define two principal relaxation times as follows:

$$1/\tau_{11}=-\int\int\phi_{11}'\hat{C}'\phi_{11}'d\Omega_{p'}\Big/\int\int\phi_{11}'^2d\Omega_{p'},$$

$$1/\tau_{\perp}=-\int\int\phi_{\perp}'\hat{C}'\phi_{\perp}'d\Omega_{p'}\Big/\int\int\phi_{\perp}'^2d\Omega_{p'}, \quad (15)$$

with

$$\phi_{11}'=\mathbf{p}'\cdot\mathbf{a}/p', \quad \phi_{\perp}'=\mathbf{p}'\cdot\mathbf{b}/p',$$

where $\mathbf{a}$ and $\mathbf{b}$ are unit vectors parallel to the major and minor axes of the ellipsoid, respectively. We obtain the following expressions for the two relaxation times:

$$\frac{1}{\tau_{11,\perp}}=\frac{48(2\pi)^3}{5h^4}m_T^{3/2}m_L^{1/2}\epsilon N_{11,\perp}, \quad (16)$$

where

$$N_{11}=T_1, \quad N_{\perp}=\frac{T_0-T_1}{2},$$

and

$$T_n=\int_0^1dxR(x)x^{2n}\left[\frac{s_L}{c_L}M_L^2\left(\frac{Kx^2}{R^2}\right)+\frac{s_T}{c_T}M_T^2\left(\frac{Kx^2}{R^2}\right)\right].$$

The matrix elements and average elastic constants are given in Table V of Herring and Vogt's paper:

$$M_L^2\left(\frac{Kx^2}{R^2}\right)=\Sigma_d^2\left(1+\frac{Kx^2W}{R^2}\right)^2\left[1+\gamma_L\left(0.15-\frac{1.5Kx^2}{R^2}+\frac{1.75K^2x^4}{R^4}\right)\right],$$

CC-0. In Public Domain. Gurukul K

Digitized by Arya Samaj Foundation Chennai and eGangotri

$$M_T{}^2\left(\frac{Kx^2}{R^2}\right)=\frac{Kx^2\Sigma_d{}^2W^2}{R^2}\left(1-\frac{Kx^2}{R^2}\right)\left(1+\gamma_T\frac{Kx^2}{R^2}\right);\quad W=\frac{\Sigma_\mu}{\Sigma_d},$$

$$c_L=c_{12}+2c_{44}+0.6c^*;\qquad \frac{1}{c_T}=\begin{cases}\dfrac{0.375}{c_{44}}+\dfrac{0.625}{c_{44}+\frac{1}{3}c^*}, & \text{(111) valley}\\[2ex] \dfrac{3}{c_{44}+\frac{1}{3}c^*}-\dfrac{2}{c_{44}+\frac{1}{2}c^*}, & \text{(100) valley,}\end{cases}$$

$$\gamma_L=\begin{cases}\dfrac{2c^*}{3c_L}, & \text{(111) valley}\\[2ex] -\dfrac{c^*}{c_L}, & \text{(100) valley}\end{cases}\qquad \gamma_T=\begin{cases}\dfrac{9}{8}c_T\left(\dfrac{1}{c_{44}}-\dfrac{1}{c_{44}+\frac{1}{3}c^*}\right), & \text{(111) valley}\\[2ex] 6c_T\left(\dfrac{1}{c_{44}+\frac{1}{2}c^*}-\dfrac{1}{c_{44}+\frac{1}{3}c^*}\right), & \text{(100) valley,}\end{cases}$$

where Σ_d and Σ_μ are the deformation potential constants for dilation and uniaxial shear. Inserting these matrix elements in Eqs. (16) and (14) we obtain the relaxation time tensor and $\hat{C}'S$ (see Appendix I).

IV. THE DISTRIBUTION FUNCTION

We shall now solve Eq. (8) for S, the isotopic part of the distribution function. Substituting Eq. (14) in Eq. (8), we obtain

$$S=\exp-\left[\int_0^\epsilon \frac{H\epsilon^{1/2}d\epsilon}{\dfrac{2}{3m_0}\left(\dfrac{e^2\mathbf{E}'\tau\mathbf{E}'+[(e^2/m_0)\mathbf{E}'\cdot\mathbf{B}']^2\bar{\tau}^3}{1+(e^2\bar{\tau}^3/m_0{}^2)[(B_x'{}^2/\tau_x)+(B_y'{}^2/\tau_y)+(B_z'{}^2/\tau_z)]}\right)+\bar{H}}\right],\tag{17}$$

where

$$H=\frac{64\pi^3m_T{}^2m_L{}^{1/2}\Sigma^{2*}}{\sqrt{2}h^4\rho};\quad \bar{H}=\frac{4\sqrt{2}}{5}m_T{}^{1/2}V^*\epsilon H.$$

We shall consider the case of a small magnetic field ($\omega^2\tau^2\ll1$) and we neglect the field-independent term in the denominator of the integrand of Eq. (17) (see Appendix II). We then obtain

$$S=\exp-(\epsilon/kT_e)^{5/2},\tag{18}$$

$$A=-\frac{dS}{d\epsilon}\mathbf{V}'\cdot\left[\tau\left(e\mathbf{E}'+e\tau\mathbf{E}'\times\frac{e\mathbf{B}'}{m_0}\right)\right],\tag{19}$$

with

$$T_e=X(\gamma)G\frac{[E\mu_aT^{3/2}/s_L]^{4/5}}{[m_Ts_L{}^2/k]^{1/5}}\left[\frac{3\bar{\Sigma}^4}{16\Sigma^{2*}N_1s_L\rho}\right]^{2/5},\tag{20}$$

where

$$X(\gamma)=\left[1+\gamma^2\left(\frac{1}{K'}-1\right)\right]^{2/5},\quad K'=K\frac{\tau_\perp}{\tau_{11}},$$

$$G=\left[\frac{\sqrt{2}\pi(27)(25)}{16^2(2+1/K)^2}\right]^{2/5},$$

and γ is the direction cosine of $\mathbf{E}$ with respect to the longitudinal axis of the ellipsoid. μ_a is the low-field mobility for acoustical phonon scattering and is related to the average deformation potential which appears in Herring and Vogt's paper [Eqs. (49) and (50)]

$$\bar{\Sigma}^4=[\xi\Sigma_d{}^2+\eta\Sigma_\mu\Sigma_d+\zeta\Sigma_\mu{}^2]^2.$$

When we consider the simple model of spherical constant energy surfaces, $\Sigma_\mu=0$ and neglect elastic anisotropy ($c^*=0$), the last factor in our expression for T_e becomes equal to 1, as does $X(\gamma)$, and Eq. (18) becomes identical with the distribution function calculated by Stratton.[2] Since the low-field mobility for acoustical phonon scattering varies as $T^{-3/2}$, our expression T_e is independent of temperature.

Using Eqs. (19) and (20) we obtain the following expressions for the mobility μ and the low magnetic-field Hall coefficient R.

$$\mu=PE^{-0.8};\quad R=B,$$

where P and B are complicated functions of the orientation of the electric and magnetic fields with respect to the crystallographic axes but are independent of the *magnitudes* of the applied fields. The field dependence of the mobility is in agreement with the experimental results of Bray and Brown.[6] A discussion of the orientation dependence will be considered in a future publication.

ACKNOWLEDGMENTS

The author expresses his sincere thanks to Professor P. Aigrain and Dr. E. Conwell for their stimulating discussions. Thanks are also due to Dr. A. Zylberstejn and D. Olechna for helpful suggestions and to the Xerox Corporation for partial support of this work.

APPENDIX I

We shall express all the required integrals of Sec. III in terms of the elementary integrals

$$\langle m,n\rangle \equiv \int_0^1 \frac{x^m dx}{[1+(K-1)x^2]^{n/2}}, \tag{A1}$$

$$\Sigma^{2*}=\Sigma_d{}^2\{\tfrac{2}{3}+\tfrac{1}{3}K(1+W)^2+\gamma_L[0.1-0.45K+1.75K^2\langle 4,2\rangle+2KW(0.05-1.5K\langle 4,2\rangle+1.75K^2\langle 6,4\rangle)$$
$$+(KW)^2(0.15\langle 4,2\rangle-1.5K\langle 6,4\rangle+1.75K^2\langle 8,6\rangle)]+\gamma_T(KW)^2(\langle 4,2\rangle-K\langle 6,4\rangle)\}, \tag{A2}$$

$$V^*=\frac{\Sigma_d{}^2}{\Sigma^{2*}}\{s_L(\langle 0,-3\rangle+2KW\langle 2,-1\rangle+K^2W^2\langle 4,1\rangle)+s_TKW^2(\langle 2,-1\rangle-K\langle 4,1\rangle)$$
$$+\gamma_Ls_L[0.15\langle 0,-3\rangle-1.5K\langle 2,-1\rangle+1.75K^2\langle 4,1\rangle+2KW(0.15\langle 2,-1\rangle-1.5K\langle 4,1\rangle+1.75K^2\langle 6,3\rangle)$$
$$+(KW)^2(0.15\langle 4,1\rangle-1.5K\langle 6,3\rangle+1.75K^2\langle 8,5\rangle)]+\gamma_Ts_T(KW)^2(\langle 4,1\rangle-K\langle 6,3\rangle)\}, \tag{A3}$$

$$T_{\substack{0\\1}}=\Sigma_d{}^2\Big\{\frac{s_L}{c_L}(\langle {}^0_2,-1\rangle+2KW\langle {}^2_4,1\rangle+(KW)^2\langle {}^4_6,3\rangle)+\frac{s_T}{c_T}KW^2(\langle {}^2_4,1\rangle-K\langle {}^4_6,3\rangle)$$
$$+\gamma_L\frac{s_L}{c_L}[0.15\langle {}^0_2,-1\rangle-1.5K\langle {}^2_4,1\rangle+1.75K^2\langle {}^4_6,3\rangle+2KW(0.15\langle {}^2_4,1\rangle-1.5K\langle {}^4_6,3\rangle+1.75K^2\langle {}^6_8,5\rangle)$$
$$+(KW)^2(0.15\langle {}^4_6,3\rangle-1.5K\langle {}^6_8,5\rangle+1.75K^2\langle {}^8_{10},7\rangle)]+\gamma_T\frac{s_T}{c_T}(KW)^2(\langle {}^4_6,3\rangle-K\langle {}^6_8,5\rangle)\Big\}. \tag{A4}$$

The integrals $\langle m,n\rangle$ are all straightforward. For $K=1$, $\langle m,n\rangle=1/(m+1)$, and for $K\neq 1$ one can easily show that

$$\langle m+2,n+2\rangle=\frac{1}{n(K-1)}\left[(m+1)\langle m,n\rangle-\frac{1}{K^{n/2}}\right] \tag{A5}$$

for $n\neq 0$. We have tabulated some of the integrals in Table I. The remaining ones are easily calculated by means of Eq. (A5).

TABLE I. Integrals.

	$K>1$	$K=1$	$K<1$
$\langle 0,-1\rangle$	$\frac{K^{1/2}}{2}+\frac{\sinh^{-1}(K-1)^{1/2}}{2(K-1)^{1/2}}$	1	$\frac{K^{1/2}}{2}+\frac{\sin^{-1}(1-K)^{1/2}}{2(1-K)^{1/2}}$
$\langle 2,-1\rangle$	$\frac{1}{8(K-1)}\left[K^{1/2}(2K-1)-\frac{\sinh^{-1}(K-1)^{1/2}}{(K-1)^{1/2}}\right]$	$\frac{1}{3}$	$\frac{1}{8(1-K)}\left[-K^{1/2}(2K-1)+\frac{\sin^{-1}(1-K)^{1/2}}{(1-K)^{1/2}}\right]$
$\langle 4,2\rangle$	$\frac{1}{(K-1)^2}\left[\frac{K-4}{3}+\frac{\tan^{-1}(K-1)^{1/2}}{(K-1)^{1/2}}\right]$	$\frac{1}{5}$	$\frac{1}{(1-K)^2}\left[\frac{K-4}{3}+\frac{\tanh^{-1}(1-K)^{1/2}}{(1-K)^{1/2}}\right]$

APPENDIX II

We see from Eq. (18) that $\bar{\epsilon}=kT_e/\Gamma(0.6)\approx\frac{3}{2}kT_e$ and therefore using Eq. (3) the zero-point scattering condition is satisfied for electric fields large enough such that

$$\sqrt{6}\left(\frac{m^*s^{*2}}{k}\right)^{1/2}(X(\gamma)G)^{1/2}\frac{[E\mu_aT^{3/2}/s_L]^{2/5}}{[m_Ts_L{}^2/k]^{1/10}}\left[\frac{3\Sigma^4}{16\Sigma^{2*}N_1s_L\rho}\right]^{1/5}>T, \tag{A6}$$

where m^* is a complicated average of the longitudinal and transverse masses and is given approximately by

$$m^*\approx\tfrac{2}{3}m_T(K^{3/2}-1)/(K-1)$$

and s^* is the average sound velocity.

For spherical constant energy surfaces and $\Sigma_\mu=c^*=0$, Eq. (20) becomes approximately

$$2.4(ms^2/k)^{2/5}[E\mu_aT^{3/2}/s]^{2/5}>T.$$

The neglect of the field-independent term in the denominator of Eq. (17) is equivalent to neglecting ms^2/kT_e compared to one. It is easily seen that the $An\{e\mathbf{E}'\cdot\nabla_{p'}A\}$ term is a correction to the distribution function due to neglecting higher order terms than the first-order spherical harmonics, i.e., terms of the form $Y_{2n}(\theta,\phi)$, etc.

Spin-Lattice Relaxation Time of Conduction Electrons in Sodium Metal*

FREDERICK VESCIAL,† N. S. VANDERVEN, AND R. T. SCHUMACHER‡
Department of Physics, Carnegie Institute of Technology, Pittsburgh, Pennsylvania
(Received 6 January 1964)

We have measured the temperature dependence of the spin-lattice relaxation time T_1 in sodium metal from 14 to 77°K. Our results agree with those of Feher and Kip, and Levy, in the range 20 to 40°K, but disagree with Feher and Kip above 40°K. As a consequence, we find marked deviation from the relation T_1T=constant even at the highest temperatures of our measurements. The temperature dependence we observe lends strong support to the recent calculation of Yafet in the temperature range 35 to 77°K.

I. INTRODUCTION

THE question of the temperature dependence of the conduction-electron relaxation time in metals has recently been re-examined by Yafet.[1] He finds that in the very low-temperature limit, $T \ll \theta_D$, where θ_D is an appropriate Debye temperature for the lattice, the spin-lattice relaxation time T_1 should vary as T^{-5}, contrary to the previous expectations that T_1T=constant over the entire high- and low-temperature range. The only metal in which a temperature-dependent T_1 has been observed over an appreciable range of temperatures is sodium. In that metal Feher and Kip[2] measured T_1 from 300 to 4°K and concluded that their data supported the relation $T_1T \cong 3.0\times10^{-6}$ sec-°K over the entire range of their measurements. In fact, their published data do not support this conclusion below 55°K, nor do the data of Levy.[3] All these investigators show longer T_1's in the range 20 to 40°K than predicted by $T_1T \cong 3.0\times10^{-6}$ sec-°K. Narrower lines than expected at 20°K were also observed in this laboratory during a recent remeasurement of the sodium conduction-electron susceptibility.[4]

We report here a remeasurement of $T_1(T)$ which supports the conclusion of Yafet[1] that $T_1(T)$ deviates from the $1/T$ dependence as T becomes less than an appropriate Debye temperature for the sodium lattice. We describe those aspects of the apparatus relevant to this particular measurement, some precautions taken in sample preparation and experimental measuring technique, and we compare our results to the conclusions of Yafet.

II. EXPERIMENTAL DETAILS

A. Microwave Apparatus

The measurements were made entirely at X band with a single klystron superheterodyne spectrometer described previously.[5] The microwave cavity was cylindrical, and was operated in the TE_{011} mode, which requires that the sample be inserted into the geometric center of the cavity. In this configuration the microwave field H_1 is vertical in the laboratory and the dc field, H_0, is in the horizontal plane. The cavity was matched by a variable coupler of the type described by Gordon.[6]

The samples, which will be described in detail below, were contained in the innermost of a series of concentric Pyrex tubes. The sample tube was 3 mm o.d., a few centimeters long and was completely sealed. The next tube, 5 mm o.d., was approximately one meter long. It was inserted into a tube 8 mm o.d., which is permanently attached to the microwave system. The 8 mm o.d. tube extends halfway into the cavity, is coaxial with it and sealed at the lower end, and in the other direction extends to the top of the Dewar system, where it forms part of an "air-lock" system similar to one described by Estle[7] Samples were changed while cryogenic liquid was still in the Dewar system by removing the 5 mm o.d. tube.

B. Cryogenic Apparatus and Temperature Measurements

The relative bulkiness of the cylindrical cavity necessitated the use of a Dewar system whose outer diameter (that of the nitrogen Dewar) is 5 in. The inner diameter of the inner Dewar is greater than $2\frac{1}{2}$ in. The cryogenic liquid used in our measurements was in all cases liquid hydrogen. However, the hydrogen is entirely excluded from the interior of the microwave cavity and the inside of the waveguide. The outermost pyrex tube is also not in direct contact with the hydrogen, but is separated from it by a cupronickel alloy sleeve which fits snugly around the Pyrex and is soldered to the top of the cavity. The sample is thus removed from direct contact with the bath by a metal sleeve and three Pyrex tubes, all of which nest together rather snugly. All the tubes except the sample tube were filled with a fraction of an atmosphere of He gas to improve the thermal contact between the sample and the bath.

Temperature measurements were made with a nominally 390-Ω carbon resistance thermometer. This thermometer was calibrated from 4.2 to 77°K by a platinum resistance thermometer which had been calibrated by the National Bureau of Standards. The carbon thermometer became rather insensitive above 50°K, but was still adequate for our measurements. The thermometer could not be placed in direct contact with the sample, which was in any event sealed in the 3-mm-o.d. tube. The top of the sample tube projected just above the top of the cavity, and the carbon thermometer was pressed into direct physical contact with the tube at that point. We relied on the physical contact plus the helium exchange gas to keep the thermometer at the same temperature as the sample. In the region from 14 to 20°K there was always adequate agreement between the temperature of the bath as deduced by vapor pressure measurements and the temperature indicated by the thermometer. Since the thermometer was not in any poorer contact with the bath than was the sample, we have no reason to believe that the sample temperature differed in any significant way from that registered by the thermometer.

Above the boiling point of liquid hydrogen data were taken by allowing the system to warm gradually after the liquid hydrogen level dropped below the bottom of the microwave cavity. During this time the field was swept back and forth through the resonance while the derivative of the resonance line was continuously recorded as was the temperature of the carbon resistance thermometer. This procedure gave data at about every 2°K, except for a few intervals during which the microwave system was being retuned. The warmup procedure from 20 to 70°K took about 60 min. Our best estimate of the type of error introduced by this procedure is that the sample was warming faster than the thermometer, and that the error became worse as the temperature became higher. Errors in temperature measurement are probably responsible for the increased scatter in the data above 50°K.

C. Sample Preparation

Our sodium samples were prepared by the technique introduced by Levy.[3] Briefly, the technique is to prepare dilute sodium-ammonia solutions, and then freeze them. Metallic sodium precipitates out upon freezing in the form of dispersed small particles. We used sodium, kindly given to us by Dr. Raymond Bowers of Cornell University, which had a resistivity ratio of more than 7000. We found it advisable to dissolve this sodium in ammonia which had first been cleaned by dissolving some normal purity sodium in it. This procedure removes any impurities in the ammonia which might react with sodium. The samples were confined to a length in the 3-mm-o.d. tube of about 2 mm in order to confine the sample to the smallest feasible volume to minimize effects of magnetic field inhomogeneity. After the required amount of ammonia had been introduced, the sample was frozen in liquid nitrogen and sealed off under vacuum a few centimeters above the sample. The 3-mm-o.d. tube was inserted in a long 5-mm-o.d. tube and stored under liquid nitrogen.

D. Some Experimental Precautions

The relaxation times which we measured were in the range from 5×10^{-8} to 5×10^{-7} sec. Such relaxation times are awkward to measure directly, so we took advantage of the equality of the transverse and longitudinal relaxation times[8] and measured the linewidth. Such a procedure is line shape-dependent, so it will be given extended attention below. Here we want to point out that at low temperatures, even for relatively short relaxation times, a serious danger to accurate measurement lies in partial saturation of the resonance line. The danger arises not from ordinary saturation broadening, but from the Overhauser effect.[8,9] We have observed at temperatures as high as 20°K effects predicted by Kaplan[10] and observed by Gueron and Ryter.[11] If the external field is swept slowly from above resonance while the rf field is strong enough to saturate the resonance even partially, the sodium nuclei will become partially polarized through the Overhauser effect. They will in turn contribute to the total field seen by the electrons an amount H^* which depends on the microwave power and the size of the sodium particles. Thus, the electrons still satisfy the resonance condition with the applied field an amount H^* below the resonance field, and absorption is still observed.

If large, the effect is readily identifiable, and it is simply required, in order to observe the natural linewidth, that the microwave power be sufficiently small. Our klystron operated at approximately 50 mW. We were able to observe Overhauser polarization at 20°K and below in this manner with powers incident on the cavity which were 20 dB down from the klystron power. Our linewidth measurements were made with powers 40 dB down from 50 mW, and we required power-independent linewidths over a 10-dB range of powers before the data was considered acceptable. Such low power levels required the full sensitivity of the superheterodyne system. This system[5] stabilizes the klystron to the sample cavity, so the single klystron superheterodyne system cannot be instantaneously retuned as the cavity and sample warm continuously above 20°K towards 77°K. Fortunately the relaxation time is short enough above 30°K to eliminate the saturation problem, and a simpler homodyne detection at higher power could be used. In this system the signal at the modulation frequency is taken directly from the

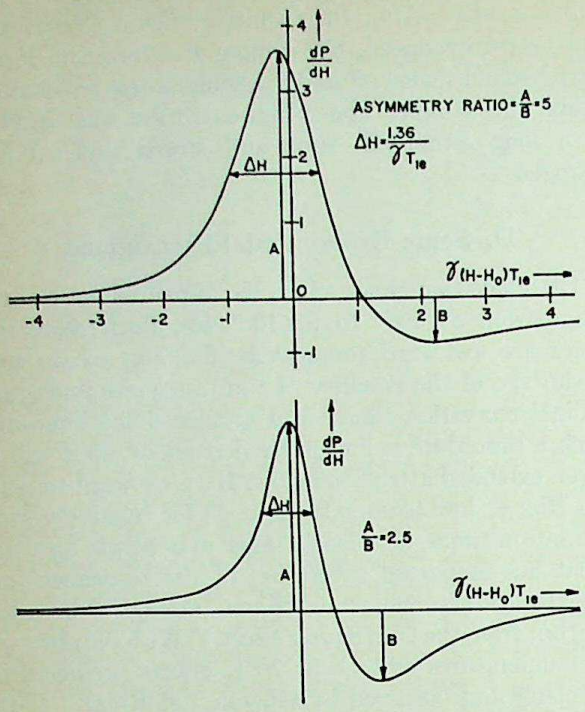

FIG. 1. (a) Derivative of ideal Dyson absorption line in the region of the anomalous skin effect. (b) Typical absorption derivative observed in our samples. Horizontal scale is not the same as in (a).

microwave crystal detector. Biasing power is provided by a small amount of microwave power reflected from the cavity, which is deliberately mismatched. The klystron is still locked to the microwave cavity, and retuning the system as the cavity frequency drifts takes only a few seconds.

We might remark parenthetically that we have made intensive measurements of the Overhauser shift in the hydrogen range, where the shift H^* becomes as large as 5 G. The sodium heat capacity in this region is large enough to prevent the metal particle temperature from rising above the bath temperature because of the microwave power absorbed by the spin system. Difficulties of this type have plagued Overhauser shift measurements on sodium in the helium region for years.[12] Unfortunately, direct measurements of the shift sufficiently precise to be of interest in themselves proved impossible, and our data was only good enough to be in qualitative agreement with the magnitude of H^* as expected from spin susceptibility[4] and Knight shift[13] measurements.

III. RESULTS AND DISCUSSION

In most of the temperature region over which our measurements were made, the conductivity of the sample is in the anomalous region; i.e., the electronic mean free path Λ is larger than the classical skin depth δ. In addition most of the sodium particles were large compared to Λ. The resonance absorption line shape for this case has been calculated by Kittel[2] based on the calculation by Dyson.[14] The derivative of the power absorbed versus $\gamma(H-H_0)T_1$ in Kittel's theory is plotted in Fig. 1. The line shape is characterized by extreme asymmetry, the ratio of the low-field peak to the high-field peak being given by $A/B=5$. The full width at half-maximum of the low-field peak is given by

$$\Delta H = 1.36/\gamma_e T_1, \tag{1}$$

where γ_e is the electron gyromagnetic ratio.

The line shape given by our samples is shown in the lower half of Fig. 1. The asymmetry is markedly less than 5:1, and was in fact always about 2.5:1. We believe our lines did not have the Dyson-Kittel shape because our samples in fact contained a mixture of particle sizes, with a substantial contribution to the signal coming from particles whose dimensions are comparable to or smaller than Λ. For these particles the line shape would be Lorentz, with $A:B=1$. This rationalization of our line shape is supported by the large amount of data taken on the Overhauser shift in the hydrogen temperature region, where we observed in detail the diminution of the intensity of the shifted line as the shift increased. This effect and its relation to particle size is discussed by Ryter.[12]

For a symmetrical Lorentz line, the relation between T_1 and ΔH is given by

$$\Delta H = 1.22/\gamma_e T_1. \tag{2}$$

For simplicity we have used Eq. (1) in converting from ΔH to T_1. A comparison of the observed and theoretical line shapes, along with the relations (1) and (2), leads us to believe that use of (1) does not result in T_1's more than 5% high. Since the temperature dependence of T_1 rather than its absolute value is our main interest, the uncertainty is of no importance.

The results of our measurements on all samples that showed a temperature-dependent ΔH to 14°K are

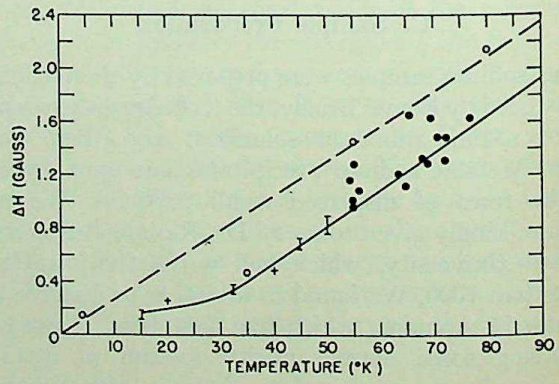

FIG. 2. ΔH versus T. ○, from Kip and Feher (Ref. 2); +, from Levy; ●, our data. Solid line and error flags explained in text. Dashed line is from the relation $T_1T=3\times10^{-6}$ sec −°K, converted to ΔH by Eq. (1) of text.

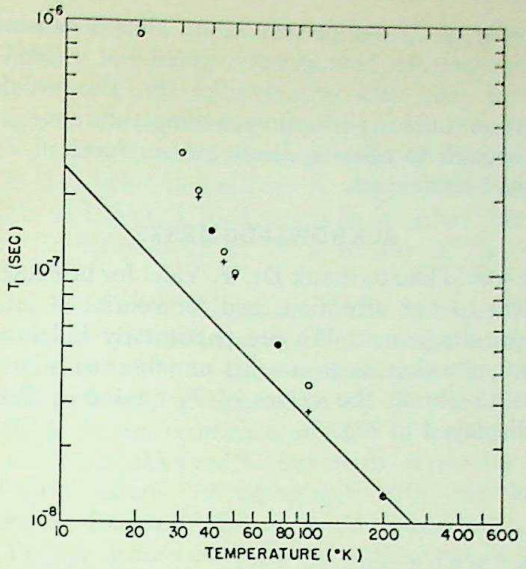

FIG. 3. The theoretical and experimental T_1's of Table I on a log-log plot. ○, Yafet; +, ●, experiment as in Fig. 2. The solid line is T_1T=constant drawn through theory and experiment at 200°K. The constant, 2.6×10^{-6} sec −°K, is not the same as in Fig. 2.

shown in Fig. 2, along with the data of Feher and Kip[2] and of Levy.[3] Approximately 25 data points below 20°K and 25 points between 30 and 50°K are represented by the smooth curve drawn through them and error flags giving the limits within which the data fall at several temperatures. The somewhat more scattered data above 50°K (twenty points) are shown as heavy dots. The straight line above 30°K is a least-squares fit to the data between 35 and 50°K; the equation of this line is

$$\Delta H=0.0277T-(0.577\pm0.010). \quad (3)$$

The data above 50°K is omitted from this fit not because of its scatter but because of line shape changes associated with the change between classical and anomalous skin effect regions.

The data, converted to T_1, is replotted in log-log form, in Fig. 3. The solid line is one drawn by Feher and Kip,[2] the dots, crosses, and circles are experiment and theory as explained below. We note several features of the results from Fig. 3. (1) Our data extrapolates at high temperatures towards the $T_1T=3.0\times10^{-6}$ sec-°K relation found by Feher and Kip. (2) If the theory of Yafet is fit to our data at 40°K it deviates significantly from T_1T=constant as high as 150°K. (3) Our data fit Yafet's theory from 77°K, our highest temperature, to 30°K, where our T_1's begin to fall well below the theory; and Yafet's theory, fit to our data at 40°K, agrees with Kip and Feher's data at high temperatures.

Feature (3) deserves discussion. The spin-lattice relaxation mechanism discussed by Yafet is an electron-phonon scattering accompanied by a spin flip. The mechanism which couples the two spin states is the spin-orbit interaction. Yafet's theory[1] has three parameters. The Debye phonon spectrum is assumed, but two Debye θ's are used, θ_N and θ_U. θ_N is the Debye temperature for longitudinal phonons; the N stands for "normal," since electron–longitudinal-phonon scattering is the normal resistivity scattering mechanism. umklapp processes are important because there is a term in the spin-flip matrix element involving only transverse phonons which vanishes for small electron scattering angle, but which contributes if the electron wave vector changes by the phonon wave vector plus a reciprocal lattice vector. Use of a different Debye θ for processes to which transverse phonons contribute corresponds to a modification of the strict Debye model which is realistic if θ_U is chosen less than θ_N. At least one transverse mode corresponding to a low θ has been observed in neutron diffraction by Woods *et al.*[15]

Dr. Yafet was kind enough to furnish us the details of his calculation, the results of which for $\theta_N=250$°K, $\theta_U=200$°K, are shown in Fig. 9 of his paper.[1] We were able to use his work to calculate the points shown in Fig. 3. The third adjustable parameter, the strength of the spin-flip matrix element, was chosen to fit the data at 40°K, and several values of θ_N and θ_U were tried. The results are quite sensitive to θ_U, with values of the pair (θ_N, θ_U) of (250°K, 80°K) and (250°K, 200°K), respectively, lying distinctly below and above the data. The points shown on Fig. 3 correspond to $\theta_N=250$°K and $\theta_U=150$°K. For $\theta_U=150$°K, longitudinal phonons contribute only from 7% to 15% to the total relaxation rate. It is worth pointing out that the Debye θ deduced from heat-capacity measurements is (156±2)°K.[16] Table I presents the calculated and measured T_1's at several temperatures.

Finally, we note that below 30°K the experimental T_1's deviate from theory; the data give $(T_1)_{\text{meas}} \cong \frac{3}{5}(T_1)_{\text{Yafet}}$ at 25°K, and the theoretical T_1 is beginning to rise very sharply just as the data are beginning to approach a temperature-independent value. Our line-

width in fact becomes temperature-independent at $\Delta H = 0.1$ G. A simple linewidth measurement of the proton resonance in a water sample of the same dimensions as the sodium sample showed the field inhomogeniety over the sample to be about 0.1 G. The field was so inhomogeneous over the small sample because the ratio of the magnet gap to the pole cap diameter was 5:12; the large gap was required in order to fit in the rather bulky microwave cavity and the glass Dewars. Thus our data may not be compared to Yafet's calculations below about 35°K, where the measured linewidths is 0.4 G. We can say in defense of our poor homogeneity that even if Yafet's calculations are correct only down to 20°K the linewidth would be on the order of $\frac{1}{10}$ our present limit. Thus a substantial improvement in homogeneity would not extend our range of valid data very significantly. The calculated relaxation times in the hydrogen temperature region are long enough to allow a direct measurement of T_1 by transient techniques.

ACKNOWLEDGMENTS

We would like to thank Dr. Y. Yafet for bringing this problem to our attention, and for continued interest and encouragement. We are particularly indebted to him for allowing us to use his unpublished numerical results to obtain the values of T_1 quoted in Table I and displayed in Fig. 3.

PHYSICAL REVIEW VOLUME 134, NUMBER 5A 1 JUNE 1964

Absence of Pronounced Quadrupole Effects in the Nuclear Resonance of In^{115} in a Noncubic Environment*

LAWRENCE H. BENNETT AND REX J. SNODGRASS†
Metallurgy Division, National Bureau of Standards, Washington, D. C.
and
Department of Physics and Astronomy, University of Maryland, College Park, Maryland

(Received 23 December 1963)

The nuclear magnetic resonance of In^{115} has been observed throughout the cubic phase of Pb-In alloys, at 77 and 300°K. The Knight shift is 0.86% and is essentially unchanged with composition. The linewidths increase rapidly with In concentration, probably mostly due to pseudodipolar interaction. The average electric field gradient at a In^{115} nucleus for any configuration of Pb neighbors is about $q \sim 3 \times 10^{22}$ cm^{-3}, about 20 times smaller than for Cu having a Zn second neighbor in the fcc Cu lattice. The small value of the field gradient is discussed in terms of the behavior of the charge oscillations, and is related to the small change in Knight shift for Pb^{207} in these same alloys.

I. INTRODUCTION

THE nuclear electric-quadrupole moment interacts with the electric field gradient at the site of the nucleus. In a position of cubic symmetry, the electric field gradient vanishes and there is no quadrupole interaction. In the liquid phase of a metal, atomic motion is usually sufficiently rapid to average out the field gradients. Knight[1] pointed out that, in some cases, strong quadrupole interactions may obliterate the nuclear magnetic resonance (NMR) signal of a quadrupolar nucleus in the noncubic lattice of the pure metal, but that the nucleus may still exhibit a strong NMR signal when substituted in the cubic environment of another metal. For example, in pure orthorhombic Ga, the nuclear magnetic resonance has been observed in the liquid phase only. However, when Ga is substituted in the face-centered cubic lattice of Cu, the cubic environment substantially reduces the quadrupole coupling for many of the Ga atoms and the nuclear magnetic resonance is observable. Knight suggested that it might be possible to make suitable alloys of other metals for which the resonances are unobservable in the pure state.

Following this suggestion, one of the present authors[2] observed a strong NMR signal of In^{115} substituted in the cubic lattice of a 95% Pb−5% In alloy. If the indium is randomly distributed throughout the lattice, about one-half of the indium atoms have only lead for first, second, and third nearest neighbors. The intensity of the In^{115} resonance compared to the Pb^{207} in this alloy led to the conclusion that *these* atoms were observed, together with some of the satellite intensity. An alternative possibility is that all In^{115} nuclei participate in the resonance but that some of the satellite intensity is smeared out.

In order to distinguish between these possibilities the

In^{115} resonance was looked for in other alloying proportions. Very surprisingly, the In^{115} resonance remained observable with almost no change in intensity per atom throughout the cubic lead phase.[3] Figure 1, for example, shows the observed room-temperature Pb^{207} and In^{115} NMR absorption derivatives in alloys containing 0.5 at.% In and 35 at.% In. There is no essential difference in the In^{115} resonance at 77°K in any of the alloys studied.

Since the start of this research, the pure quadrupole resonance of In^{115} in tetragonal indium metal has been discovered[4,5] with a room-temperature quadrupole coupling constant of approximately 30 Mc/sec. The high-field nuclear resonance of In^{115} in indium metal has also been observed,[6,7] but with extremely large quadrupole effects in agreement with the known quadrupole coupling constant in the tetragonal lattice. The In^{115} resonance has also been observed in liquid indium,[8] but here the rapid motion washes out quadrupole interactions. Nuclear magnetic resonance studies[9] of In^{115} in an unstrained single crystal of InSb revealed negligible quadrupole interactions, due to the high symmetry of the zinc blende lattice of InSb. Thus, none of these other results is directly comparable with our surprising observation of the absence of pronounced quadrupole effects in the noncubic environment of the nondilute Pb-In alloy.

In Sec. II we present the experimental data on the In^{115} NMR absorption derivatives linewidths, centers and relative intensities as a function of concentration of In in Pb, magnetic field, and temperature. In Sec. III, we discuss the significance of the observation of the In^{115} resonance in the "noncubic" environment of the high indium concentration alloys in lead. We relate this absence of pronounced quadrupole effects to the small changes in Knight shift in the Pb^{207} resonance in these same samples discussed in a preceding paper.[10]

II. EXPERIMENTAL METHODS AND RESULTS

Indium, a column III element, is dissolved in lead, a column IV element. Lead is a face-centered-cubic metal with melting point of 327°C. All measurements were made in the cubic phase which persists up to about 68 at.% In. In^{115} is 96% abundant, has a nuclear spin $I=9/2$, a large nuclear magnetic dipole moment (5.5 n.m.), and a large electric quadrupole moment (1.16 b).

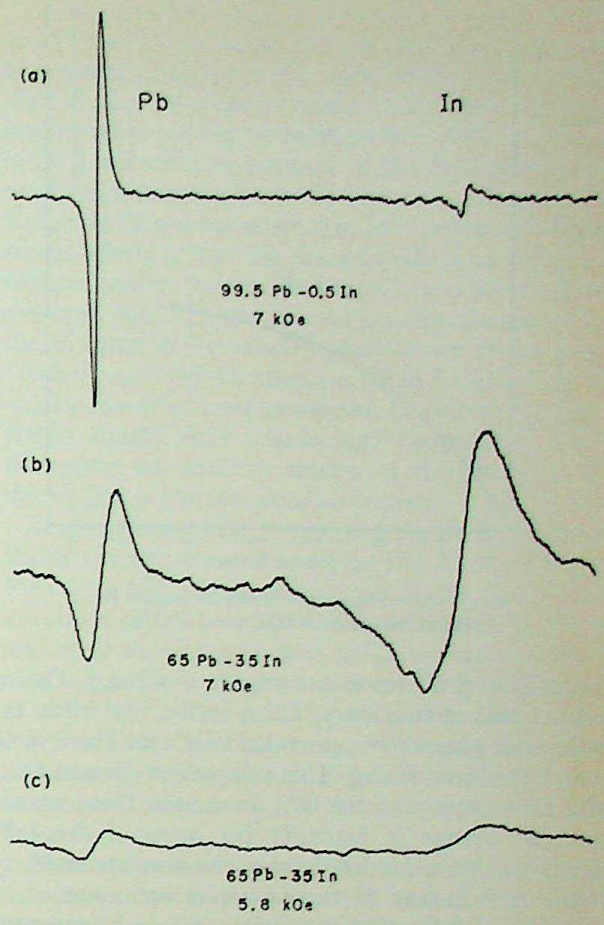

FIG. 1. First derivative of the room-temperature nuclear magnetic resonance absorptions of Pb^{207} and In^{115} in (a) 99.5% Pb−0.5% In at 7.0 kOe, (b) 65% Pb−35% In at 7.0 kOe and (c) 65% Pb−35% In at 5.8 kOe.

All of the resonances were observed at both 77° and 300°K with a Varian wide-line spectrometer. The experimental techniques and the preparation of the alloys have been discussed previously.[10,11] Typical resonances are shown in Fig. 1. Since the Pb^{207} and In^{115} resonance differ in shape and width, it is somewhat misleading to compare the recorded absorption derivatives in order to determine relative intensity. Instead, a point by point integration was made of each resonance, and the relative areas of the resulting absorption curves were compared. The assumption was made that the absorption is zero in the wings when the derivative is zero. This assumption has the effect of ignoring flat wings, and thus underestimating the contribution of In^{115} satellites.

If we make the reasonable assumption that we are observing all of the Pb^{207} nuclei, then a comparison of the relative intensities of the Pb^{207} and In^{115} resonances *in the same sample* gives an indication of the portion of

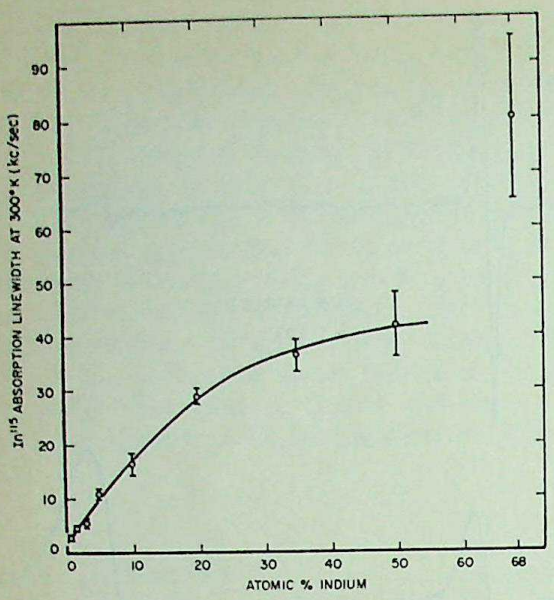

FIG. 2. In^{115} absorption linewidth versus In concentration at 300°K and 7.0 kOe.

the possible In^{115} resonance we are observing. This is independent of frequency, filling factor, and other experimental parameters, provided only that there is no modulation broadening. This comparison showed that, with the exception of the 68% In sample, there was almost no change in intensity per atom of the In^{115} throughout the cubic lead phase. The absolute intensity of the In^{115} in any of these samples corresponded to about 10 to 20% of that possible, in good agreement with the intensity expected from the central transition alone. We conclude that we are observing only the central line of essentially all In^{115} nuclei in the alloys, at both 77 and 300°K.

There is virtually no second-order quadrupole shift at 7.0 kOe or above. For the 35% In sample, Fig. 1[(b) and (c)] shows the room-temperature resonance absorption derivatives of In^{115} and Pb^{207} at 7.5 and at 5.8 kOe. The In^{115} resonance at the lower field shows some sign of second-order broadening. Any shift in center between these two In^{115} resonances (normalized to 5.8 kOe) is less than 1 kc/sec.

The presence of substantial ordering or clustering would of course change the main result of this paper, that we are observing only small quadrupole effects in a *noncubic* environment. An x-ray study[12] of the 20% In and the 35% In sample used in this research revealed no short-range order. The short-range order parameter in the ith shell around an A atom is defined as $\alpha_i=1-P_{AB_i}/X_B$, where P_{AB_i} is the probability of a B atom in the ith shell around an A atom, and X_B is the mole fraction of B. If α_1 was ≈-0.05 or greater in magnitude, it would have been detected. Clustering ($\alpha_1>0$) was not checked. A short-range order parameter equal to 0.14 was suggested recently.[13] Even if the short-range order were this high, fewer than 1% of the In would be in cubic environments in the 50-50 alloy.

The In^{115} linewidth as a function of In concentration is shown in Fig. 2. The increase in the In^{115} linewidth with In concentration can be understood if the pseudodipolar interaction is assumed to be about 10 times the ordinary dipolar. The pseudodipolar interaction was found to be about 10 times the dipolar for the Pb^{207} linewidth[10] in these same samples. No careful studies of the field dependence of the linewidth was made—it is believed that a combination of second-order quadrupolar broadening at the lower fields, and anisotropic and inhomogeneous isotropic Knight shift broadening[10] at the higher fields could be important. The 68% In point does not fall on the smooth curve in Fig. 2. From the Pb^{207} Knight shifts, we had previously[10] concluded that this alloy was in a two-phase region.

The resonance center is largely independent of concentration, occurring at 6.586±0.001 Mc/sec at 7000 Oe. This corresponds to a Knight shift of 0.86±0.01%, which is close to the value found in the tetragonal phase of pure In[7] (0.82±0.04% for the isotropic shift), or in the liquid phase of In metal[8] (0.79±0.03%, the ± taking into account the variation with temperature, and chemical shifts). There is no *a priori* reason for expecting this close agreement.

III. DISCUSSION

The most important result of this work is the observation of the In^{115} resonance in the "noncubic" environment of nondilute Pb–In alloys. This result was unexpected in view of the large quadrupole moment of In^{115} and the observations of Rowland and Bloembergen[14] on the Cu–Zn system. In that case Cu was the solvent, Zn the solute. In pure Cu, the Cu^{63} resonance is reduced by cold working to 0.4 times the intensity in the well-annealed metal. An average electric field gradient of $q=1.6\times10^{22}$ cm^{-3} produced by cold working accounts for this observation. As Zn is added to Cu, the Cu^{63} intensity is further reduced until the resonance is unobservable for Zn concentrations of more than about 20%. Rowland concluded that no Cu^{63} nuclei were observed when Zn destroyed the cubic symmetry in the first or second coordination shell. Rowland estimated that a gradient $q>1.6\times10^{23}$ cm^{-3} is needed to account for the loss of Cu^{63} nuclear contributions to the NMR line for Zn nearest and second-nearest neighbors. In a recent direct measurement, Redfield[15] showed that the quadrupole frequency for second neighbors was 1980 kc/sec (corresponding to $q=7\times10^{23}$ cm^{-3}), and for first was probably greater than 5 Mc/sec, consistent with Rowland's estimate.

In order to contrast the Pb-In results with the Cu-Zn work, it may be meaningful to think of In as the solvent,

TABLE I. Average electric field gradients at nuclei in metals.

	Cold worked Cu	Cu Having Zn 2*d* neighbors	In in In-Pb	Al in Al-Mg or Al-Zn alloys
$q(cm^{-3})$	1.6×10^{22}	70×10^{22}	3×10^{22}	17×10^{22}

Pb as the solute. We do not observe the In in the dilute region (high In concentration) due to the tetragonal structure. But, consider a hypothetical cold-worked cubic In metal in analogy to the cold-worked cubic Cu metal. As the solute (Pb) is added, the In^{115} intensity per atom would be expected to decrease. Thus, for example, we would expect the In^{115} resonance in the 50% In–50% Pb alloy to be unobservable (unless there is substantial clustering or ordering, which does not seem to be the case). In fact, the resonance intensity in the 50% In–50% Pb alloy is very large, corresponding to the observation of the central transition of *all* the In^{115} nuclei. Using a method described by Rowland,[16] and assuming we have no more second-order effects than discussed in Sec. II of this paper, we obtain $q<4.6\times10^{22}$ cm^{-3} for the average electric field gradient at a In^{115} nucleus for any configuration of Pb neighbors. From the fact that the satellites do not contribute to the observed lines, we find $q>1.4\times10^{22}$ cm^{-3}. Thus we can take $q\approx3\times10^{22}$ cm^{-3} as the average gradient at the In nuclei, which is comparable to the field gradient in pure cold-worked Cu, and is 20 times smaller than that found for Cu having Zn second-nearest neighbors, as is shown in Table I.

Kohn and Vosko[17] have explained the magnitude of the field gradients at the Cu site due to various solute atoms[14] on the basis of a redistribution of the conduction electron charge density near the solute.[18] The reduction in Cu NMR absorption intensity with increasing solute concentration was taken as confirmation of a long-range oscillatory behavior of the electron density. This same type of oscillatory behavior was shown to be responsible for the change in Knight shifts in silver,[19,20] cadmium,[20] and the alkali metals.[21]

In the case of Pb-In, it has already been pointed out[10] that the changes in Knight shift of the Pb^{207} upon the addition of In are small. No definite conclusion could be reached as to the importance of the charge oscillations in the lead-indium system. In any case size effects are probably too big to be neglected. We have not yet made a quantitative estimate of the field gradients. A possible explanation for both the small change in Pb^{207} Knight shift and the absence of In^{115} pronounced quadrupole effects is that the charge oscillations are greatly damped or that they oscillate rapidly and are effectively averaged out. It might then be appropriate to say that the In atoms in the cubic Pb phase screen themselves to "look almost like" Pb atoms, as far as Knight shifts and quadrupole effects are concerned. Of course, the anisotropic Knight shift broadening[10] depends on the In disrupting the cubic symmetry of the lattice so this description is not completely adequate.

It is also interesting to compare the Pb-In work with Webb's measurements[22] on Al-Zn and Al-Mg. For both Pb^{207} and Al^{27} only small changes in the Knight shift are observed. The average electric field gradient q at the site of an aluminum nucleus which is nearest neighbor of a solute (Zn or Mg) atom is found by Webb to be 17×10^{22} cm^{-3}. This is an intermediate value between In-Pb and Cu-Zn. It appears as if the effective valence difference between adjacent metals having higher group (or atomic) valences is less than for those with lower valences.

The angular correlation of the γ-γ cascade of In^{111} in thin layers has been measured[23] as a function of In concentration. This experiment shows a relatively large increase in anisotropy in going from almost pure lead to Pb-1.5% In. Kaiser attributes this increase to the electric field gradients at an indium atom due to its nearness to other indium atoms. He then compares his result to Bloembergen and Rowland's observation of the rapid loss in Cu NMR intensity upon addition of Zn. Our results show that the In-Pb result should not be compared to the Cu-Zn work. However, it is possible that an increased quadrupole interaction, reflected in the anisotropy, is associated with a first-order splitting of the satellites.

Nuclear Magnetic Resonance in Lead Alloys*

Rex J. Snodgrass† and Lawrence H. Bennett
Metallurgy Division, National Bureau of Standards and Department of Physics and Astronomy, University of Maryland, College Park, Maryland

(Received 31 January 1964)

The Pb^{207} nuclear magnetic resonance has been measured in a series of lead base primary solid solutions containing Cd, In, Sn, Sb, Hg, Tl, and Bi as solutes. The central resonance frequency of Pb^{207} shifts in proportion to the solute concentration and in the opposite direction to be explained by impurity charge screening of the Thomas-Fermi type. The fractional change in Knight shift for all solutes is small $\Delta k/k \approx 0.05\ c$. The important parameter in determining the change in Knight shift seems to be the difference in valence between the impurity atoms and the lead atoms. The absorption linewidths broaden rapidly upon the addition of solute. In the absence of a quantitative calculation it is not possible to determine if the small shifts, large widths, and small quadrupole effects of In^{115} are consistent with the theory of long-range oscillations of electronic charge. However, there is evidence that this theory may be capable of explaining our data.

THE nuclear magnetic resonance (NMR) of Pb^{207} has been accurately measured in a series of lead base primary solid solutions containing second (Cd, In, Sn, Sb) and third (Hg, Tl, Bi) long period solutes. This is the first report of comprehensive Knight shift measurements on a polyvalent nontransition metal matrix. It is especially interesting to see if the theory[1] developed by Friedel, Blandin, and Daniel concerning the long-range oscillation of electronic charge density around impurity atoms in monovalent and divalent metals is capable of explaining our data for a polyvalent material. The major conclusion is that, in qualitative agreement with the Friedel theory, the valence of the solute is the controlling factor in the change of Knight shift with solute concentration.

Figure 1 shows the change in Pb^{207} resonance frequency from pure lead metal at 7 kOe and 300°K as a function of solute concentration.[2] The central resonance frequency of Pb^{207} shifts in proportion to the solute concentration (c). The shifts are in the opposite direction to be explained by impurity charge screening of the Thomas–Fermi type. The fractional change in Knight shift for all solutes is small $\Delta k/k \approx 0.05\ c$. The experimental points were omitted for clarity. The experimental error is of the order of the separation of the In and Tl lines in Fig. 1.

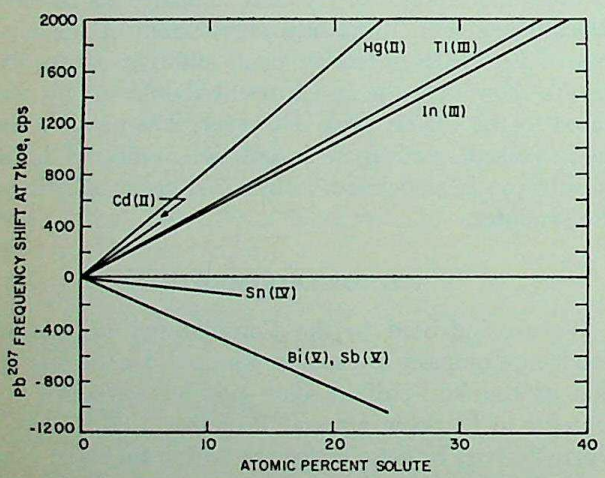

FIG. 1. Change in Pb^{207} Knight shift versus solute concentration at 300°K.

The lead solid solution lattice spacings[3] for the same solutes are shown in Fig. 2. A comparison of Figs. 1 and 2 shows that the frequency shifts partially correlate with lattice parameter changes. However, Bi and Sb give identical changes in Knight shift while the former expands and latter contracts the Pb lattice. Tl and In are more widely separated in lattice spacings than in resonance frequencies. Sn causes a larger change in lattice parameter than Tl, but a much smaller change in Knight shift (and in the opposite direction) to Tl. The correlation of the Knight shift results with Pauling or Goldschmidt radii is not good at all. From this we conclude that "size effects" are not the controlling factor in determining the Knight shift in these alloys. It is not surprising that there is partial correlation with lattice parameter data since the lattice spacing reflects not only size effects, i.e., misfit between solvent and solute, but also valence effects. The important parameter seems to be the difference in valence between the impurity atoms and the lead atoms. However, superposed on this may be a slight period dependence associated with impurities of equal valence which belong to different periods of the periodic table.[4] A pure valence effect would perhaps predict zero shift for tin. The observed shift is indeed small. Similarly, the small deviation of Cd and In from Hg and Tl, respectively, may be a period effect. However, Sb does not deviate from Bi.

The absorption linewidths are shown in Fig. 3. They broaden rapidly upon the addition of solute. It was shown previously[2] that the Pb^{207} resonance depends linearly upon the applied magnetic field for the Pb-In alloys. Since the line shapes are predominantly Lorentzian, especially for the dilute alloys, it is difficult to estimate second moments for comparison with theory. The anomalously large breadth due to Bi may be associated with its large magnetic moment, high-spin and high-isotopic abundance, together with a large exchange or pseudoexchange coupling constants. It is also possible that T_1 effects enter.

In conclusion, it seems somewhat surprising that the change in Pb Knight shift is so small, while the increase in widths is large. We believe the small change in Knight shift and the absence of pronounced quadrupole effects[5] at the quadrupolar In^{115} nucleus in Pb-In alloys are related. In the absence of a quantitative calculation it is not possible to determine if the small shifts, large widths, and small quadrupole effects of In^{115} are consistent with the theory of long-range oscillations of electronic charge. However, there is evidence that this theory may be capable of explaining our data. (1) The shifts correlate with valence. (2) The sign of the shifts is in the opposite direction to be explained by Thomas-Fermi screening. (3) The absorption linewidths are field-dependent. This might also be due to anisotropic Knight-shift broadening, but we have not excluded inhomogeneous isotropic Knight-shift broadening.

Magnetic Properties of Nearly Free Electrons.* Nonoscillatory Magnetic Susceptibility

M. L. GLASSER
Battelle Memorial Institute, Columbus, Ohio
(Received 30 December 1963)

The partition function is derived for a gas of electrons in the presence of a weak periodic potential and uniform magnetic field. From it the steady terms in the free energy and the zero-field–zero-temperature total electronic magnetic susceptibility are calculated. The results are applied to the alkali metals. The nonadditivity of the paramagnetic and diamagnetic susceptibilities and the inadequacy of the effective mass approximation are discussed.

I. INTRODUCTION

THE purpose of this note is to derive expressions for the nonoscillatory free energy and magnetic susceptibility of a degenerate, nearly free electron gas. That is, we consider a gas of noninteracting electrons in the presence of a weak potential, due to a lattice of positive charges, and a uniform magnetic field. The free energy of the system is evaluated to second order in the temperature and field parameters with both paramagnetic and diamagnetic terms in the Hamiltonian taken into account; however, only nonoscillatory behavior is considered. The effect of the lattice on the de Haas–van Alphen oscillations will be the subject of a future report.

The calculation was made with two ends in view. First, considering the success of the pseudopotential concept,[1–3] it appears that the nearly free electron approximation has computational value as well as being merely instructive. Second, we wish to go beyond the limitations of the effective mass approximation for describing lattice effects in the context of magnetic properties. A calculation is performed in Sec. III using available pseudopotential parameters for the alkali metals Li, Na, and K. There exists no completely satisfactory calculation of the role of correlation in metallic properties for the density range into which these metals fall and, since this topic is outside the scope of the present study, we shall only point out that corrections can be estimated by interpolation methods.[4] Quantitative accord with experiment thus can not be expected, but it is proposed that for metals with small energy gaps the effect of the lattice is qualitatively accounted for. The criterion suggested is that the ratio of the energy gaps to the Fermi level be much less than unity.

II. CALCULATION

We consider N noninteracting electrons moving in a weak periodic potential $V(r)$, which occupies a very large volume Ω, in the presence of a magnetic field represented by the vector potential $\mathbf{A}=(-H_0y,0,0)$. An electron will therefore be described by the Hamiltonian

$$\mathcal{H}=(1/2m)(\mathbf{P}-(e/c)\mathbf{A})^2+2\mu_0H_0S_z+V(\mathbf{r})\equiv\mathcal{H}_0+V(\mathbf{r}). \quad (1)$$

As is well known,[5] the eigenstates of $\mathcal{H}_0$ are (apart from normalization)

$$|k_xnk_z,\sigma\rangle=e^{-\frac{1}{2}(\eta-\eta_0)^2}H_n(y-y_0)e^{i(k_zx+k_zz)}\chi_\sigma, \quad (2a)$$

$$E_\sigma(n,k_z)=2\mu_0H_0(n+1/2)+\hbar^2k_z^2/2m+\mu_0H_0\sigma, \quad (2b)$$

where μ_0=Bohr magneton; χ_σ=spin state, $\sigma=\pm1$; $\eta=(eH/\hbar c)^{1/2}y$, $\eta_0=-(\hbar c/eH)^{1/2}k_x$; H_n=nth Hermite polynomial.

The thermodynamic properties of the system can be studied conveniently by means of the partition function

$$Z(\gamma)=\mathrm{Tr}\{\exp[-\gamma(\mathcal{H}_0+V)]\}, \quad \gamma=1/kT. \quad (3)$$

Using the Schwinger trace formula[6] (the variable of integration has been changed to $u=\gamma s_1$)

$$Z(\gamma)\cong\mathrm{Tr}\{e^{-\gamma\mathcal{H}_0}\}-\gamma\,\mathrm{Tr}\{V(\mathbf{r})e^{-\gamma\mathcal{H}_0}\}+\tfrac{1}{2}\gamma^2\,\mathrm{Tr}\left\{\int_0^1 du\,V(\mathbf{r})e^{-\gamma\mathcal{H}_0(1-u)}V(\mathbf{r})e^{-\gamma\mathcal{H}_0u}\right\}\equiv Z_0(\gamma)-Z_1(\gamma)+Z_2(\gamma). \quad (4)$$

Since the Zeeman term commutes with the remainder of the Hamiltonian, the spin part of the trace is performed very simply to give

$$Z(\gamma)=2\cosh(\mu_0H_0\gamma)[z_0(\gamma)-z_1(\gamma)+z_2(\gamma)]. \quad (5)$$

$z_0(\gamma)$ is known from the work of Sondheimer and

Wilson[7]:

$$z_0(\gamma)=\Omega\alpha\gamma^{-3/2}(\mu_0 H_0\gamma)\,\mathrm{csch}(\mu_0 H_0\gamma),\qquad \alpha=(m/2\pi\hbar^2)^{3/2}. \tag{6}$$

$z_1(\gamma)$ can be calculated directly if $V(\mathbf{r})$ is represented as a Fourier series

$$V(\mathbf{r})=\sum_{\mathbf{K}} V_{\mathbf{K}} e^{-i\mathbf{K}\cdot\mathbf{r}}, \tag{7}$$

where the $\mathbf{K}$'s are reciprocal lattice vectors. Representing the trace in the form

$$\mathrm{Tr}\{B\}=\frac{\Omega^{2/3}}{(2\pi)^2}\int dk_x\int dk_z\sum_{n=0}^{\infty}\langle k_x n k_z|B|k_x n k_z\rangle, \tag{8}$$

and using the generating function for products of Hermite polynomials[8] we obtain

$$z_1(\gamma)=\gamma V_0 z_0(\gamma), \tag{9}$$

where V_0 is the average crystal potential. For simplicity it will be assumed that V has a center of symmetry.

The evaluation of $z_2(\gamma)$ is straightforward but tedious. We begin with the expression

$$z_2(\gamma)=\tfrac{1}{2}\gamma^2\frac{\Omega^{4/3}}{(2\pi)^4}\int_0^1 du\int dk_x dk_x'\int dk_z dk_z'\times\sum_{n,n'}|\langle k_x n k_z|V(r)|k_x' n' k_z'\rangle|^2\times\exp\{-\gamma E(n',k_z')(1-u)+E(n,k_z)u\}. \tag{10}$$

First the spatial integrals over $\mathbf{r}$ and $\mathbf{r}'$ in the matrix elements can be done, except for the y and y' integrals, making use of (8). The sums over n and n' are evaluated next using the generating function[8] and the y and y' integrals then performed in terms of the variables $y\pm y'$. At this point the remaining integrals, except for the u integration, are done without difficulty leading to the result

$$z_2(\gamma)=\tfrac{1}{2}\gamma^2 z_0(\gamma)\sum_{\mathbf{K}} V_{\mathbf{K}}^2\times\int_0^1\exp\left\{-\frac{\hbar c}{eH}\mathbf{K}_\perp^2\mu-\frac{\gamma\hbar^2}{2m}\mathbf{K}_{\parallel}^2 u(1-u)\right\}du. \tag{11}$$

$\mathbf{K}_\perp$ and $\mathbf{K}_{\parallel}$ are the components of $\mathbf{K}$, perpendicular and parallel to the magnetic field, and

$$\mu^{-1}=\coth(\mu_0 H_0\gamma u)+\coth[\mu_0 H_0\gamma(1-u)]. \tag{12}$$

Combining (5)–(11) we have

$$Z(\gamma)=Z_0(\gamma)\{1-\gamma V_0+\tfrac{1}{2}\gamma^2 V_0^2+\tfrac{1}{2}\gamma^2\sum{}' G(\mathbf{K},\gamma)V_{\mathbf{K}}^2\}, \tag{13}$$

where $G(\mathbf{K},\gamma)$ is the integral in (11) and

$$Z_0(\gamma)=2\Omega\alpha\gamma^{-3/2}(\mu_0 H_0\gamma)\coth(\mu_0 H\gamma) \tag{14}$$

is the partition function for free electrons. For convenience, the term $K=0$ has been separated from the sum and this is denoted by the prime.

For comparison the partition function has also been calculated for the case where the diamagnetic terms in (1) are omitted. This can be carried out easily using plane-wave states; the result is

$$Z'(\gamma)=Z_0'(\gamma)\left\{1-\gamma V_0+\tfrac{1}{2}\gamma^2 V_0^2+\gamma^{5/2}\binom{1}{-\alpha}\sum{}' V_K^2\int\frac{d^3k}{(2\pi)^3}\frac{e^{-\gamma\epsilon(k)}}{\epsilon(k-K)-\epsilon(k)}\right\}, \tag{13'}$$

where

$$Z_0'(\gamma)=2\Omega\alpha\gamma^{-3/2}\cosh(\mu_0 H_0\gamma),\qquad \epsilon(k)=\hbar^2k^2/2m.$$

It follows from these expressions that to second order in the potential the paramagnetic and diamagnetic effects of the field are not simply additive.

The free energy and other thermodynamic properties can now be calculated. Since we consider here only the steady susceptibility, we may simply disregard the poles of (13) lying off the real axis in the inverse temperature plane.[9] It is convenient at this point to separate $Z(\gamma)$ into field-dependent and independent parts retaining terms of no higher than second order in the field. Introducing the parameter $\beta=\mu_0 H_0$ we find $\mu\cong\beta\gamma S[1-\frac{1}{3}(\beta\gamma)^2 S]$ where $S=u(1-u)$ and $G(\mathbf{K},\gamma)=\frac{1}{2}I_0[\frac{1}{4}\gamma\epsilon(\mathbf{K})]+\beta^2\gamma^3(\epsilon(K_\perp)/96)I_2[\frac{1}{4}\gamma\epsilon(\mathbf{K})]$, where

$$I_n(x)=\int_0^1\frac{y^n e^{-xy}}{(1-y)^{1/2}}. \tag{15}$$

Thus,

$$Z(\gamma)=Z^{(0)}(\gamma)+\beta^2 Z^{(1)}(\gamma),$$

where

$$Z^{(0)}(\gamma)=2\Omega\alpha\gamma^{-3/2}\{1-\gamma V_0+\tfrac{1}{2}\gamma^2 V_0^2+\tfrac{1}{4}\gamma^2\sum{}' V_K^2 I_0[\tfrac{1}{4}\gamma\epsilon(K)]\}, \tag{16a}$$

$$Z^{(1)}(\gamma)=2\Omega\alpha\gamma^{-3/2}\{\tfrac{1}{3}\gamma^2-\tfrac{1}{3}\gamma^3 V_0+\tfrac{1}{6}\gamma^4 V_0^2+\tfrac{1}{12}\gamma^4\sum{}' V_K^2 I_0[\tfrac{1}{4}\gamma\epsilon(K)]\}+(1/192)\gamma^5\sum{}' V_K^2\epsilon(\mathbf{K}_\perp)I_2[\tfrac{1}{4}\gamma\epsilon(K)]. \tag{16b}$$

The quantity $\Phi=F-n\zeta$, $(n=N/\Omega)$, will now be calculated using Eq. (14) of Ref. 9. Asymptotic expansions in powers of the degeneracy parameter $(\gamma\zeta)$ can be obtained for the contributions of the first three terms of (16a) and (16b) to obtain Φ. For the remaining terms the procedure described in Ref. 9 would be permitted only if $\gamma\zeta\gg\frac{1}{4}\gamma\epsilon(K)$; since this is not the case for the alkali metals, the relevant parameter for these terms is $a=4\zeta/\epsilon(K)$.

The calculation as outlined gives

$$\Phi=\Phi_0^{(0)}+\gamma^{-2}\Phi_1^{(0)}+\beta^2\Phi_0^{(1)}+(\beta/\gamma)^2\Phi_1^{(1)}, \tag{17}$$

where

$$\Phi_0^{(0)} = -(2/\sqrt{\pi})\alpha\{(8/15)\zeta^{5/2} - \tfrac{4}{3}V_0\zeta^{3/2} + V_0^2\zeta^{1/2} + \tfrac{1}{4}\sum' V_K^2[\epsilon(K)]^{1/2} f(a)\}, \quad (18a)$$

$$\Phi_1^{(0)} = -\tfrac{1}{3}\pi^2(2\alpha/\sqrt{\pi})\{\zeta^{1/2} - \tfrac{1}{2}V_0\zeta^{-1/2} - \tfrac{1}{8}V_0^2\zeta^{-3/2} + \sum' V_K^2[\epsilon(K)]^{-3/2} g(a)\}, \quad (18b)$$

$$f(a) = \sqrt{a} + (a-1)\tanh^{-1}\sqrt{a},$$

$$g(a) = a^{-1/2}(1-a)^{-1}; \quad (19)$$

$$\Phi_0^{(1)} = -(2\alpha/\sqrt{\pi})\{\tfrac{2}{3}\zeta^{1/2} - \tfrac{1}{3}V_0\zeta^{-1/2} - \tfrac{1}{12}V_0^2\zeta^{-3/2} + \tfrac{2}{3}\sum' V_k^2[\epsilon(K)]^{-3/2} g(a) + \tfrac{1}{6}\sum' V_K^2(\epsilon(\mathbf{K}_1)/[\epsilon(K)]^{5/2}) h(a)\}, \quad (20a)$$

$$\Phi_1^{(1)} = -\tfrac{1}{3}\pi^2(2\alpha/\sqrt{\pi})\{-\tfrac{1}{12}\zeta^{-3/2} - \tfrac{1}{8}V_0\zeta^{-5/2} - \tfrac{5}{32}V_0^2\zeta^{-7/2} + (16/3)\sum' V_K^2[\epsilon(K)]^{-7/2} g''(a) + \tfrac{4}{3}\sum' V_K^2(\epsilon(\mathbf{K}_1)/[\epsilon(K)]^{9/2}) h''(a)\}, \quad (20b)$$

and

$$h(a) = \tfrac{3}{2}\tanh^{-1}\sqrt{a} + \frac{a^{1/2}(5-3a)}{2(1-a)^2}. \quad (21)$$

In order to use these expressions, the chemical potential must be known to second order in the various parameters. It can be calculated by solving the equation $(\partial\Phi/\partial\zeta)_\Omega + n = 0$. Except in rare cases, the temperature and field dependences of ζ are small enough to be neglected. Hence we need retain only $\Phi_0^{(0)}$ in this equation and solve for ζ to second order in the lattice potential. This calculation is easily carried out and yields

$$\zeta = \zeta_0[1 + (V_0/\zeta_0) - \tfrac{1}{2}\zeta_0^{3/2}\sum' V_K^2[\epsilon(K)]^{-1/2} f'(a_0)], \quad (22)$$

where $\zeta_0 = \frac{1}{4}(9\pi n^2)^{1/3}(2\pi\hbar^2/m)$ and $a_0 = 4\zeta_0/\epsilon(K)$.

The magnetic susceptibility can now be calculated. Putting (17) into the formula $\chi = -(1/H)(\partial F/\partial H)|_\Omega$ we find $\chi = -2\mu_0^2[\Phi_0^{(1)} + (kT)^2\Phi_1^{(1)}]$. To second order, the temperature-independent susceptibility is

$$\chi_0 = \chi_0^{\text{free}}[1 - (1/8\zeta_0^2)\sum' V_K^2 F(a_0)], \quad (23)$$

where

$$F(a_0) = (a_0)^{1/2}\tanh^{-1}(a_0)^{1/2} - \frac{a_0}{1-a_0} - \frac{1}{4}\frac{\epsilon(\mathbf{K}_1)}{\epsilon(K)}a_0^{3/2}h(a_0), \quad (24)$$

and $\chi_0^{\text{free}} = \mu_0^2/\zeta_0$ is the susceptibility for free electrons. A similar formula can be obtained for the temperature-dependent term.

An equation, resembling (23), for the paramagnetic susceptibility was published recently by Abe.[10] His formula is derived along the lines of this calculation in the Appendix.

III. DISCUSSION

In this section the results of the preceding analysis are applied to the alkalis Li and Na, these being the only metals for which the spin susceptibility has been measured. We shall cast our analysis for these metals in the form of a one-parameter model in terms of the lowest nonzero Fourier coefficient of the crystal potential. This is determined by the energy gap at the zone surface and estimates from band calculations[3,10] are listed in Table I. An estimate for sodium based on Callaway's[11] pseudopotential showed that the sum in (23) is given almost entirely by the contributions fron the reciprocal lattice vectors of shortest length. The results obtained by summing over only these vectors and using the Fourier coefficients listed in Table I are shown in Table II. $F(a_0)$ is a universal function for a given lattice; for the bcc case $F(a_0) = -6.33$ for the vectors of type $2\pi/a$ (1, −1, 0) and −4.29 for those of type $2\pi/a$ (1,0,1) where a is the lattice constant. The calculation for Na carried out using Callaway's pseudopotential gave a result much larger than that listed in Table II. This is consistent with the observation that the energy gap (at the point N) found by Callaway is an order of magnitude larger than that found in most other calculations.

Estimates of the correction to the susceptibility due to correlation have been made on the basis of Silverstein's[4] work and are listed under χ^* in Table I. The entries in Table II denoted by a star were obtained by including these adjustments. The starred values of the paramagnetic susceptibility are in close agreement with Abe's[10] values, obtained by a Sampson-Seitz procedure. Considering that the sum in (23) has been underestimated and that correlation has been accounted for in a very crude fashion, agreement with experiment for Li and Na appears to be satisfactory.

Also listed in Table II are values for the "diamagnetic susceptibility" obtained by subtracting χ_p (A5) from

TABLE I. Pseudopotential and free electron parameters for the alkali metals.

χ_0 (23). Because of the nonadditivity of diamagnetic and paramagnetic effects, discussed below in more detail, these values correspond only roughly to the Landau-Peierls diamagnetism. There is some evidence[12] that the diamagnetic susceptibility is only slightly affected by correlation; thus, much of the correlation contribution is subtracted off by this procedure. The close agreement between theory and experiment here is strong evidence in favor of a pseudopotential theory of these metals.

In the course of this calculation it was discovered that the same basic method has been applied by Samoilovich and Rabinovich[13] to study the diamagnetism of nearly free electrons; where comparable, their results agree with this calculation. However, due to the nonadditivity of the susceptibilities, the result of adding their expression to Abe's differs from (23); indeed

$$\Delta=[\chi_d(\mathrm{SR})+\chi_p(\mathrm{Abe})-\chi_0(23)]/\chi_0{}^{\mathrm{free}}$$
$$=\frac{1}{16\zeta_0{}^2}\sum{}'\, V_K{}^2\frac{\epsilon(\mathbf{K}_1)}{\epsilon(K)}[a_0(1-a_0)^{-2}-\tfrac{1}{2}a_0{}^{3/2}h(a_0)].$$

For lithium, $\Delta=0.62$, while for sodium, $\Delta=0.012$. Therefore care must be taken in separating the paramagnetic and diamagnetic susceptibilities for comparison with experiment. Since the diamagnetic susceptibility is not directly measured, it is believed that the estimates in Table II are more significant than those of Samoilovich and Rabinovich. The existence of this nonadditivity has been discussed in a general way by Blount.[14] This feature would appear to be a source of considerable error in previous calculations of diamagnetic susceptibilities.

In conclusion, a comparison can be made with the effective-mass approximation within the scope of the nearly free electron model. The susceptibility is given in terms of the effective mass ratio by[7]

$$\chi_0/\chi_0{}^{\mathrm{free}}=\tfrac{3}{2}(m^*/m)^{3/2}-\tfrac{1}{2}(m/m^*)^{1/2}. \quad (25)$$

In the nearly free electron approximation m^*/m, averaged over the Fermi surface, is

$$m^*/m=1+(1/4\zeta_0{}^2)\sum{}'\, V_K{}^2(a_0)^{1/2}\tanh^{-1}(a_0)^{1/2}. \quad (26)$$

Combining (25) and (26) gives

$$\chi_0/\chi_0{}^{\mathrm{free}}=1+(5/8\zeta_0{}^2)\sum{}'\, V_K{}^2(a_0)^{1/2}\tanh^{-1}(a_0)^{1/2},$$

which differs significantly from (23).

APPENDIX

Using (13′) and proceeding as in the body of the text we find

$$\Phi'=\Phi_0'+\Phi_1'+\Phi_2'+\Phi_2'', \quad (A1)$$

where

$$\Phi_0'=-\pi/\gamma(m/2\pi\hbar^2\gamma)^{3/2}[B_5\{\gamma(\zeta+\mu_0H)\}+B_5\{\gamma(\zeta-\mu_0H)\}],$$
$$\Phi_1'=\pi V_0(m/2\pi\hbar^2\gamma)^{3/2}[B_3\{\gamma(\zeta+\mu_0H)\}+B_3\{\gamma(\zeta-\mu_0H)\}],$$
$$\Phi_2'=-\pi\gamma/2V_0{}^2(m/2\pi\hbar^2\gamma)^{3/2}[B_1\{\gamma(\zeta+\mu_0H)\}+B_1\{\gamma(\zeta-\mu_0H)\}],$$

and

$$B_\sigma(\lambda)=\frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty}s^{-\sigma/2}\csc\pi s e^{\lambda s}ds$$

is an integral discussed in another paper.[9] It is convenient to handle Φ_2'', corresponding to the last term in (13′), somewhat differently. We first calculate $z''(E)$, the inverse Laplace transform of the corresponding term in $Z'(\gamma)/\gamma^2$. Then we obtain

$$\Phi_2''=\sum{}'\, V_K{}^2\int_0^\infty\frac{\partial f_0}{\partial E}\{g(K,E+\mu_0H)+g(K,E-\mu_0H)\}dE,$$

where f_0 is the Fermi function and

$$g(K,\lambda)=(2\pi)^{-3}\int_{\epsilon(k)<\lambda}d^3k[\epsilon(\mathbf{k}-\mathbf{K})-\epsilon(\mathbf{k})]^{-1}.$$

In the zero-temperature limit (A1) becomes

$$-\Phi(T=0)=[1/\Gamma(\tfrac{7}{2})](m/2\pi\hbar^2)^{3/2}\times\{[(\zeta+\mu_0H)^{5/2}+(\zeta-\mu_0H)^{5/2}]-\tfrac{5}{2}V_0[(\zeta_0+\mu_0H)^{3/2}+(\zeta-\mu_0H)^{3/2}]+(15/8)V_0{}^2[(\zeta+\mu_0H)^{1/2}+(\zeta-\mu_0H)^{1/2}]\}+\sum{}'\, V_K{}^2\{g(K,\zeta+\mu_0H)+g(K,\zeta-\mu_0H)\}. \quad (A2)$$

This leads to

$$\chi_p=\frac{4}{\sqrt{\pi}}\mu_0{}^2\left(\frac{m}{2\pi\hbar^2}\right)^{3/2}\zeta^{1/2}\left[1-V_0/\zeta-\tfrac{1}{8}(V_0/\zeta)^2+\frac{2\pi}{\zeta}\left(\frac{m}{2\pi\hbar^2}\right)\sum{}'\frac{V_k{}^2}{K^2-4k_0{}^2}\right], \quad (A3)$$

where k_0 is the free electron Fermi momentum. The chemical potential is obtained as before. Inserting (22) into (A3) leads to Abe's[10] expression

$$\chi_p/\chi_p{}^{\mathrm{free}}=1+(1/8\zeta_0{}^2)\times\sum\frac{V_K{}^2}{u^2-1}\left\{1+\frac{1-u^2}{2u}\ln\left|\frac{u+1}{u-1}\right|\right\}, \quad (A4)$$

where $\chi_p{}^{\mathrm{free}}=3\mu_0{}^2n/2\zeta_0$, and $u=K/2k_0=1/\sqrt{a_0}$.

Electron Paramagnetic Resonance of Fe^{3+} in the Strong Axial Field of $PbTiO_3$ Host

DENIS J. A. GAINON
Electronic Research Division, Clevite Corporation, Cleveland, Ohio

(Received 16 December 1963; revised manuscript received 10 February 1964)

An electron paramagnetic resonance investigation has been made of single crystals of tetragonal $PbTiO_3$. A spectrum attributed to Fe^{3+} was found which can be described by the spin Hamiltonain: $\mathcal{H}=g_{\parallel}\beta H_z S_z + g_{\perp}\beta(H_x S_x + H_y S_y)$ with $S=\frac{1}{2}$, $g_{\parallel}=2.009\pm0.005$ and $g_{\perp}=5.97\pm0.02$ at room temperature. These values are explained in terms of a strong tetragonal component of the crystalline field.

INTRODUCTION

LEAD titanate is a ferroelectric which is isomorphous at room temperature with tetragonal barium titanate and possesses a Curie point at 490°C, where the structure changes to cubic symmetry. The cell dimensions are $a=3.904$ Å and $c=4.150$ Å at 20°C. Small single crystals can be grown, but ceramics of $PbTiO_3$ tend to fracture when cooled through the Curie point. The purpose of this work has been to study the paramagnetic resonance spectrum of $PbTiO_3$ and to correlate the results with the known properties of this substance.

MEASUREMENTS AND RESULTS

Single crystals of $PbTiO_3$, grown from a KF flux melt in platinum crucibles, occur in the form of small plates or cubes up to several millimeters which can be yellow, green, or black. It is not at present possible to grow large single domain crystals.

Measurements were made primarily at room temperature[1] using a Varian V-4502 spectrometer working at about 8.8 Gc/sec with a magnetic field modulation frequency of 400 cps.

All the crystals studied show the same spectrum, which is essentially composed of three resonance lines. The lines are relatively broad; the absorption derivative peak-to-peak value is about 50 G. Variation of the orientation of the magnetic field relative to the crystallographic axes shows that each of the lines belongs to a paramagnetic impurity of effective spin $S=\frac{1}{2}$ and follows the spin-Hamiltonian

$$\mathcal{H}=g_{\parallel}\beta H_z S_z+g_{\perp}\beta(H_x S_x+H_y S_y),$$

with

$$g_{\parallel}=2.009\pm0.005,$$
$$g_{\perp}=5.97\pm0.02.$$

The only difference between the three lines is the orientation of the Z axis which, for each line, corresponds to one of the crystal axes. It is therefore natural to conclude that the spectrum is produced by the same impurity in the three possible orientations of domains (twinning of 180° being magnetically unobservable). This is confirmed by the fact that the relative intensity of the lines is strongly variable from one crystal to another, showing a different distribution of the domains. The three lines can be roughly equal; but also one or two of them can be of weaker intensity or unobserved, particularly in the crystals occurring in the form of plates. Among the cubes, the most extreme departure from random distribution was found in a crystal possessing about 80% of the domains in the same orientation.

The identification of $g_{\perp}$ is given by rotation of the magnetic field around one of the crystal axes. In this case the domains whose Z axes always remain perpendicular to the direction of H correspond to the orientation independent resonance line.

DISCUSSION

The measurements show that the paramagnetic impurity responsible for the spectrum is located in a position of local tetragonal symmetry and therefore probably substituted for an ion in the lattice.

Several considerations allow us to identify this impurity as Fe^{3+}. The signal is relatively strong, and spectrographic analysis of nominally pure samples shows that iron is the impurity present in the highest concentration (between 0.05 and 0.5 at. %). Crystals intentionally iron-doped gave the same spectrum; no additional resonance lines appeared. The resonance of Fe^{3+} is relatively strong in the other titanium compounds of perovskite-type structure, $BaTiO_3$[2] and $SrTiO_3$,[3] which are grown basically by the same method. No trace was found of the five-line spectrum characteristic of Fe^{3+} in tetragonal symmetry in any of the $PbTiO_3$ samples. The iron could possibly be in a reduced state (Fe^{2+} is expected to be unobserved at room temperature). The oxidation of Fe^{2+} to Fe^{3+} was apparently done without difficulty in $BaTiO_3$.[2] In $PbTiO_3$, heating in air for several hours, at temperatures up to 1000°C, then in oxygen (flow of 3.25 l/min for 40 h at 800°C) did not change the spectrum, suggesting that the iron was in the trivalent state prior to the oxidation.

[1] Investigation of the spectrum up to 300°C and down to −120°C did not produce any fundamental change. In particular, the transition to a multiple cell structure reported at −100°C when cooling slowly (see Ref. 9) did not produce a transformation of the spectrum.

Although other ions which may be paramagnetic are present in the crystal, i.e., titanium, platinum,[4] niobium, and copper,[5] they are not expected to have the observed g values and spectral intensity.

Because of size considerations, Fe^{3+} is expected to substitute for Ti^{4+} in the lattice, and its paramagnetic spectrum can be explained in terms of a strong axial field. The problem was theoretically studied by Griffith.[6] Fe^{3+} in its high-spin form is in the ${}^6S_{5/2}$ state. Under the action of a tetragonal crystalline field, this ground state splits into three twofold degenerate levels and its behavior in the presence of a magnetic field can be described by an adequate spin-Hamiltonian. If, however, the coefficient D of S_z^2 in the spin-Hamiltonian, proportional to the zero-field splitting, is much larger than the magnetic field energy, the lowest doublet is not mixed with the highest ones and the spectrum is described by a new spin-Hamiltonian with $S'=\frac{1}{2}$, $g_{11}'\cong 2$, and $g_1'\cong 6$. This effect was observed by Griffith and Bennett *et al.*,[7] but with relatively low precision in a few organic compounds (haemoglobin derivatives).

Several facts help to explain the large zero-field splitting of Fe^{3+} in $PbTiO_3$. The work of the above authors suggests that a D of at least 1 cm^{-1} is required to observe a true g_1 of 6 if the minimum wavelength available is about 3 cm. Although studies at shorter wavelengths would provide further information, a minimum D of 1 cm^{-1} seems consistent with the crystalline structure of $PbTiO_3$. The relation between D and the coefficient A_2^0 of Y_2^0 in the development of the crystalline field potential is not completely understood, but an extrapolation of the tentative quadratic relation given by Nicholson and Burns[8] leads to an A_2^0 at least two times larger in $PbTiO_3$ than in $BaTiO_3$. This is in accord with the main feature in $PbTiO_3$, which is the large displacement of the Pb and Ti ions, leading to a strong tetragonal component. Pb moves through 0.47 Å (0.05 Å for Ba in $BaTiO_3$) and Ti through 0.30 Å (0.10 Å in $BaTiO_3$) relative to the almost undistorted framework of oxygen ions. The ratio c/a of the cell dimensions is 1.063 in $PbTiO_3$, about six times larger. The spontaneous polarization calculated from ionic displacements is about three times larger than for $BaTiO_3$.[9] Thus, the observed EPR spectrum of Fe^{3+} appears consistent with the strong tetragonal crystalline field of $PbTiO_3$. It should be noted that possible distortions due to the noncompensated charge of Fe^{3+} may locally modify the crystal field.

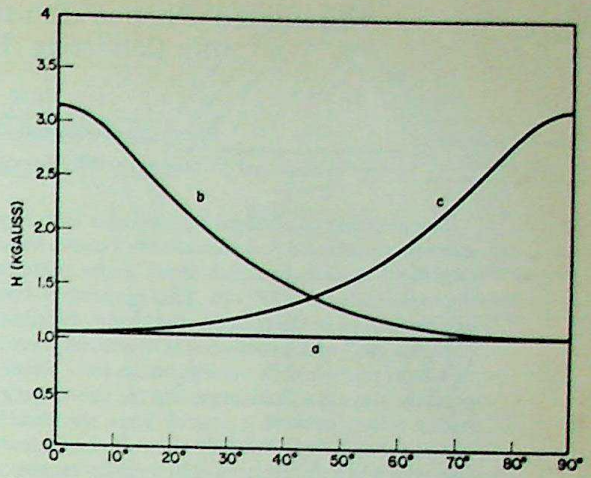

FIG. 1. Angular dependence of the three resonance lines for rotation of the magnetic field around one of the symmetry axes. Curve (a) corresponds to domains whose Z axes always remain perpendicular to the magnetic field. Curves (b) and (c) correspond to domains whose Z axes lie in the plane of rotation of H.

After this work was completed we learned from Müller[10] that similar resonances have been observed in cubic $SrTiO_3$ which have an intensity about 0.15 times that of the central transition of the cubic spectrum. Accurate determination of g_1 at two different frequencies allowed these workers to calculate a value of $|2D|=2.85\pm0.15$ cm^{-1}. They concluded that the only possible explanation for such a large D is that local charge compensation takes place at a nearest oxygen site. An interpretation of the $PbTiO_3$ spectrum in terms of local charge compensation would imply (1) that this charge compensation occurs only along the direction of polarization (since the resonance lines are of unequal intensities) and (2) that all the Fe^{3+} ions are locally compensated in an equivalent manner (since no other spectrum due to Fe^{3+} is detected).

ACKNOWLEDGMENTS

The author received crystals both from F. J. Scholz and Sandia Corporation, Albuquerque. He wishes to thank A. P. Greifer for the oxidation experiment, Dr. T. R. Sliker for valuable help and discussions, and Professor S. H. Christensen of Kent State University for a review of the manuscript.

[4] Z. Sroubek, Z. Zdansky, and E. Simanek, Phys. Stat. Solidi 3, 165 (1963), observed in $BaTiO_3$ at 78°K a signal that they attribute to Pt^{3+}. Their crystals, however, were doped with about 0.4 at. % niobium, which acts like a donor, to reduce the valence state of diamagnetic Pt^{4+}. The fact that our samples contained only about 0.03 at. % niobium is additional evidence that the spectrum is not due to Pt^{3+}.

[5] In some crystals a weaker signal is observed, following the same spin-Hamiltonian as the strong one but with $g_{11}=2.00\pm0.01$ and $g_1=2.24\pm0.01$. This may be eventually attributed to Cu^{2+}.

Stimulated Phonon Emission by Supersonic Electrons and Collective Phonon Propagations

E. W. PROHOFSKY
Sperry Rand Research Center, Sudbury, Massachusetts

(Received 23 December 1963; revised manuscript received 27 January 1964)

The emission of phonons by electrons with supersonic drift velocities is examined, and the crystal momentum transferred to a piezoelectric phonon band is determined. This momentum is transferred principally to a band of phonons which are in a cone centered about the direction of electron drift and of frequencies approximately 10^{10}–10^{11} cps. This momentum-transfer process is stimulated in the sense that it amplifies any variations in the phonon momentum distribution. In particular, it will amplify a collective wave in the "phonon gas" which corresponds to a sound wave in a particle gas. The collective wave is described in terms of a local particle drift velocity and a local temperature. In a phonon gas, temperature plays the role that pressure plays in a particle gas. By the use of energy and momentum conservation equations, it is shown that such a collective wave is possible when the usual large losses are overcome. The derived gain and expected loss of the collective wave are shown to be comparable in CdS at room temperature. The current saturation observed when the electron drift velocity exceeds the sound velocity appears in the self-consistent solutions of the electron and phonon systems.

I. INTRODUCTION

THE observation of an anomalously slow phonon propagation has recently been reported in CdS crystals under conditions of acoustic gain.[1] This has been interpreted as a collective phonon propagation similar to the collective phonon wave which describes second-sound propagation in super-fluid helium. In nonconducting solids the collective phonon wave in a "phonon gas" could be considered analogous to a sound wave in a molecular gas. The collective wave would then be a density fluctuation in the phonon distribution, much like a sound wave is a particle density fluctuation in a particle gas. In a macroscopic description an increase in phonons gives rise to an increase in temperature. Temperature plays a role in phonon transport similar to pressure in particle gas transport. The collective phonon wave could be described equally well as a temperature fluctuation wave.

The propagation of such a collective phonon wave in a solid has been examined in some detail.[2] It was found that umklapp collisions (which have no counterpart in molecular gases) would destroy the crystal momentum of the phonons and damp the collective propagation. In solids, at all but lowest temperatures, this damping term is much larger than the harmonic term, and diffusion, (i.e., normal thermal conductivity) rather than harmonic propagation, occurs. At very low temperatures the umklapp collision rate is greatly reduced and collective waves may be possible, but the reduction in normal collisions would then tend to disrupt the waves. Normal collisions are necessary to maintain the collective nature of the wave, just as particle collisions are necessary for sound propagation in particle gases. These two conditions, long umklapp relaxation time and short normal relaxation time, are extremely difficult to satisfy simultaneously.

In a semiconducting solid, particularly those with piezoelectric phonon modes, one can transfer energy and crystal momentum from electrons to the phonons. It has been shown by Hutson, McFee, and White[3] that for ultrasonic waves, i.e., low-frequency phonons, the internal losses of the phonons can be more than compensated for when $v_d > v_s$. Here, v_d is the electron drift velocity and v_s the sound velocity. If such a mechanism could transfer crystal momentum to phonons capable of participating in a collective wave, which would overcome the internal losses, it would be possible to propagate the type of collective phonon wave discussed. Whether or not a particular phonon mode could participate in a collective wave would depend on how strongly coupled the mode was to the bulk of the collective wave by the mixing collisions.

The transfer of momentum or energy to phonons has been examined by White[4] for low frequencies, i.e., $q\Lambda < 1$, where q is the phonon wave vector and Λ is the electron free path. In this range, the electrons are able to equilibrate to their local surroundings. The best description of this system is in terms of the classical fields and currents used by White. For higher frequency phonons, where $q\Lambda > 1$, a better description of the system involves quantum mechanical electron and phonon states which undergo collisions. Pippard[5] has discussed the interaction mechanism for high-frequency phonons from a degenerate electron band with imposed drift velocity, $v_d > v_s$. Spector[6] has derived the amplification of high- and low-frequency phonons using a free-electron gas model for conduction of electrons in metals. Neither of these approaches is ideally suited to examine the highly nondegenerate-electron distribution which exists

in CdS under conditions of acoustic gain. Paranjape[7] has discussed the amplification of high-frequency sound waves using a quantum mechanical approach suitable to nondegenerate electron distributions.

This paper will examine the transfer of momentum to high-frequency phonons using a golden-rule scattering integral technique suitable to nondegenerate-electron distributions in direct semiconductors. This momentum-transfer mechanism will, in turn, be used to evaluate the momentum transferred to collective phonon disturbances. It is believed that the high-frequency phonons will be most important in the collective wave behavior for two reasons: The number of higher frequency modes is much greater than that of low-frequency modes, and the mixing collision rate should be much less for low frequencies. This drop-off of mixing collision rate will supply a lower limit to the phonon frequencies involved in the collective wave. Those modes which have a lifetime longer than the period of the collective wave cannot be equilibrated within the collective wave.

In Sec. II, the first-order stimulated phonon emission and momentum-transfer rates are evaluated for a model in which there is a piezoelectric phonon mode and a nearly free, nondegenerate-electron band.

The results of Sec. II show that the electrons are strongly coupled to phonons of moderately high frequencies, but the interaction drops very rapidly beyond a certain cutoff frequency due to the mass mismatch between electrons and high-energy phonons. Energy and momentum transfer, upon collision, is most efficient for particles of roughly the same mass. An apparent phonon mass is

$$m_p = h\nu/v_s^2, \tag{1.1}$$

where h is Planck's constant, ν the frequency, and v_s the velocity of sound. The frequency most strongly coupled to electrons is that for which $m_p = m_e$, where m_e is the electron mass. This frequency is roughly $\nu = 10^{11}$ cps. The actual peak frequency found in Sec. II is very close to this value, but varies with temperature as it is effected by such factors as the available phonon and electron phase space and the average electron energy. The frequency dependence of the efficiency of energy and momentum transfer is greatly modified when the coupling has a frequency dependence, as is the case in deformation potential scattering.

The cutoff of the interaction for high-phonon frequencies enhances the probability of collective wave propagation. The phonon momentum losses rise sharply with frequency. Pumping momentum into a low-frequency band can give rise to a situation similar to that encountered in anomalous thermoelectric power.[8] The situation is illustrated in Fig. 1. A low-frequency band of phonons becomes "hot" with respect to the bulk of the thermal phonons. The losses from this band are slow because of a bottleneck which keeps these phonons from equilibrating with higher frequencies. The high-frequency umklapp relaxation time is very fast, and the thermal phonons remain uneffected in the propagation of the lower-frequency band.

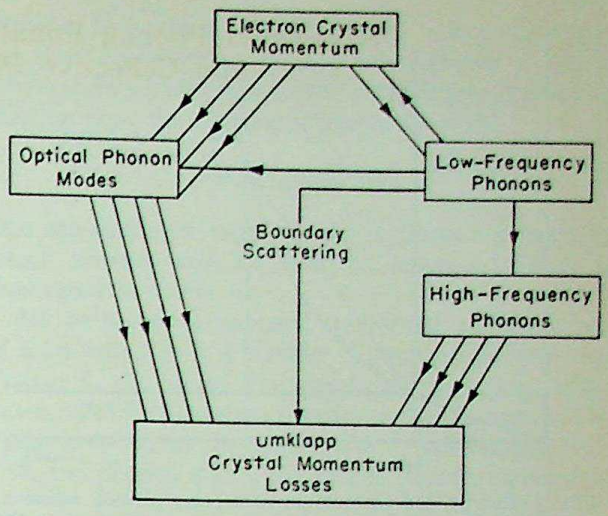

FIG. 1. Crystal momentum relaxation flow chart. Electrons accelerated by an electric field lose crystal momentum in collisions with optical and low-frequency acoustic phonons. For low electron drift velocities the relaxation to optical modes dominates. When $v_d > v_s$ the coupling to low-frequency acoustic modes becomes dominant. This low-frequency band can become hot since the momentum flowing into it can be greater than its losses to the high-frequency modes.

The emission process for $v_d > v_s$ is somewhat similar to Čerenkov radiation. As described in Sec. II, it, too, is limited to a forward cone centered about the direction of electron drift. The active phonon band which may support collective oscillations is a medium-frequency band of phonons occupying a cone in phonon-phase space centered about v_d.

The expression for the crystal-momentum transfer, found in Sec. II, is only valid in a region where $v_d \approx v_s$. The use of perturbation theory appears valid, as the dimensionless coupling parameter described by Froelich[9] is

$$\alpha = \left[\frac{\hbar}{2\rho\nu}\right]^{1/2}\left(\frac{ep}{d}\right)[\hbar\nu]^{-1} = \left[\frac{ep}{d}\right]\left[\frac{\pi}{\rho\hbar}\right]^{1/2}\nu^{-3/2}, \tag{1.2}$$

where ρ is the lattice density, e the electronic charge, p the proper piezoelectric constant, and d a dielectric constant. The parameter is certainly small for frequencies of the order of 10^{10}–10^{11} cps. For low values of electric field, the electron relaxation is mainly due to collisions with optical modes. This relaxation time is roughly 10^{-11}–10^{-12} sec, and the inequality $q\Lambda > 1$ is also satisfied for phonon frequencies of the order of 10^{11} cps.

The problem of the normal collision rate is discussed in Sec. III. The collisions between phonon states in the active band are primarily due to higher-order electron

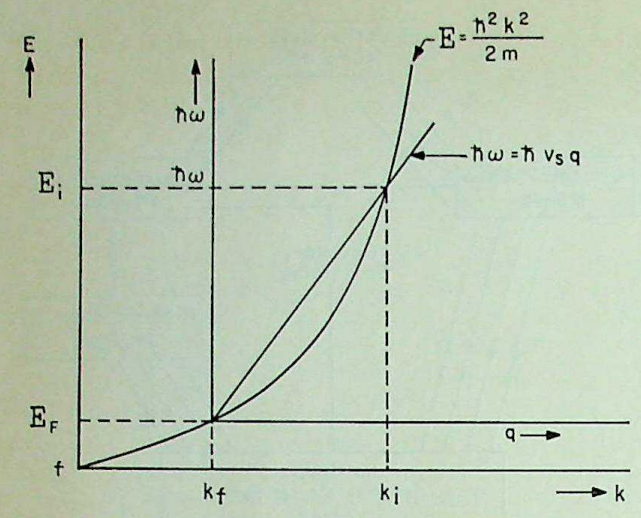

FIG. 2. Energy and momentum conserving phonon emission. The phonon dispersion relation $\hbar\omega=\hbar v_s q$ is superimposed on the electron dispersion relation $E=\hbar^2k^2/2m$. A possible phonon (ω,q) can be emitted in an energy and momentum conserving process if (1) $E_i=\hbar\omega+E_F$, and (2) $k_i=q+k_F$, where i and F refer to the initial and final electron states. All such double intersections insure that these two conditions are satisfied. The double intersections cease when the line is tangent to the curve when $E_i=E_F$ and the velocity of this state is equal to the vleocity of sound.

phonon collisions. The electrons, in this case, play a role very similar to that of the rotons in liquid helium. The same conditions which bring about large momentum transfer ($v_d>v_s$) cause this second-order collision mechanism to have a focusing effect on the phonons. That is, it tends to make the final phonon state more likely to be within the gain cone than the initial phonon state. The inability of the electron to transfer large amounts of energy to the phonons tends to keep the final state within the frequency limit of the active phonon band.

In Sec. IV, the equations for energy and crystal momentum conservation are applied to the active phonon band; the equation of conservation of momentum is applied to the electrons; and the interaction developed in Sec. II is used to couple the equations. A zero-order solution exists which describes the equilibrium distortion in the electron distribution (current), and the phonon distribution (heat flow) under the high electric field conditions. This solution shows a marked current saturation similar to that first reported by Smith.[10] In addition, solutions for displacements about this equilibrium exist which correspond to the collective propagation discussed. Throughout this section the excess energy stored in the electron distribution is ignored compared to that stored in the phonon distribution. Plasma effects are ignored because the electron density is assumed very small.

In Sec. V, numbers such as electron mass, piezoelectric constant, etc., are substituted into the equations that have been developed. The gain of the system is then compared to the expected phonon crystal momentum losses.

[10] R. W. Smith, Phys. Rev. Letters 9, 87 (1962).

II. STIMULATED PHONON EMISSION BY ELECTRONS IN PIEZOELECTRIC MATERIALS

In the quantum limit, i.e., $\mathbf{q}\cdot\mathbf{A}>1$, interactions involving electrons and phonons must conserve energy and crystal momentum modulo $\hbar\mathbf{G}$ ($\mathbf{G}$ being a reciprocal lattice vector). The possible initial and final states in which an electron emits or absorbs a single phonon in a normal collision (i.e., $\hbar\mathbf{G}=0$) can be determined by using a diagram similar to the one in Fig. 2. The curved line represents a dispersion relation for an electron in one dimension and is assumed to be a quadratic function of the momentum. The curve in Fig. 2 could be related to excited electrons in a direct material such as CdS. The straight line represents the acoustic phonon-dispersion relation; the slope equals the velocity of sound.

If the origin of the phonon line were placed at any point on the electron curve, a second intersection by the phonon line would imply conservation of energy and momentum between the initial and final electron states determined by the two intersections. All possible interactions correspond to some possible placements of the curves that result in two intersections. It can be seen that such intersections cease when the phonon line is just tangent to the electron curve. At this point, the energy and momentum of the emitted phonon have decreased to zero. The velocity of this limiting electron state is equal to the velocity of sound. For emission, the initial electron state must be on the high-energy side of the tangent point (i.e., $v_e>v_s$), and the final state must be on the low-energy side (i.e., $v_e<v_s$). For absorption, the initial and final states are reversed. In the case of a quadratic-electron-dispersion relation, the initial and final $\mathbf{k}$ values are equidistant from $\mathbf{k}'$, the location of the tangent point.

In a three-dimensional solid, the dispersion relation for electrons is a bowl-shaped hypersurface in four-

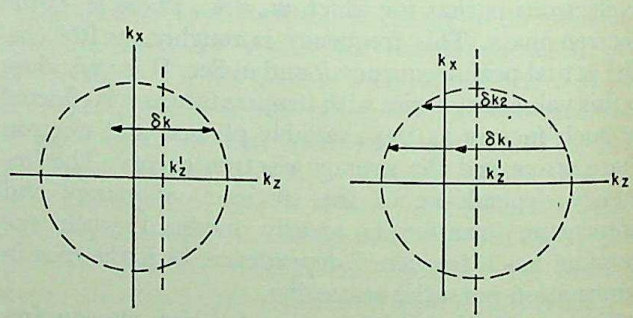

FIG. 3. Electron population inversion with respect to phonon emission. (This mechanism has been discussed by Pippard, Ref. 5.) The dashed circle represents phenomenologically the electron distribution in k space. The dashed line at k_z' represents those states whose velocity is equal to the sound velocity in the z direction. Emission or absorption of a phonon with $q=-\delta k$ involves initial and final states which are symmetrically spaced about the plane k_z'. In the figure on the left the electron distribution is at rest and there are fewer electrons on the high-energy side of k_z'. In the figure on the right the electron drift velocity is equal to the sound velocity and there are as many electrons on the high-energy side of k_z'. For greater drift velocities there will be more electrons on the high-energy side giving rise to a population inversion with respect to emission of phonons in the z direction.

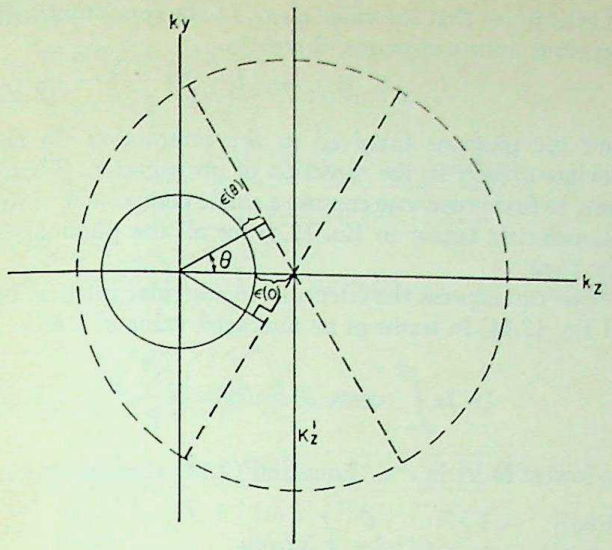

FIG. 4. The extent of population inversion for phonons not parallel to v_d. The solid-line sphere corresponds to the velocity of sound in any direction. The dashed sphere represents the electron distribution with a large drift velocity $v_d = v_s + \epsilon_0$. Phonons oriented at an angle θ will see a population inversion for $\epsilon(\theta) > 0$, where $\epsilon(\theta) = v_d \cos\theta - v_s(\theta)$.

dimensional space. Since only one phonon is involved in these processes, we may still use a one-dimensional phonon-dispersion line to examine the emission of phonons with one orientation. The origin of the phonon line is placed at a point on the electron-dispersion surface, and a second intersection implies a possible momentum and energy conserving process. The line and hypersurface will have a tangent point which will play a role similar to the tangent point in the one-dimensional analysis.

Based on the above discussion, it can be seen that a surface could be drawn in electron $\mathbf{k}$ space perpendicular to the direction of the emitted or absorbed phonon wave vector $\mathbf{q}$ at $\mathbf{k}'$, where $\mathbf{v}_e(\mathbf{k}') = \mathbf{v}_s$. All emission processes have the initial electron state on the high-energy side of this surface and the final state on the low-energy side. The change in electron wave vector, $\Delta\mathbf{k} = -\mathbf{q}$, is exactly bisected by this surface when the electron dispersion relation is quadratic in the momentum.

Pippard[5] has pointed out, in arguments based on a diagram similar to that of Fig. 3, that the phonon-emission rate could be greatly enhanced if the electron-drift velocity v_d were made greater than the sound velocity. In such a case, the centroid of the electron distribution in $\mathbf{k}$ space is outside the surface described in the preceding paragraph. Therefore, more electrons in states of high energy are opposite holes on the other side of this surface, and electron transition to the lower states is very probable. One can speak of a population inversion in $\mathbf{k}$ space with respect to phonon emission.

The emission of phonons for a given orientation in space will be shown as a first approximation to be proportional to a parameter ϵ, where

$$\epsilon = v_d - v_s, \tag{2.1}$$

where v_d is the electron drift velocity and v_s the sound velocity. For different phonon orientations, as those whose wave vector make an angle θ with the direction of electron flow, the emission is proportional to

$$\epsilon(\theta) = v_d \cos\theta - v_s. \tag{2.2}$$

One can define an angular cone in phonon q space in which phonon emission will be enhanced. This is demonstrated in Fig. 4.

All the collisions discussed are normal, and the effect of such collisions is a transfer of momentum from one system to the other. The population inversion, when $v_d > v_s$, favors momentum transfer to the phonons in the "gain cone" from the electrons. For well-defined electron and phonon states, the rate of phonon emission is

$$\left.\frac{\partial N_q}{\partial t}\right|_{\text{col}} = \frac{2\pi}{\hbar}\sum_{kk'} g^2\{[N(q)+1]f(k)[1-f(k')] - N(q)f(k')[1-f(k)]\} \times \delta(\mathbf{k}'-\mathbf{q}-\mathbf{k})\delta(\mathcal{E}_{k'}-\hbar\omega-\mathcal{E}_k), \tag{2.3}$$

where $N(q)$ is the occupation number of phonon mode q, $f(k)$ is the occupation number of the initial electron state, and $f(k')$ is the occupation number of the final electron state. The factor g is the coupling constant, or matrix element, for the coupling of the electron transition and the phonon. This energy can be written as

$$g = \frac{xep}{d} = \left(\frac{\hbar}{2\rho\omega_q}\right)^{1/2}\frac{ep}{d}, \tag{2.4}$$

where x is a normalized phonon displacement, e the charge on the electron, p the appropriate component of the piezoelectric tensor parallel to the phonon displacement, d the appropriate dielectric constant, ρ the lattice density, and ω_q the frequency of the phonon mode $\mathbf{q}$.

For high temperatures we assume $N(q) > 1$. This is equivalent to ignoring the spontaneous emission in comparison to the stimulated emission.

$$\left.\frac{\partial N}{\partial t}\right|_{\text{col}} \approx \frac{2\pi}{\hbar}\sum_{kk'} g^2 N[f(k)-f(k')] \times \delta(\mathbf{k}'-\mathbf{q}-\mathbf{k})\delta(\mathcal{E}_{k'}-\hbar\omega-\mathcal{E}_k). \tag{2.5}$$

For a quadratic electron dispersion relation,

$$k = (m^*/\hbar)v_s + (q/2) + k_{x,y}, \tag{2.6}$$

$$k' = (m^*/\hbar)v_s - (q/2) + k_{x,y}. \tag{2.7}$$

For drift velocities near the velocity of sound let

$$v_d = v_s + \epsilon. \tag{2.8}$$

One may assume that the electron distribution under high field is a Fermi distribution centered at $k_z = (m^*/\hbar)v_d$. That is,

$$f[(m^*/\hbar)v_d] = f_0(0), \tag{2.9}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

where $f_0(k)$ is the equilibrium Fermi distribution. Substituting Eq. (2.8) into Eq. (2.5), and summing over k_x', k_y', k_z' to eliminate the $\delta(\mathbf{k})$ function,

$$\left.\frac{\partial N(q)}{\partial t}\right|_{\text{col}} = \frac{2\cdot 2\pi}{8\pi^3\hbar}\sum_k g^2 N(q) \times\left[f_0\left(\frac{q}{2}-\frac{m^*}{\hbar}\epsilon+k_{x,y}\right)-f_0\left(\frac{q}{2}+\frac{m^*}{\hbar}\epsilon+k_{x,y}\right)\right] \times\delta(\mathcal{E}_{k'}-\hbar\omega-\mathcal{E}_k)\approx\frac{-1}{2\pi^2\hbar}\sum_k g^2 N(q) \times\frac{\partial f_0}{\partial E}\,\text{grad}_k E\cdot\frac{m^*}{\hbar}\cdot 2\epsilon\delta(\mathcal{E}_{k'}-\hbar\omega-\mathcal{E}_k) \quad (2.10)$$

as f_0 has reflection symmetry.

Summing over k_z to eliminate $\delta(\mathcal{E})$,

$$\left.\frac{\partial N(q)}{\partial t}\right|_{\text{col}} = \frac{1}{2\pi^2\hbar}\int_{k_{x,y}} g^2 N(q) f_0\left(\frac{q}{2}+k_{x,y}\right) \times\left[1-f_0\left(\frac{q}{2}+k_{x,y}\right)\right]\frac{1}{KT}\frac{m^*}{\hbar}2\epsilon dk_x dk_y. \quad (2.11)$$

After replacing the remaining sums by integrals and carrying out the integration over $dk_x dk_y$ we obtain

$$\left.\frac{\partial N(q)}{\partial t}\right|_{\text{col}} = \frac{1}{2\pi}\frac{1}{\hbar^4}m^{*2}g^2 N(q)\epsilon \times\left[1-\tanh\left(\frac{\hbar^2q^2}{16m^*KT}-\frac{E_F}{2KT}\right)\right]. \quad (2.12)$$

The total crystal momentum transferred via this process is

$$\left.\frac{\partial}{\partial t}\langle\hbar\mathbf{q}\rangle\right|_{\text{col}} = \sum_q \hbar\mathbf{q}\left|\frac{\partial N(q)}{\partial t}\right|_{\text{col}}. \quad (2.13)$$

Replacing the summation by an integral, Eq. (2.13) becomes

$$\left.\frac{\partial\langle\hbar\mathbf{q}\rangle}{\partial t}\right|_{\text{col}} = \frac{1}{16\pi^4\hbar^4}\int m^2g^2\hbar q\cos\theta N(q)\epsilon(\theta) \times\left[1-\tanh\left(\frac{\hbar^2q^2}{16m^*KT}-\frac{E_F}{2KT}\right)\right]2\pi q^2\sin\theta d\theta dq. \quad (2.14)$$

The interesting range of θ runs from zero to θ', where θ' describes a gain cone in $\mathbf{q}$ space, and

$$\epsilon(\theta') = (v_s+\epsilon)\cos\theta' - v_s = 0, \qquad \cos\theta' = \frac{1}{1+\epsilon/v_s}. \quad (2.15)$$

It is assumed that the value $\epsilon/v_s \ll 1$ to be consistent with previous approximations, therefore

$$\theta' \approx (2\epsilon/v_s)^{1/2} < 1, \quad (2.16)$$

and the phonons involved in the interaction do not deviate greatly in the direction of propagation. Therefore, to first order, one can use a single component of the piezoelectric tensor in Eq. (2.4) for all the phonons in the cone.

One can express the effects of the angular integration of Eq. (2.14) in terms of an averaged value of $\epsilon(\theta)$.

$$\bar{\epsilon} = 2\pi\int_0^{\theta'}\cos\theta\epsilon(\theta)\sin\theta d\theta \approx 2\pi\frac{\epsilon^2}{v_s}, \quad (2.17)$$

to lowest order in ϵ/v_s. Equation (2.14) then becomes

$$\left.\frac{\partial\langle\hbar q\rangle}{\partial t}\right|_{\text{col}} = \frac{1}{8\pi^2}\frac{1}{\hbar^4}m^{*2}g^2\frac{\epsilon^2}{v_s}\int N(q)\hbar q \times\left[1-\tanh\left(\frac{\hbar^2q^2}{16m^*KT}-\frac{E_F}{KT}\right)\right]q^2dq. \quad (2.18)$$

For a nondegenerate electron gas the term in the square brackets can be simplified as

$$1-\tanh\left(\frac{\hbar^2q^2}{16m^*KT}-\frac{E_F}{2KT}\right) \approx\frac{\hbar^3n}{2(2m^*KT)^{3/2}}\frac{1-\tanh(\hbar^2q^2/16m^*KT)}{1+\tanh(\hbar^2q^2/16m^*KT)}, \quad (2.19)$$

where n is the electron density. A further simplification occurs if we define a temperature T_s by

$$KT_s = \tfrac{1}{2}m^*v_s^2; \quad (2.20)$$

and Eq. (2.18) becomes

$$\left.\frac{\partial\langle\hbar q\rangle}{\partial t}\right|_{\text{col}} \approx\frac{\pi}{8}\frac{1}{\hbar}m^{*2}g^2v_s^3(KT_sKT)^{-3/2}\frac{\epsilon^2}{v_s}n\int\hbar qN(q) \times\frac{[1-\tanh(\hbar^2v_s^2q^2/32KT_sKT)]q^2dq}{1+\tanh(\hbar^2v_s^2q^2/32KT_sKT)}. \quad (2.21)$$

We now allow for a distortion in the phonon field characterized by the phonons within the gain cone having a net drift velocity $\boldsymbol{\lambda}$. In this case, the distorted phonon probability distribution becomes

$$N(q) = N_0(q)+\boldsymbol{\lambda}\cdot\hbar\mathbf{q}\frac{1}{KT}N_0(N_0+1), \quad (2.22)$$

where N_0 refers to the equilibrium Bose distribution. It is now possible to separate the momentum transfer process into two parts, i.e.,

$$\left.\frac{\partial\langle\hbar q\rangle}{\partial t}\right|_{\text{col}} = R_1\frac{\epsilon^2}{v_s}+R_2\frac{\epsilon^2\lambda}{v_s^2}, \quad (2.23)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

where

$$R_1=\frac{\pi^2}{2}\frac{m^{*2}}{\rho v_s}\left(\frac{ep}{d\hbar}\right)^2\left(\frac{T}{T_s}\right)^{3/2}n \times\int x^2\frac{1}{e^x-1}\frac{1-\tanh[(1/32)(T/T_s)x^2]dx}{1+\tanh[(1/32)(T/T_s)x^2]} =\frac{\pi^2}{2}\frac{m^{*2}}{\rho v_s}\left(\frac{ep}{d\hbar}\right)^2\left(\frac{T}{T_s}\right)^{3/2}n\int r_1(x)dx, \quad (2.24)$$

$$R_2=\frac{\pi^2}{8}\left(\frac{ep}{d\hbar}\right)^2\frac{m^{*2}}{\rho v_s}\left(\frac{T}{T_s}\right)^{3/2}n \times\int x^3\,\mathrm{csch}^2\frac{x}{2}\frac{1-\tanh[(1/32)(T/T_s)x^2]dx}{1+\tanh[(1/32)(T/T_s)x^2]} =\frac{\pi^2}{2}\left(\frac{ep}{d\hbar}\right)^2\frac{m^{*2}}{\rho v_s}\left(\frac{T}{T_s}\right)^{3/2}n\int r_2(x)dx, \quad (2.25)$$

where

$$x=\hbar v_s q/KT. \quad (2.26)$$

The first term on the right-hand side of Eq. (2.23) describes spontaneous emission—spontaneous in the sense that the drifting electron distribution loses momentum to a nondrifting phonon distribution. The second term is a stimulated-emission term—stimulated in the sense that momentum is transferred at a rate determined by the net momentum present in the phonon system. This stimulated term describes a process whose net effect is a linear amplification of the net local momentum of the phonon distribution. The function $r_2(x)$ is greater than $r_1(x)$, and the "stimulated" emission term can be comparable to the "spontaneous" one.

The function, $(T/T_s)^{3/2}r_2(\nu)$, is plotted in Fig. 5 for several values of T/T_s. The values of T/T_s correspond to helium, nitrogen, and room temperature for free electron masses, and room temperature for an effective mass of $0.2m_0$. At low-phonon frequencies $q\Lambda<1$ this quantum approach is not valid. A more valid approach at these low frequencies is White's,[4] as previously discussed. The increase in the gain for phonons (as T/T_s increases) reflects the increased stimulation due to the presence of greater numbers of phonons. The shift in the frequency of maximum gain reflects the fact that the electrons have more energy and are more capable of emitting higher energy phonons.

III. NORMAL PHONON COLLISIONS AND HIGHER ORDER ELECTRON PHONON COLLISIONS

Phonons undergo collisions with other phonons via the anharmonic terms of the interatomic forces. Collisions in which no net crystal momentum is lost are called normal collisions. Such normal collisions are necessary for the propagation of a collective wave and establishing a local temperature. The collective wave

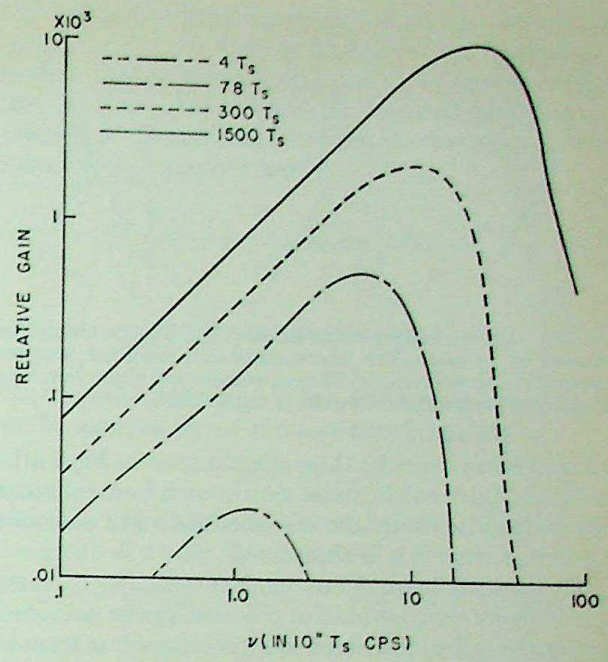

FIG. 5. Relative stimulated momentum gain as a function of phonon frequency. The function $r_2(\nu)$ is plotted for $T=4T_s$, $78T_s$, $300T_s$, and $1500T_s$. These temperatures correspond roughly to liquid helium, liquid nitrogen, and room temperature for $m^*\approx m_e$, and room temperature for $m^*\approx 0.2m_e$.

examined in this paper, however, must be propagated within a restricted band of lower-than-thermal frequencies, since the momentum loss of thermal phonons is much greater than the momentum gain available to the system. As pointed out in Sec. I, only the slow rate of equilibration of these low frequencies to the thermal reservoir makes the collective wave possible. Normal collisions in which momentum is transferred to phonon states outside of this restricted band will dissipate the momentum of the collective wave and give rise to damping. Instead of colliding among themselves, the low-frequency phonons within the restricted band are more likely to collide via the anharmonic perturbations with thermal-frequency phonons due to the much larger number of available states at higher frequencies. These collisions play the same role in this restricted-band collective wave as do the umklapp collisions in thermal phonon collective waves. The rate of these processes proceeding in the absence of carriers, i.e., dark attenuation in photoconductors, will be an estimate of the momentum losses from the restricted band to the thermal reservoir.

The slow rate of relaxation of the hot phonon band gives rise to a relaxation bottleneck. The phonons within this hot band are more likely to undergo further collisions with electrons before relaxation can occur. Successive electron-phonon collisions or higher order electron-phonon collisions are the fastest mixing collisions in the band and will set up a somewhat distorted equilibrium within the hot phonon band. The essential mixing collisions necessary for the propagation of the

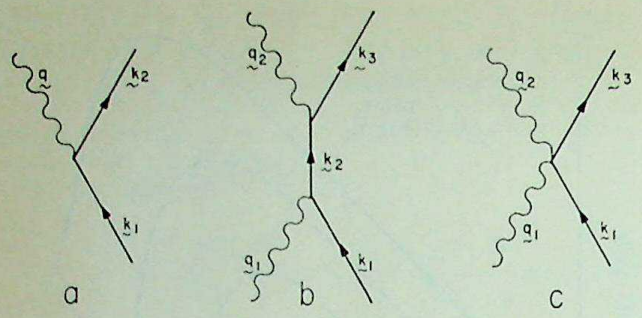

FIG. 6. (a) First-order phonon emission. (b) Phonon absorption followed by emission. The intermediate state need not conserve energy if it is short-lived. (c) Phonon emission and absorption. The existence of an intermediate state is not specified.

collective wave will be those diagrammed in Figs. 6(b) and 6(c). There will be some contribution from collisions [Fig. 6(b)] in which the intermediate state need not conserve energy if it is short lived.

The effect of large electronic drift velocities on these second-order electron-phonon processes can be examined qualitatively by describing the processes in a manner analogous to the emission problem of Sec. II. The change in electronic configuration in these second-order processes is the same as it would be if the process were an emission or absorption of an apparent phonon with energy and momentum equal to the differences in energy and momentum between the initial and final phonon states. The enhancement of a particular interaction occurs where $v_d > v_a$, where v_a is the apparent emitted phonon velocity and is

$$v_a = \frac{\Delta\omega}{\Delta q} = \frac{v_s}{1+(q_1/\Delta q)[1-\cos(\varphi-\theta)]}, \quad (3.1)$$

where q_1, Δq, φ, and θ are illustrated in Fig. 7. A gain cone extending over an angle φ' for these second-order processes can be defined where

$$\cos\varphi' = \cos\theta' \frac{1}{1+(q_1/\Delta q)[1-\cos(\varphi'-\theta)]}, \quad (3.2)$$

where $\cos\theta'$ is given in Eq. (2.15). Because of the electron population inversion, all interactions involving states q_2 whose vectors terminate on the ω_2 line inside φ' will tend to be apparent emissions, since the net interaction is more probable if q_2 is the final state and q_1 the initial state. For q_2 terminating outside φ' the net interaction favors transitions with q_2' as initial state and q_1 as final state. On the basis of this analysis it is seen that the mixing collisions tend to keep the excess phonon population within the gain cone where it is amplified, rather than outside the gain cone where it could be quickly damped. Furthermore, the focusing effect of the second-order collisions contribute to the net momentum gain of the phonon distribution.

One can easily obtain a lower limit of the second-order scattering from those intermediate states k_2 [Fig. 6(b)] in which energy is conserved. The second-order matrix element from second-order perturbation theory is

$$(k_3q_2|V^2|k_1q_1) = \sum_{k_2} \frac{(k_2|V^1|k_1q_1)(k_3q_2|V^1|k_2)}{E(k_1)+\hbar\omega_1-E(k_3)-i/2\Gamma}, \quad (3.3)$$

where Γ is an energy related to the finite lifetime of the intermediate state. That group of states k_2 in which energy is conserved has a resonant energy denominator, and the matrix element takes on a Breit-Wigner form. In the case of strongly enhanced first-order processes, the main part of the broadening will come from processes like "a" in Fig. 6. In this situation, the contribution to the scattering by the energy-conserving intermediate states will be approximately equal to the rate of first-order absorption processes. The final states of these higher order processes will lie in the same frequency band as the first-order emission processes. The contribution to mixing, from processes in which the intermediate state is not an energy conserving one, is expected to be small. This is because of the small size of the parameter α defined in Eq. (1.2) which determines the relative size of terms in this perturbation expansion.

A better understanding of the relative magnitudes of the emission and absorption rates can be achieved by examination of Fig. 3. When $v_d = v_s$ the electron distribution is symmetrically distributed such that the probability of absorption and emission are equal. The rate of both processes is very large because the energy and momentum in both the electron and phonon systems are ideally distributed for such interactions. The net transfer of momentum or energy is zero as the two processes cancel each other. An increase in drift velocity gives rise

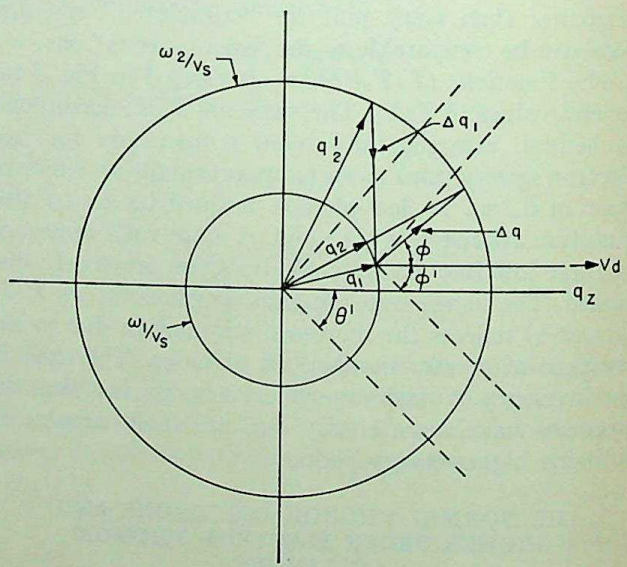

FIG. 7. Higher order electron phonon processes. These processes can be described in terms of the emission or absorption of apparent phonons. Two such processes are shown which have different changes in wave vector q_2-q_1 or $q_2'-q_1$ for a fixed energy difference $\omega_2-\omega_1$. This is equivalent to a variable apparent velocity. The cone φ' is the gain cone for these apparent phonons. Emission or absorption of these apparent phonons will be more probable depending on whether q_2 is inside or outside φ'. θ' is the gain cone for first-order processes.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

to a net phonon gain by increasing the emission rate relative to the absorption rate. The mixing rate, which is limited by the slower of the two processes (absorption or emission), would then be decreased due to the decrease in the absorption rate. If successive first-order processes are the dominant contribution to the mixing collisions, an increase in net gain will be accompanied by a decrease in the mixing rate. The ability to propagate a collective wave will depend on achieving a delicate balance between the gain and the mixing rate.

Higher temperatures will broaden the electron distribution and therefore reduce the sharpness of the population inversion for a given electron drift velocity. The phonon momentum gain per phonon mode actually decreases with increasing temperature [see Eq. (4.35)]. Higher temperatures will therefore tend to increase the mixing collision rate; lower temperatures will increase the gain. For a given drift velocity there is a temperature in which the two conflicting requirements for collective propagations may be simultaneously satisfied. Higher temperature will reduce the gain, and lower temperatures will reduce the mixing rate.

IV. CURRENT SATURATION AND COLLECTIVE WAVES

An equation for conservation of electron momentum can be derived from the Boltzmann transport equation and written as

$$\frac{\partial}{\partial t}\langle \hbar k_i\rangle+\frac{\partial}{\partial x_j}\langle v_j \hbar k_i\rangle-\frac{Ee}{\hbar}\left\langle\frac{\partial f}{\partial k_i}\right\rangle=\Delta\hbar q\Big|_{\text{col}}, \quad (4.1)$$

where the brackets refer to expectation values over the electron distribution. For a spatially uniform electron distribution, the second term is zero. When the drift velocity is less than the velocity of sound, the collision term can be simplified by a relaxation time approximation and becomes

$$\Delta\hbar q|_{\text{col}}=(-nmv_d/\tau_0), \quad (4.2)$$

where nm is the total electron mass per unit volume and τ_0 is the electron relaxation time. For materials such as CdS at room temperature, the electron relaxation is mainly due to collision with optical phonon modes. That part of the relaxation which is to optical modes, should remain relatively unaffected when v_d exceeds v_s. If we add the collision terms of Eq. (2.23) to represent the greatly enhanced part of the relaxation, Eq. (4.1) becomes

$$\frac{\partial}{\partial t}nmv_d-\frac{Ee}{\hbar}\left\langle\frac{\partial f}{\partial k}\right\rangle=-\frac{nmv_d}{\tau_0}-R_1\frac{\epsilon^2}{v_s}-R_2\frac{\epsilon^2\lambda}{v_s^2}; \quad (4.3)$$

and, using the usual definition of mobility μ, this becomes

$$\frac{\partial}{\partial t}nmv_d-\frac{nm\mu E}{\tau_0}=-\frac{nmv_d}{\tau_0}-R_1\frac{\epsilon^2}{v_s}-R_2\frac{\epsilon^2\lambda}{v_s^2}. \quad (4.4)$$

Equations for the conservation of energy and crystal momentum for the "hot" phonon band can be similarly derived. The conservation of energy is needed in this case, as the phonons are the thermal and inertial reservoir of the combined electron-phonon system. The conservation equations are

$$\frac{\partial}{\partial t}\langle\hbar q_i\rangle+\frac{\partial}{\partial x_j}\langle v_j\hbar q_i\rangle=\langle\Delta\hbar q_i\rangle_{\text{col}}, \quad (4.5)$$

$$\frac{\partial}{\partial t}\langle\hbar v_s q\rangle+\frac{\partial}{\partial x_j}\langle v_j\hbar v_s q\rangle=\langle\Delta\hbar v_s q\rangle_{\text{col}}. \quad (4.6)$$

The variation of energy in the restricted phonon band can be specified by an effective temperature

$$T=T_0+T_1, \quad (4.7)$$

where T_1 may fluctuate. The distribution function for this group of modes then becomes

$$N(q)=[\exp|\hbar v_s q-\hbar\lambda\cdot\mathbf{q}/K(T_0+T_1)|-1]^{-1}, \quad (4.8)$$

where λ is the phonon drift described in Sec. II. Using Eq. (4.7) and (4.8), Eqs. (4.5) and (4.6) become

$$\frac{\partial}{\partial t}M\lambda+\frac{\partial}{\partial z}\gamma CT_1=R_1\frac{\epsilon^2}{v_s}+R_2\frac{\lambda\epsilon^2}{v_s^2}-\frac{M}{\tau_\lambda}\lambda, \quad (4.9)$$

$$\frac{\partial}{\partial t}CT_1+\frac{\partial}{\partial z}D\lambda_1=v_s(\Delta\hbar q)_{\text{col}}. \quad (4.10)$$

Here, τ_λ refers to collisions which transfer momentum out of the active phonon band, C is the specific heat of the phonon band, γ is the average of $\cos^2\theta$ over the cone of phonons making up the phonon band, M and D are constants which depend on the ambient temperature as

$$M=\frac{1}{8\pi^3}\int\hbar q\cos\theta\frac{\cos\theta\hbar q}{KT}N_0(q)[N_0(q)+1]q^2\times\sin\theta dq d\theta d\varphi$$

$$=\frac{1}{4\pi^2}\frac{\gamma(KT_0)^4}{\hbar^3 v_s^5}\int x^4\operatorname{csch}^2\frac{x}{2}dx\int_0^{\theta'}\sin\theta d\theta, \quad (4.11)$$

$$D=\frac{1}{4\pi^2}\frac{\gamma(KT_0)^4}{\hbar^3 v_s^3}\int x^4\operatorname{csch}^2\frac{x}{2}dx\int_0^{\theta'}\sin\theta d\theta. \quad (4.12)$$

It is understood that the integral over x includes only those frequencies in the "hot" phonon band.

A static equilibrium solution can be found by setting time and space derivatives equal to zero and solving for ϵ_0 and λ_0. Equations (4.4) and (4.9) become

$$\frac{-nm}{\tau_0}\mu E=\frac{-nm}{\tau_0}(v_s+\epsilon_0)-\frac{R_1\epsilon_0^2}{v_s}-\frac{R_2\epsilon_0^2\lambda_0}{v_s^2}, \quad (4.13)$$

$$0=\frac{R_1\epsilon_0^2}{v_s}+R_2\frac{\epsilon_0^2\lambda_0}{v_s^2}-\frac{M\lambda_0}{\tau_\lambda}. \quad (4.14)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The sum of these equations is

$$\frac{nm}{\tau_0}\beta=\frac{nm}{\tau_0}\frac{\epsilon_0}{v_s}+\frac{M}{\tau_\lambda}\frac{\lambda_0}{v_s}, \tag{4.15}$$

where

$$\beta=\frac{\mu E}{v_s}-1 \tag{4.16}$$

and is the effective excess field driving the system. The righ-hand side of Eq. (4.15) consists of the net loss from the combined electron-phonon system due to electrons and phonons colliding outside the system. The resulting cubic equation for ϵ_0 or λ_0 can be easily solved in two limits: for $0<\beta\ll 1$

$$\epsilon_0/v_s=\tfrac{1}{2}\beta, \tag{4.17}$$

and for $\beta\approx 1$

$$\epsilon_0/v_s=(R_2/2R_1)^{1/2}\beta^{1/2}. \tag{4.18}$$

The current saturation, observed in CdS crystals[10] when the electron-drift velocity is comparable to or exceeds the sound velocity, is explained by these equations. At low electric field ($\alpha<0$) the coupling between Eqs. (4.13) and (4.14) is negligible. The primary electron damping is due to the optical phonon modes and normal resistive behavior results. When $v_d\approx v_s$ the further current increases Δj for increases in field are given by

$$\Delta j=ne\Delta\epsilon_0=ne\tfrac{1}{2}\mu\Delta E. \tag{4.19}$$

This causes a knee in the current voltage curves where the slope drops to one-half its original value. At very high electric fields the saturation increases and Δj becomes proportional to the square root of E. Accompanying this saturation, a net drift is set up in the phonon distribution described by λ_0, where

$$\frac{\lambda_0}{v_s}=\frac{nm\tau_\lambda}{M\tau_0}\left(\beta-\frac{\epsilon_0}{v_s}\right). \tag{4.20}$$

Although the electrons are capable of conforming to the instantaneous phonon distribution very quickly, it will take a time, roughly equal to the phonon relaxation time, for the phonons to achieve their equilibrium value. Such a delay in achieving equilibrium can explain the observed transient behavior in CdS.[10]

It is emphasized that these solutions are valid only in bulk material. No attempt has been made to introduce the effect of boundary conditions or spatial variations. The size of the sample should certainly effect transient time, particularly for small crystals. Also, no attempt has been made to include the effects of the low-frequency $q\Lambda<1$ phonons on saturation. It is felt, however, because of the greater number of available high-frequency modes, that the effect of the low-frequency phonons will not be too important.

The electron-phonon system can be examined for its behavior under slight departures from equilibrium. The parameters ϵ, λ, and T can be allowed to vary in both time and space about their equilibrium values, i.e., $\epsilon=\epsilon_0+\epsilon_1$, $\lambda=\lambda_0+\lambda_1$, $T=T_0+T_1$, where

$$\begin{aligned}\epsilon_1&=\epsilon_1{}^0e^{i(\Omega t-lz)},\\ \lambda_1&=\lambda_1{}^0e^{i(\Omega t-lz)},\\ T_1&=T_1{}^0e^{i(\Omega t-lz)}.\end{aligned} \tag{4.21}$$

Equations (4.4, 4.9, and 4.10) become

$$i\Omega nm\epsilon_1{}^0=-A\lambda_1{}^0-B\epsilon_1{}^0-(nm/\tau_0)\epsilon_1{}^0, \tag{4.22}$$

$$i\Omega M\lambda_1{}^0-il\gamma CT_1{}^0=B\epsilon_1{}^0+A\lambda_1{}^0-(M/\tau_\lambda)\lambda_1{}^0, \tag{4.23}$$

$$i\Omega CT_1{}^0-ilD\lambda_1{}^0=v_s[B\epsilon_1{}^0+A\lambda_1{}^0-(M/\tau_\lambda)\lambda_1{}^0], \tag{4.24}$$

where

$$A=R_2(\epsilon_0{}^2/v_s{}^2) \tag{4.25}$$

$$B=2[R_1(\epsilon_0/v_s)+R_2(\epsilon_0\lambda_0/v_s{}^2)]. \tag{4.26}$$

The dispersion relation for simultaneous solution of Eqs. (4.22)–(4.24) has roots which describe the collective propagation discussed. This dispersion relation is

$$-\Omega^2-2i\Omega[A'-(1/\tau_u)]+\gamma\bar{v}_s{}^2l^2=0, \tag{4.27}$$

where

$$A'=A/M, \tag{4.28}$$

$$B'=B/nm, \tag{4.29}$$

and

$$\bar{v}_s{}^2=D/M. \tag{4.30}$$

Substituting in Eqs. (4.25), (4.11), and (2.26), this becomes

$$A'=8\pi^4\left(\frac{ep}{d}\right)^2\frac{\hbar v_s{}^4m^{*2}n}{(KT)^4\rho}\left(\frac{T}{T_s}\right)^{3/2}n \times\frac{\epsilon_0}{v_s}\frac{\int x^3\,\mathrm{csch}^2\frac{x}{2}\,\frac{[1-\tanh(1/32)(T/T_s)x^2]dx}{1+\tanh[(1/32)(T/T_s)x^2]}}{\int x^4\,\mathrm{csch}^2\frac{x}{2}dx}, \tag{4.31}$$

where the approximation

$$\int\cos^2\theta\sin\theta d\theta\approx\epsilon/v_s \tag{4.32}$$

has been used. Equation (4.32) holds for small ϵ/v_s. A simplifying approximation can be made in Eq. (5.1) by assuming

$$[1-\tanh y]=\begin{cases}1 & y<0.5\\ 0, & y>0.5\end{cases}, \tag{4.33}$$

and expanding the $\mathrm{csch}x/2$ functions for small values of x. The maximum value of x in the integrals is then given by

$$x_{\max}=4(T_s/T)^{1/2}. \tag{4.34}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Carrying out the integral to x_{max}, Eq. (4.31) becomes

$$A' = 3\pi^4 \left(\frac{ep}{d}\right)^2 \frac{\hbar v_s^4 m^{*2}}{(KT)^4 \rho} \left(\frac{T}{T_s}\right)^2 n \frac{\epsilon_0}{v_s}. \quad (4.35)$$

The damping of the collective wave is

$$\omega_I = \tfrac{1}{2}(1/\tau_\lambda - A'), \quad (4.36)$$

where A is the stimulated momentum gain rate for a phonon distortion due to phonon emission by the electrons. When $\omega_I < 0$ a phonon distortion will grow rather than be damped.

In a more detailed treatment of this problem, one would retain the q dependence of both A' and $1/\tau_\lambda$. The gain band would be defined as those phonon modes for which

$$(1/\tau_\lambda)(\mathbf{q}) - A'(\mathbf{q}) < 0. \quad (4.37)$$

The loss due to $1/\tau_\lambda(\mathbf{q})$ will modify the frequency distribution of the gain band. The value of gain at various frequencies shown in Fig. 5 is greater than the net gain by an amount equal to $1/\tau_\lambda(\omega)$, since the losses increase with increasing frequency and the density of frequencies participating in collective waves will be shifted to lower frequencies. The angular distribution of the hot phonons will also be affected since the gain cone should be defined by that angle at which the net gain is zero.

An exact determination of the collective wave velocity would require a more thorough investigation of the role of the mixing collisions as well as detailed knowledge of the loss mechanisms which damp the wave. The problem is in knowing the extent of the cone over which $\cos^2\theta$ must be averaged in the determination of γ of Eq. (4.9). The mixing collisions bring about transfers of momentum which involve phonon modes well outside the gain cone. The effect of the drag of this additional specific heat on the modes involved in the transport of momentum is not as yet understood. If the entire forward half of the phonon distribution is involved in the local thermalization process [i.e., determining T_1 of Eq. (4.9)], the value of γ will be $\frac{1}{3}$. A restriction to some smaller cone would increase this value. The maximum value of γ is $\gamma = 1$, and this would occur when the cone is limited to a line in the direction of current flow. The absence of mixing collisions would also give rise to an apparent value of $\gamma = 1$.

The factor $\bar{v}_s^2$ of Eq. (4.9) should be a weighted average over all the excitations participating in the collective wave. This is important in the case of second-sound propagation in He II as the admixture of rotons slows the collective wave velocity.[11] In the wave discussed in this paper, the electrons participate in the collective wave and should be averaged in. The effect of the electrons should be very small due to their relatively small numbers and small mass. The phonons involved in the wave also have varying velocities. This is because the phonons having piezoelectric fields become impure modes in some directions. In CdS the piezoelectric mode along the "C" axis is a longitudinal mode. The effect of the different velocities of phonons for large angles, off the direction of propagation, is reduced by the factors of $\cos\theta$ in the constants M and D of Eqs. (4.11) and (4.12). This change in velocity with orientation would also effect the extent of the gain cone, etc., with orientation.

[11] K. R. Atkins, *Liquid Helium* (Cambridge University Press, Cambridge, England, 1959), p. 148.

V. CONCLUSION

The observation of an anomalously slow acoustic propagation in CdS has been recently reported.[1] The effect is directly related to the passage of a piezoelectrically active shear wave through the crystals under conditions of acoustic gain. The anomaly could only be explained as a wave traveling in the CdS with a velocity just slightly faster than $1/\sqrt{3}v_s$, where v_s is the velocity of the piezoelectric shear wave. This shear wave is the slowest of the possible sonic waves in CdS. The pulses were observable only with applied voltages such that the electrons had drift velocities roughly 50 percent greater than the velocity of sound. For drift velocities, roughly twice the velocity of sound, the pulses were damped out. Similarly, the pulses were observed only over a small range in temperature near 300°K. Higher and lower temperatures caused the wave to be damped. At low temperatures the velocity of the wave was observed to increase as the wave was damped. These observations can be explained on the basis of the theoretical development of a collective-wave propagation presented above.

The collective wave consists of a harmonic fluctuation in the density of phonons within an active phonon band (phonon frequencies $\sim 10^{10}$–10^{11} sec^{-1}). This could also be described as a harmonic temperature fluctuation in the active band. The phonon density (temperature) fluctuations in turn, have a frequency equal to that of the shear wave which generated them (shear wave frequency $\sim 10^7$ sec^{-1}). The role of the initial shear wave was to introduce a single-frequency perturbation, which when amplified, could be coherently detected.

The propagation of a collective wave requires that two conditions be satisfied: (1) The gain in crystal momentum of the active phonon band must exceed the losses, and (2) mixing collisions among phonons within the band must be sufficiently frequent that a local temperature can be defined within a collective wavelength.

In Sec. II of this paper, the momentum gain for piezoelectrically active phonons has been evaluated. The gain mechanism is such that the electrons couple only to a band of phonons of frequencies 10^{10}–10^{11} cps. In CdS, under conditions approximating those of the experimental observation, (i.e., at room temperature with $n = 10^{13}$ and $p \approx 10^7$ D/esu)[12] the gain in the band given by Eq. (4.35) is

$$A' \approx 10^3(\epsilon/v_s)\ \text{sec}^{-1}. \quad (5.1)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

That is, this gain is great enough, at large electric field strengths, to overcome active phonon-thermal relaxation times of 10^{-8} sec.

The losses which this gain would have to overcome to satisfy condition (1) are the losses from the active phonon band to thermal-phonon reservoir. These processes are due to the anharmonic perturbations and do not involve electrons. The phonon-thermal phonon relaxation time for the phonon frequencies expected to be of importance is difficult to estimate, and direct measurements at these frequencies and temperatures in CdS are not available. The difficulty arises because the active band lies between very high ultrasonic frequencies and very low thermal frequencies. Woodruff and Ehrenreich[13] have shown that the phonon-phonon damping increases roughly as ω^2 in the ultrasonic region, and as ω for higher frequencies. The extrapolation to the frequencies important in collective wave propagation could be approximated by a variation as ω^n with $1<n<2$.

The dark relaxation time (i.e., no carriers) measured by Kroger[14] in CdS crystals, which have shown collective wave propagation, is 10^{-3}–10^{-4} sec^{-1} at 10^7 cps. If one extrapolates from 10^7 cps to the higher frequencies of the active phonon band, a very large part of the phonon band which is capable of supporting collective waves [satisfying condition (2)] will have stimulated gain greater than the losses. The net gain would be the difference between two large numbers, roughly the order of 10^8 sec^{-1}. From Eq. (4.35) it can be seen that the momentum gain decreases for decreasing electric field and for higher temperatures. This decrease in gain would explain the observed damping of the collective wave at lower electric fields and higher temperatures.

As pointed out in Sec. III, the major contribution to mixing collisions probably comes from successive absorption and emission processes. This combined rate is limited by the slower of these two processes. When the electron drift velocity is exactly v_s the rates of the two processes are expected to be equal. For higher drift velocities (i.e., higher external fields) the absorption rate, and therefore the mixing rate decreases. Higher temperatures tend to enlarge the spread in the electron distribution and would bring the absorption and emission rates closer together. Lower temperatures, on the other hand, tend to make the electron distribution more compact, which would decrease the absorption rate relative to the emission rate. The rate of mixing collisions then has opposite temperature and voltage dependence than the net gain. This loss of coherence, or second viscosity damping, would account for the damping of the collective wave at high electric fields and low temperatures. The increase in velocity with onset of loss of coherence or second viscosity is also observed in second-sound propagation.[11] It comes about because for few mixing collisions a large part of the collective wave energy travels straight through as unhindered phonons. With no normal collisions the energy transfer velocity would be v_s.

Another cause for decrease in the observability of the collective waves at low temperature is the decrease in the energy and momentum content of the effective band. Figure 5 shows the total crystal momentum transferred to the entire band for various temperatures. It can be seen that the total magnitude of the entire collective wave decreases with temperature.

We expect the mixing collision rate to be comparable to the rate of Eq. (5.1). Therefore, the highest collective frequencies possible at room temperature would be roughly 10^8 cps. For frequencies of 10^6 cps and lower, the collective wavelength would be as large or larger than the size of readily available crystals. The experimentally observed wave was observed at a frequency of 10^7 cps.

PHYSICAL REVIEW VOLUME 134, NUMBER 5A 1 JUNE 1964

Optical Harmonic Generation in Single Crystal $BaTiO_3$

ROBERT C. MILLER
Bell Telephone Laboratories, Murray Hill, New Jersey
(Received 21 January 1964)

Second-harmonic generation (SHG) of the Nd-doped $CaWO_4$ optical maser beam in ferroelectric $BaTiO_3$ has been investigated. Each of the three nonlinear coefficients which determine the magnitude of the SHG have been measured from room temperature to near the Curie temperature. It is found that all three coefficients have the same temperature dependence as the spontaneous ferroelectric polarization. The symmetry of the nonlinear coefficients required for a dispersionless, lossless SHG mechanism, namely, $d_{15}=d_{31}$ for $BaTiO_3$, applies over the entire measured temperature range. The effects on SHG due to antiparallel ferroelectric domains are described. The circumstances under which random as well as special antiparallel domain arrays can produce either an enhancement or a degradation of the second-harmonic intensity are discussed. Because of the dependence of SHG on the domain structure, the determination of the nonlinear coefficients requires single-domain crystals. A method for preparing suitable $BaTiO_3$ single-domain crystals is described. These crystals are also useful for investigations of the characteristics of ferroelectric domain growth.

INTRODUCTION

QUANTITATIVE studies of the second-harmonic generation[1] (SHG) of optical maser beams in ferroelectric crystals are interesting for several reasons. All ferroelectric crystals[2] have optical, electrical, and other properties that undergo large changes with temperature so that one might also expect the efficiency of SHG in these crystals to vary with temperature in some pronounced manner. In addition, ferroelectric crystals have a domain structure that can be influenced with an external electric field; and, as will be discussed, the ferroelectric domain structure can have a maked effect on the production of the second harmonic.[3–7] Neither the domain effects nor the marked temperature dependence of SHG will occur with the usual nonferroelectric piezoelectric crystal. Ferroelectric barium titanate is, in many respects, a good choice as a material for an investigation of these nonlinear effects. For example, suitable crystals are readily available, the point group (C_{4v}) is simple, it is among the most efficient nonlinear materials known,[6] the Curie temperature (120°C) is easily attained, its optical properties are well suited to SHG with at least one of the commonly used optical masers, and its domain dynamics are quite well understood.[2]

From the point group of $BaTiO_3$, it can be shown that the second-order polarization $\bar{P}_{2\omega}$ has the form,[1,6]

$$\bar{P}_{2\omega}=\begin{bmatrix}0&0&0&0&d_{15}&0\\0&0&0&d_{15}&0&0\\d_{31}&d_{31}&d_{33}&0&0&0\end{bmatrix}\begin{bmatrix}E_x^2\\E_y^2\\E_z^2\\2E_yE_z\\2E_xE_z\\2E_xE_y\end{bmatrix}. \quad (1)$$

In this equation, $\bar{P}_{2\omega}$ is the dielectric polarization at twice the maser frequency ω, d_{ij} are the nonlinear coefficients, and E_i are the optical electric fields in the medium. Inspection of Eq. (1) readily shows that c-domain ferroelectric plates, i.e., plates with the ferroelectric direction (z axis) normal to the major surfaces, are not very useful for a study of SHG. One would like to use a-domain plates, i.e., samples with the ferroelectric direction in the plane of the major surfaces of the plate, so that with appropriate use polarizers and analyzers, one can determine each of the three nonlinear coefficients. There is some indication in the literature that a-domain samples are difficult to prepare; and, furthermore, that they may be unstable.[8] In addition, since SHG is influenced by antiparallel ferroelectric domains,[6] one must prepare a-domain samples which are free of antiparallel domains, i.e., they must be single domain crystals. A method for preparing samples suitable for these SHG studies will be described.

The a-domain samples prepared for the SHG studies are also useful for another type of investigation. With electrodes along two opposite edges so that electric fields can be applied along the crystal z axis, one can study the domain dynamics of polarization reversal, i.e., the nucleation and growth of the antiparallel domains. In recent years, studies[2] of domain dynamics through the direct observation of the domains have been largely restricted to investigations of the sidewise motion of the 180° domain walls—the boundaries between antiparallel domains. With the a-domain sam-

ples, one can for the first time observe in detail directly with a microscope the forward growth (growth in the direction of the spontaneous polarization) of the antiparallel domains under nearly ideal conditions. These phenomena, however, will not be described in this paper.

This paper discusses an analysis of some of the effects of antiparallel ferroelectric domains on SHG, the preparation of single crystals of $BaTiO_3$ suitable for studies of SHG and the forward growth of antiparallel domains, the determination of all the nonlinear coefficients as a function of temperature, and a brief discussion of these and other related experimental results.

EFFECTS OF FERROELECTRIC DOMAINS ON SHG

The effects which will be considered are those due to antiparallel domains. Effects which arise with twinned crystals due to mixed a- and c-domain configurations will not be discussed. Barium titanate will be treated in some detail, however, the phenomena to be described are not specific to $BaTiO_3$—they will occur with all ferroelectric crystals.

Consider what happens when an optical maser beam is at normal incidence on a $BaTiO_3$ crystal platelet. The maser beam fundamental produces a second harmonic forced wave[9,10] in the crystal as indicated in Fig. 1. This wave, which will be expressed as

$$E_{2k_1} \propto l_c \exp i(2k_1x-2\omega t) \tag{2}$$

is tied to the fundamental maser light wave, $\exp i(k_1x-\omega t)$. In these expressions, ω is the frequency of the fundamental light wave, and k_1 the propagation constant in the medium. The quantity l_c is the coherence length,[1] which will be described in more detail in the next paragraph. The plane of polarization of the forced wave is determined by the nonlinear coefficient involved in the SHG process. For ease of presentation, the phenomenon to be described will be illustrated with the nonlinear coefficient d_{33} so that all polarizations, including the ferroelectric polarization, are in the same plane.

Boundary conditions imposed by Maxwell's equations, namely, the tangential components of E and H, must be continuous across the surface of the crystal, require that a free second-harmonic wave[9,10] also be present in the crystal. This wave, which is produced at the surface, is expressed by

$$E_{k_2} \propto -l_c \frac{n_1+1}{n_2+2} \exp i(k_2x-2\omega t), \tag{3}$$

where k_2 is the propagation constant in the medium appropriate to the second-harmonic frequency. The quantities n_1 and n_2 are the indices of refraction at the fundamental- and second-harmonic frequencies, respectively. A reflected second-harmonic wave of small amplitude is also generated but will not be discussed further.[9,10] Since dispersion between the fundamental- and second-harmonic frequencies is usually present, $2k_1$ will not in general be equal to k_2 so that the forced and free waves, which are initially out of phase by π at $x=0$, travel with different velocities. The second harmonic intensity I_2 in the crystal is the result of the interference between these two waves, and can be approximated by

$$I_2 \propto |E_{2k_1}+E_{k_2}|^2. \tag{4}$$

Since $(n_1+1)/(n_2+1)$ is nearly unity, I_2 at $x=0$ is essentially zero compared to the maximum value of I_2 which first occurs at x equal to one coherence length l_c where the two waves are in phase; and then provided no domain walls are present, at successive odd multiples of l_c. The minima occur at even multiples of l_c. This oscillating phenomenon is illustrated near the bottom of Fig. 1. The coherence length l_c is given by

$$l_c=\pi/(k_2-2k_1)=\lambda/4(n_2-n_1), \tag{5}$$

where λ is the free-space wavelength of the fundamental.

Now, consider what happens to these two second-harmonic waves when they traverse a 180° domain wall

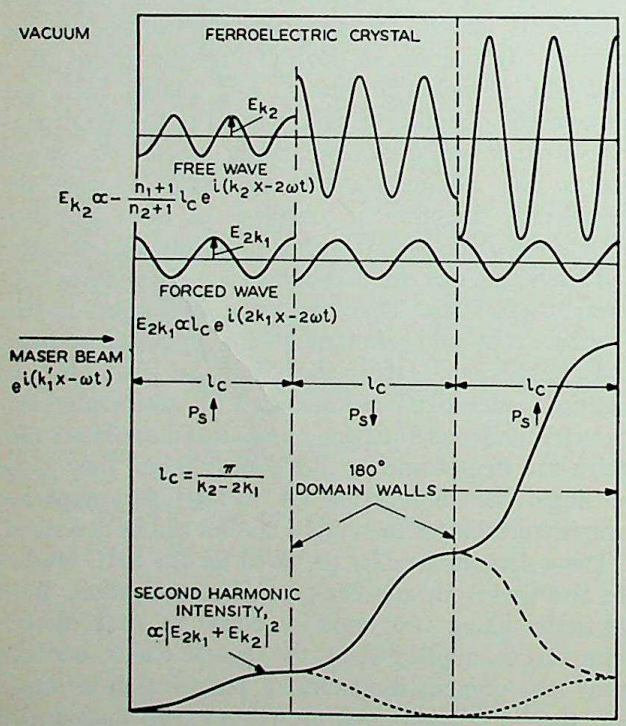

FIG. 1. Illustration of the enhancement of SHG due to antiparallel ferroelectric domains, one coherence length, l_c, thick. The forced and free second-harmonic waves are shown at the top of the figure and the resultant second-harmonic intensity at the bottom of the figure. At each domain wall the forced wave changes phase by π, and the free wave increases in amplitude by an amount equal to twice that of the forced wave. The dotted, dashed, and solid curves at the bottom of the figure show the effect on the second-harmonic intensity of zero, one, and two 180° domain walls.

where the normal to the wall is in the beam propagation direction. Since the z axes in two antiparallel domains are in opposite directions, Eq. (1) says that the phase of the second-order polarization wave $\bar{P}_{2\omega}$, and hence that of E_{2k_1}, will change by π on traversing the wall. The effect of the wall on the free wave is determined by the requirement that the tangential components of the E and H fields at frequency 2ω be continuous across the domain wall. For a wall at $x=x_0$, the free-wave changes from the form given in Eq. (3) to

$$-l_c\left[\frac{(n_1+1)}{(n_2+1)}-\frac{(n_1+n_2)}{n_2}\exp i(2k_1-k_2)x_0\right]$$
$$\times\exp i(k_2x-2\omega t), \quad (6)$$

for $x>x_0$. Thus, in the case of the free wave, the domain wall in general introduces a change in amplitude as well as a change in phase. A reflected second-harmonic wave is also produced at the wall; however, since its amplitude is down from that of the transmitted second-harmonic wave by more than three orders of magnitude, the reflected wave will not be considered further. Assume as shown in Fig. 1, that a wall is at $x_0=l_c$, in which case the maximum increase in E_{k_2}, and hence I_2 is obtained. Setting $n_1\approx n_2$, i.e., small dispersion, one sees from Eq. (6) that the amplitude of the free wave increases by a factor of 3. Therefore, the maxima of the total second-harmonic intensity increase by a factor of 4 due to the first "properly" placed domain wall. In addition, the minima are no longer zero, but are equal to the maxima obtained in the absence of the 180° wall. Each properly placed 180° wall results in an increase of the amplitude of the free wave by $(n_1+n_2)/n_2\approx 2$ times the amplitude of the forced wave. With N properly placed walls, the part of I_2 which does not average to zero with x can be shown to increase by a factor equal $[1+(1+2N)^2]/2$. The largest enhancement one can obtain from this process occurs when the 180° walls are present at $x=l_c$, $2l_c$, $3l_c$, etc., up to the crystal thickness l. The effect is then to increase the coherence length from l_c to the crystal thickness l. With the Nd maser and $BaTiO_3$, $l_c=2.1\times10^{-4}$ cm for d_{33}[6] so that for a crystal of typical thickness, 2×10^{-2} cm, and with domain walls spaced l_c apart, one has $N_{\max}=10^2$ or a SHG enhancement of 2×10^4, a very large effect.

For an array of N 180° domain walls situated randomly in the crystal, the resultant second-harmonic electric field is given by

$$E\propto l_c[(-1)^N e^{i2k_1x}-e^{ik_2x}(1-2\exp(-i\pi x_1/l_c)$$
$$+2\exp(-i\pi x_2/l_c)-2\exp(-i\pi x_3/l_c)+\cdots$$
$$+2(-1)^N\exp(-i\pi x_N/l_c))], \quad (7)$$

where the walls are placed at $x=x_1$, $x=x_2$, etc., and it is assumed that $n_1=n_2$ except in l_c. Then, for $2Nl_c<l$, Eq. (7) gives a second-harmonic intensity enhancement proportional to $(1+2N)$, where again only the part of I_2 that does not average to zero with x is considered. The restriction that $2Nl_c<l$ is required so that in averaging the product of Eq. (7) and its complex conjugate one can permit each phase $\pi x_i/l_c$ to vary from 0 to 2π. Thus, even a random array of antiparallel domains can produce a substantial enhancement of the second harmonic in a ferroelectric crystal.

For $l_c\gg l$, i.e., when the free and forced waves propagate at very nearly the same velocity, Eq. (7) can be used to show that the intensity of the resultant SHG is proportional to the square of the difference between the total thickness of domains of one sign minus that for domains of the opposite sign. Since SHG for $l\gg l_c$ in the absence of domains[1] is proportional to l^2, antiparallel domains will have a serious degrading effect on SHG under "velocity matched" conditions.

In the case just treated, the crystal was assumed to consist of slabs of antiparallel domains with the normals to the walls parallel to the beam direction. If the wall normals are perpendicular to the beam direction the analysis given above does not apply. In the latter situation, one has second-harmonic coherent light beams emerging from the crystal with the phase of all the beams coming from domains polarized in one direction out of phase by π with those beams coming from domains polarized in the opposite direction. In an unfocused beam experiment with a few antiparallel domains present so that the cross sections of the radiating volumes are much larger than a wavelength, the emerging beams will be nearly parallel and will not interfere with each other and reduce the second-harmonic intensity below that which one would observe with a single-domain crystal. However, when diffraction effects become large, that is, when the cross sections of the radiating areas are comparable to a wavelength, the emergent beams are no longer nearly parallel to that they can interfere destructively with each other and reduce the second-harmonic output below that which one would observe with one or a few domains.

The optimum domain array for SHG is one where the crystal consists of sheets of antiparallel domains, each l_c thick, with the wall normals parallel to the beam direction. The question arises as to how one can produce such domain arrays. One possible method that would apply to crystals which undergo second or higher order ferroelectric phase transitions,[2] such as potassium dihydrogen phosphate (KDP), Rochelle salt, and triglycine sulfate (TGS), involves the formation of a domain pattern, as the crystal goes from the paraelectric to the ferroelectric phase, which is determined by the minimum free energy.[2] In the case of Rochelle salt, theory and experiment give a domain spacing obtained in this manner which is proportional to the square root of crystal thickness.[11] (This crystal thickness refers to the direction of the ferroelectric polariza-

tion.) Thus, one may be able to produce a suitable array using this technique. This method will not work for crystals such as $BaTiO_3$ which undergo first-order phase transitions since the domain pattern formed on cooling through the phase transition is in this case determined by independent nuclei and not by the minimum free energy.[2]

It may be possible to produce desired domain arrays with electric fields. There is some evidence that the number of domains per unit area is determined by the magnitude of the field producing them,[12] so that with a suitable choice of the magnitude and the duration of the field, one may be able to produce useful domain patterns. A combination of electrical and thermal treatment may also be found useful.

Order of magnitude enhancements of the second-harmonic have been observed with both $BaTiO_3$ and TGS when antiparallel domains were known to be present. In these experiments, the ferroelectric domains had probably either circular, or approximately square, cross sections in the $BaTiO_3$; and probably lenticular, or circular, cross sections in TGS.[2] Thus, in neither case did the antiparallel domain configuration approximate the ideal slab structure. However, in no case was a decrease of the second harmonic observed when antiparallel domains were known to be present which shows that the enhancement effects of the 180° walls are larger than the degrading effects such as those due to small radiating areas.

A somewhat similar arrangement for enhancing SHG in quartz where $l_c < l$ was described earlier[1,9] and consists of stacking crystal plates in such a way so as to produce the effects shown in Fig. 1 and described in the text.

PREPARATION

Since no method of preparing samples suitable for the present experiments has been given in the literature, the techniques employed to produce the crystals will be described in some detail. Clear, undoped crystal plates of the order of 2×10^{-2} cm thick (grown by the Remeika method[13]) with clean smooth surfaces were selected and then etched in concentrated H_3PO_4 at 155°C sufficiently long to reduce the sample thickness by at least 5×10^{-3} cm. The samples were then rinsed in water, alcohol, and dc poled in distilled water with platinum electrodes. After poling, the specimens were examined with a polarizing microscope and only those samples which had large, unstrained c-domain areas were selected. Of these crystals, only those which had areas a millimeter or so on a side that were sufficiently plane parallel to give a few interference fringes with visible monochromatic light were used. These selected crystals were then cleaved, or broken, with a razor blade such that with much patience and some luck one obtained a c-domain sample, rectangular in shape, several millimeters on a side, with the sides parallel to the a axes. Then air-drying silver-paste electrodes were painted on the more perfect two opposite edges and dc fields of a few kV/cm were applied to pole the sample a domain. The poling process was monitored with a polarizing microscope and the process usually hastened by heating the sample with a focused light beam to a temperature below but near the Curie temperature. When the poling process was complete, the light and field were removed and the resultant a-domain sample examined. At this point, the samples would in most cases be without antiparallel domains. If a few antiparallel domains did appear, they were usually readily eliminated with fields of a few hundred volts per centimeter. In the studies of SHG, a field of this magnitude was always kept on the sample while under investigation to insure that no antiparallel domains were present. However, even under these conditions, both twinning and antiparallel domains usually occur at temperatures above approximately 110°C. For this reason, coupled with the fact that going through the Curie temperature is frequently a destructive operation, almost all the studies were made at temperatures less than about 110°C. There was no indication that these a-domain samples were unstable, i.e., over periods of months, no changes in the domain structure were observed.

SHG STUDIES

Figure 2 shows a schematic drawing of the essential components of the experimental arrangement for studying SHG in $BaTiO_3$. For ease of analysis of the data, a careful alignment was made so that the polarization of the laser beam was in the xz plane of the crystal and at 45° to the x and z crystalline axes. Table I gives the nonlinear coefficients d_{ij} involved in SHG as determined from Eq. (1) for various orientations of the polarizer and analyzer with respect to the crystal z axis. As seen in the table, special orientations of the polarizing elements enable one to observe separately SHG from each of the three nonlinear coefficients. The polarizing elements in Fig. 2 are set to observe SHG due to d_{15}.

To make quantitative comparisons between nonlinear

coefficients, it is necessary to consider the interference effects that occur between the second-harmonic forced wave produced by the maser beam, and the free second-harmonic light wave produced at the surface of the crystal. As mentioned in an earlier section, this interference effect, which was first demonstrated in quartz,[14] produces a second-harmonic wave whose amplitude varies in a periodic manner along the beam direction from essentially zero to some maximum value. For d_{33} in $BaTiO_3$ and a crystal of thickness l, the second-harmonic intensity, I_{33} generated by the fundamental intensity I_1 is given by

$$I_{33} \propto I_1^2 f(n) d_{33}^2 l_{33}^2 \sin^2(\pi l/2l_{33}), \tag{8}$$

where $f(n)$ is a function of the indices of refraction, and l_{33} is the coherence length. The function $f(n)$ is given by

$$f(n) = \frac{n_2}{(n_1+1)^3(n_2+1)^3(n_1+n_2)}. \tag{9}$$

In Eq. (8), the intensities are those measured outside of the crystal. Sufficient data on the indices of refraction of $BaTiO_3$ are not available to calculate the coherence length from Eq. (5) so that it must be determined experimentally from the data. The second-harmonic intensity is observed as the crystal is rotated about the z axis and then plotted as a function of angle. This rotation changes the path length of the beam in the crystal so that the periodic variation of the second harmonic is observed. These data on the angular dependence of I_{ij} are then used to determine l_{ij}, and are extrapolated to normal incidence to obtain relative values of d_{ij}. Room temperature determinations of d_{ij} and l_{ij} were given earlier,[6] but are also given here in Table II.

The temperature variation of the nonlinear coefficients is calculated from observations of the second harmonic intensity versus temperature. Figure 3 shows some of the data for the coefficient d_{31}. The oscillations present in the data occur due to changes in the magnitude of l_{31} through the temperature dependence of n_2-n_1.[6] Data on both the angular and temperature dependence of the second-harmonic intensity are required to determine directly the direction in which l_{ij} changes with temperature. For example, in the case of d_{15}, it is found that $dI_{15}/d\theta$ is negative when dI_{15}/dT is positive so that l_{15} must be increasing with temperature. Similar considerations show that l_{31} and l_{33} both decrease with temperature. These experimentally determined temperature dependences for l_{ij} are in the direction one would predict from the limited data on the optical properties of the negative uniaxial $BaTiO_3$ crystal. The published data[2] show that the index of refraction for the ordinary ray is temperature-independent while the index of refraction of the extraordinary ray increases with temperature and becomes equal to the ordinary index of refraction at the transition temperature.

Since $f(n)$ in Eq. (9) is very nearly temperature-independent, the temperature variation of the amplitude of the maxima shown in Fig. 3 arises from changes in l_{31} and d_{31}. Since l_{31} is known from the room temperature data on the angular dependence of the second harmonic intensity, and each oscillation of the second harmonic shown in Fig. 3 represents the introduction of two additional coherence lengths, l_{31} can be determined as a function of temperature. The temperature variation of d_{31} can then be calculated from Eq. (8). Figure 4 shows data obtained in the manner just described on the temperature variation of each of the nonlinear coefficients for $BaTiO_3$. The relative values of d_{ij} were computed at the intensity maxima and are normalized so

TABLE I. Orientations of polarizer and analyzer to determine nonlinear coefficients in $BaTiO_3$.[a]

Polarizer	Analyzer	Nonlinear coefficient
0°	0°	d_{33}
90°	0°	d_{31}
90°	90°	none
45°	0°	d_{33} and d_{31}
45°	90°	d_{15}

[a] The angles are between the transmission direction of the electric field in the polarizing element and the z axis in the crystal.

TABLE II. Room temperature $BaTiO_3$ nonlinear coefficients and coherence lengths.

d_{ij}[a]	l_{ij}
$d_{15}=35\pm3$	$1.57\pm0.12\,\mu$
$d_{31}=37\pm3$	$2.90\pm0.14\,\mu$
$d_{33}=14\pm1$	$2.07\pm0.04\,\mu$

[a] The d_{ij} are relative to d_{15} for KDP where $d_{15}=1.00$.

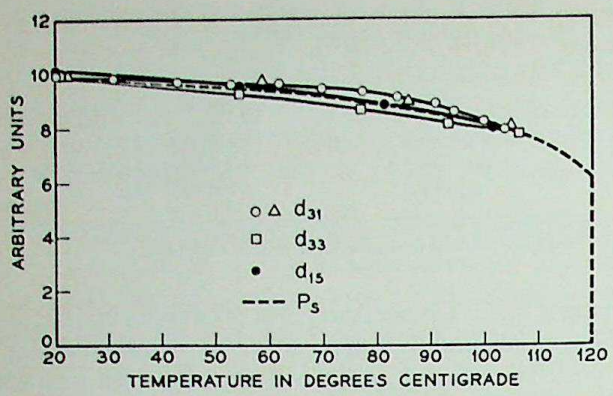

FIG. 4. The temperature dependence of the three nonlinear coefficients in $BaTiO_3$. All three have been normalized to 10 at 20°C. Within the experimental uncertainties of the measurements, all three coefficients vary with temperature as the spontaneous polarization which is also plotted in the figure and normalized to 10 at 20°C. The experimental points were calculated from the maxima of the second-harmonic intensity versus temperature data similar to that shown in Fig. 3.

that they all equal 10 at room temperature. All three coefficients were measured as a function of temperature with a crystal 2.48×10^{-2} cm thick, and in addition d_{31} was also measured with a second crystal 6.25×10^{-3} cm thick. In the case of the coefficient d_{15}, the curve shown in Fig. 4 is an average of six temperature runs. Although not shown in Fig. 4, it has been found that the d_{ij} decrease to zero discontinuously at the temperature where the crystal goes through a first-order phase transition from a ferroelectric phase into a nonpiezoelectric phase.[2] The discontinuous decrease of the second-harmonic intensity at the phase transition is consistent with the first-order phase transition. The temperature dependence of the spontaneous polarization of $BaTiO_3$ (26 $\mu C/cm^2$ at 300°K) normalized to 10 at room temperature, is also shown in Fig. 4. Note that all d_{ij} vary with temperature within a few percent of each other and P_s. The temperature dependence of the d's will be discussed in the next section.

DISCUSSION

Attempts to describe the temperature dependence of the d_{ij}'s given in Fig. 4 in terms of $P_s(T)n$ show that $n=1$ results in the best over-all fit to the data. Empirical fits more "accurate" than that given by $d_{ij}(T)\propto P_s(T)$ can be obtained for d_{31} and d_{33}, however, these fits are in some cases not physically significant, e.g., d_{ij} does not go to zero as P_s goes to zero, and furthermore complicated empirical fits would not seem justified at this stage since within the experimental uncertainties of the measurements $d_{ij}(T)$ and $P_s(T)$ have the same temperature dependence. Therefore, the temperature dependence of each of the three nonlinear coefficients for $BaTiO_3$ from 20°C to about 105°C can be described by

$$d_{ij}(T)=\alpha_{ij}P_s(T) \qquad (10)$$

in which $P_s(T)$ is the temperature-dependent spontaneous polarization, and α_{ij} is independent of temperature. The question arises as to the significance of Eq. (10). At first glance there may be some objection to trying to describe a purely optical property such as d_{ij} in terms of P_s which is a dc or at most a low-frequency characteristic. However, there is at least one purely optical quantity whose temperature dependence is described by some power of P_s. Namely, in $BaTiO_3$ the birefringence is proportional to P_s^2.[15] Also in KDP, the temperature dependence of the change in birefringence consequent on passing through the ferroelectric phase transition is proportional to P_s^2.[16] Therefore, at this point one can say that it may not be simply fortuitous that Eq. (10) describes the temperature dependence of the d_{ij}.

There are few other data with which one can compare the present results or test the general validity of Eq. (10). SHG studies of KDP both above and below the Curie temperature, 123°K, have been described in two recent publications.[5,7] Since SHG occurs in KDP both above and below the Curie temperature (it is piezoelectric in both phases) the temperature dependence of SHG in KDP will be different from that of $BaTiO_3$. The onset of ferroelectricity in KDP involves a phase change from the point symmetry D_{2d} for the paraelectric form, to the point symmetry C_{2v} for the ferroelectric phase. This lowering of the crystal symmetry results in the introduction of one nonlinear coefficient, d_{33}, not present in the paraelectric phase. Therefore, the temperature dependence of d_{33} will be different from that of the coefficients which are also present in the high-temperature phase. If it turns out that Eq. (10) does indeed have some general validity, it would be reasonable to propose that the temperature dependence of the nonlinear coefficients for a ferroelectric crystal which is piezoelectric in the paraelectric phase, such as KDP, is given by

$$d_{ij}(T)=d_{ij}^0+\alpha_{ij}P_s(T), \qquad (11)$$

where d_{ij}^0 is a temperature-independent nonlinear coefficient characteristic of the paraelectric phase. The change in the nonlinear coefficient in going through the phase change is described by $\alpha_{ij}P_s(T)$. For the new coefficient, d_{33}, which appears when the crystals becomes ferroelectric, $d_{33}^0=0$.

Himbarger and Bjorkstam[7] observe no significant change in the second-harmonic intensity from KDP in going from room temperature, through the phase transition, to 80°K. The data, which were obtained with a 0° ruby rod and therefore not a highly polarized maser beam, indicate that any discontinuity in the coefficients at the transition temperature is small. In terms of Eq. (11), these data would imply that $d_{ij}^0\gg\alpha_{ij}P_s$ except for d_{33} and also that $d_{33}\ll$ all other d_{ij}. The coefficient d_{33}

is reported by van der Ziel and Bloembergen[5] to be at least an order of magnitude smaller than the coefficients in the paraelectric phase. However, in disagreement with the data of Himbarger and Bjorkstam, van der Ziel and Bloembergen find that the nonlinear coefficients which are present in both phases change by factors ranging from about 3 to 0.2 as the crystal symmetry is lowered. Furthermore, except for the change in these coefficients at the phase transition, they are temperature-independent. The temperature dependence of d_{33} has not been determined. The discrepancy between the results of these two investigations on KDP could be due to effects arising from antiparallel ferroelectric domains; however, both groups were clearly aware of this complication. Discontinuities in the coefficients at the Curie temperature coupled with temperature-independent coefficients in the ferroelectric phase as reported by van der Ziel and Bloemberger are not consistent with Eq. (11).

Kleinman[17] has used a thermodynamic approach to show that if SHG arises from a nondispersive, nonlossy process, e.g., a high-frequency electronic mechanism, symmetry in addition to that required by the point group of the crystal will appear in the tensor which describes the second-order polarization coefficients. Data[6,18,19] on the Kleinman symmetry condition in a wide variety of crystals show that the additional symmetry is indeed present in the second-order polarization tensors. This symmetry condition requires for $BaTiO_3$ that $d_{15}=d_{31}$. As is evident in Table I, this condition is satisfied at room temperature within the approximately $\pm 10\%$ experimental uncertainties. The data shown in Fig. 4 demonstrate that the Kleinman symmetry condition is also satisfied over the entire measured temperature range.

A phenomenological theory[2] of ferroelectricity in which the Helmholtz free energy is expressed as a power series in the polarization has been quite successful, especially in the case of $BaTiO_3$ (Devonshire's theory), in explaining much experimental ferroelectric data. The validity of the Kleinman symmetry condition mentioned above, and the more general symmetry relations for nonlinear optical effects in lossless media derived using energy considerations by Pershan[20] both suggest that it may prove fruitful to extend the ferroelectric thermodynamic approach into the optical region. This approach would give $d_{ij}(T)$ expressed as a power series in P_s with the coefficients of the various terms determined from the free-energy expression for the paraelectric phase. For $BaTiO_3$ only odd powers of P_s will occur in d_{ij}, while d_{ij} for KDP will involve all powers of P_s. Therefore Eq. (10) includes only the first term for $BaTiO_3$, and Eq. (11) the first two terms for KDP. However, dispersion does occur between the present optical frequencies and the frequencies at which the various coefficients in the free-energy expression have been determined. Therefore, coefficients for the free-energy expression at optical frequencies as well as clarification of the KDP second harmonic data and/or additional SHG measurements with other ferroelectric crystals are required before the full significance of Eqs. (10) and (11) can be ascertained.

Another phenomenon which will be discussed briefly is the possible effect on the SHG due to a temperature dependence of the absorption edge in the $BaTiO_3$ crystals. As the crystal is warmed, the absorption edge, about 4000 Å at room temperature, shifts to slightly longer wavelengths.[21] It has been suggested[22,23] that the efficiency of SHG should increase as the second-harmonic wavelength approaches that of the absorption edge; however, to date, no data supporting this suggestion have been presented. In fact, data[6] on SHG in CdS show that d does not change significantly when the absorption edge is moved thermally through the frequency of the second harmonic. In any event, this edge effect would if anything give an increasing d_{ij} with temperature, which is opposite to what is observed. Therefore, if the proximity of the edge to the second-harmonic frequency is affecting the temperature dependence of the present data, it is being dominated by a still larger effect which results in d_{ij} which decrease with increasing temperature.

ACKNOWLEDGMENTS

The author would like to thank Dr. D. A. Kleinman for numerous informative discussions on many aspects of this paper; and Dr. J. A. Giordmaine, Dr. A. Ashkin, and Dr. G. D. Boyd for suggestions which resulted in an improved manuscript. The assistance of A. Savage in obtaining some of the data is also acknowledged. The fine $BaTiO_3$ crystals which made this research possible were kindly supplied by J. P. Remeika.

Specific Heat of Niobium between 0.4 and 4.2°K*

B. J. C. VAN DER HOEVEN, JR., AND P. H. KEESOM
Purdue University, Lafayette, Indiana

(Received 26 December 1963)

Below 3.3°K, the normal-state specific heat of niobium, measured in a magnetic field of 17 kG, can be represented by $C_n = 7.79T + 0.094T^3$ mJ/mole deg. This corresponds to a value of the Debye parameter at 0°K, $\Theta(0)$, of 275°K. The specific heat in the superconducting state does not appear to be anomalous, as has been reported.

INTRODUCTION

THEORY predicts that the lattice specific heat of a superconductor should be the same in both the normal and superconducting states. The normal-state specific heat is a sum of an electronic term γT and the lattice term C_{ln}. Since for sufficiently low temperatures the superconducting electronic contribution C_{es} becomes negligible, the total superconducting-state specific heat C_s is equal to the lattice contribution C_{ls}. So, for reduced temperatures above $T_c/T = 5$ one expects $C_s = C_{ln}$.

Two independent measurements of indium have provided an exception to this rule, however.[1,2] The superconducting specific heat C_s was found to be 10–20% less than the normal lattice contribution C_{ln}. A similar anomaly was reported by Hirshfeld *et al.* for niobium.[3] Recent conversations with Dr. Boorse have encouraged independent measurements and he was kind enough to offer one of his samples. The results are reported below.

EXPERIMENT

The apparatus was the He^3 cryostat described previously.[4] A germanium thermometer, similar in composition to the one described in an earlier publication[5] was used. Resistance range of the thermometer was 40Ω at 4.2°K, 120Ω at 1.0°K, and 500Ω at 0.4°K. The thermometer was calibrated in separate runs at zero field and at 17 kG. Magnetoresistance of the thermometer, $\Delta\rho/\rho$, varied from minus 2% at 4.2°K to plus 8% at 0.4°K. The 1962-He^3 temperature scale of Sydoriak and Roberts[6] for the range 0.4 to 1.2°K was used in conjunction with a paramagnetic salt thermometer for values below 0.5°K for the zero-field measurements and the 1958-He^4 temperature scale[7] above 1.0°K. An expansion of $1/T$ in powers of $\ln R$ up to $(\ln R)^3$ was done on an IBM-7090 digital computer, using the method of least squares as described by Moody and Rhodes.[8]

Total correction for the addenda (thermometer, heater, and glyptal) was less than 10% of the total heat capacity of the sample in the superconducting state at the lowest temperature. As the heat capacity of the addenda is known within ±3%, this introduces an error of at most 0.3% in the specific heat. Use was made of the most recent data of Ho *et al.*[9] for the constantan heater wire.

Normal-state measurements were made with a new set of cans incorporating the use of a superconducting Nb_3Zr wire solenoid with an inner diameter of 2.5 cm. The working volume was 1.5 cm in diameter and 3.5 cm long. A field of 17 kG was applied. In the superconducting state, a Helmholtz coil arrangement was employed to cancel the earth's magnetic field. The cylindrical sample of 0.365 moles was the same one used by Hirshfeld *et al.* with a small piece cut from the bottom. Dimensions were 1.3 cm in diameter, and

length 3.5 cm. The estimated experimental accuracy is ±2%.

RESULTS

The results for the superconducting and normal states are listed in Table I. They are also plotted in the form C/T versus T^2 in Fig. 1, together with a few points from the smoothed curve of the data of Hirshfeld *et al.* The two measurements are in very good agreement within combined experimental error. Up to 3.3°K the normal state data may be represented by

$$C_n = 7.79T + 0.094T^3 \text{ mJ/mole deg.}$$

The coefficient of the T^3 term α corresponds to a Debye parameter at 0°K, $\Theta(0)$, equal to 275°K.

In Fig. 2 is plotted an expanded portion of C_s/T versus T^2 up to $T^2=4$. If one plots here the values of

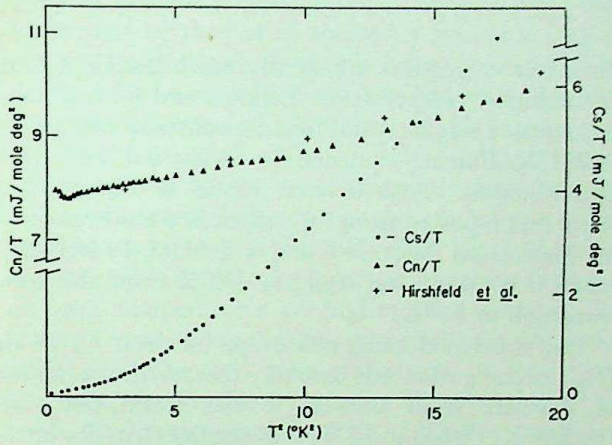

FIG. 1. C_s/T and C_n/T versus T^2.

C_s/T found by Hirshfeld *et al.*, no difference is observed. Two slopes are drawn representing the $\Theta(0)$ value of these measurements and the same quantity given by Hirshfeld *et al.* of 238°K. The small positive intercept of C_s/T (0.022 mJ/mole deg²) will be discussed later. It is clear from this graph that the anomaly disappears using the new value of $\Theta(0)=275$°K.

The data for $C_{es}/\gamma T_c$ can be very well represented by $a\cdot\exp(-bT_c/T)$. Plotting in this manner yields values of $a=8.31$ and $b=1.53$, very close to those predicted by the BCS theory of $a=8.5$ and $b=1.44$.

DISCUSSION

The lattice specific heat of a metal may be expressed as

$$C_l = 1944(T/\Theta(T))^3 \text{ J/mole deg},$$

where the Debye parameter is a function of tempera-

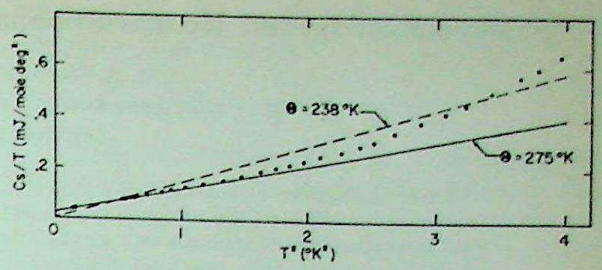

FIG. 2. C_s/T versus T^2.

ture. As mentioned before, the agreement between the values for the specific heat as measured by Hirshfeld *et al.* and these measurements are in excellent agreement within experimental error. However, the additional points at lower temperatures and with higher magnetic field modify the interpretation of the results. The initial value of Θ is now 275°K, in excellent agreement with the value derived from velocity of sound measurements by Alers and Waldorf of 277°K.[10] At 3.3°K, the value of the Debye parameter gradually decreases to a value of 238°K above 4.5°K, indicating the presence of a T^5 or higher term in the specific heat.

The increase of the normal-state specific heat at the lowest temperature may be a latent heat contribution due to insufficient quenching of the superconductivity. However, the magnitude of this deviation is within our experimental accuracy and could be due to inaccuracies in the thermometer calibration curve.

In Fig. 2 one observes that the specific heat points C_s/T gradually become tangent to the slope corresponding to $\Theta=275$°K at 1°K. The points do not fall below this line. Thus, the condition that $C_s=C_{ln}$ is met and no anomaly is observed.

The positive intercept of this curve with the C_s/T axis of 0.022 mJ/mole deg² indicates a small contribution of normal electrons. Comparing this to the value of γ in the normal state, one deduces that 0.3% of the niobium was normal. This effect may be attributed to strains or impurities. Trapping of the earth's magnetic field would make a contribution an order of magnitude too small. However, the lattice specific heat should not be influenced by this small contribution.

In conclusion it appears unnecessary to assume that the specific heat of superconducting niobium is anomalous.

ACKNOWLEDGMENT

The authors are indebted to Dr. Boorse who put his sample at their disposal.

Superconducting and Normal Specific Heats of a Single Crystal of Niobium*

H. A. LEUPOLD AND H. A. BOORSE†
Pupin Physics Laboratories, Columbia University, New York, New York

(Received 24 January 1964)

The anomalous specific heat found in a polycrystalline sample of niobium and previously reported from this laboratory by Hirshfeld, Leupold, and Boorse (HLB) prompted complete remeasurements both in the normal and superconducting phases on a single crystal with lower tantalum content. The thermal constants of the single crystal show only small differences from the polycrystal in the same temperature range, the single-crystal values being $T_c=9.20$°K and $\Theta=241$°K between about 10° and 3°K. The normal-state single-crystal measurements agree with measurements on the HLB polycrystal made both in this laboratory and by van der Hoeven and Keesom at Purdue University. The latter measurements were carried to about 0.4°K in a field of 17 kG. As a result of their investigation, they report a Debye Θ of 275°K in the region below 3°K. With this value of Θ, the anomaly in the specific heat disappears. As both the single-crystal results and the van der Hoeven and Keesom values agree in the mutually measured ranges, Θ is taken to be 275°K. The corresponding value of γ is found to be 7.80 mJ/mole deg^2. The usual exponential behavior of the electronic specific heat $C_{es}/\gamma T_c=ae^{-bT_c/T}$ with $a=8.21$ and $b=1.52$, is observed over a restricted temperature range. Below $t=5$ the data exhibit larger values than predicted by the exponential in agreement with a number of other superconductors. The value of the energy gap at 0°K was found to be 3.69 kT_c. Overall comparisons are made with the BCS theory and a modification due to Swihart.

I. INTRODUCTION

EXTENSIVE measurements of the specific heat of niobium in the temperature interval from approximately 12 to 1.2°K have been reported previously from this laboratory.[1–3] The latest measurements made by Hirshfeld, Leupold, and Boorse[3] (HLB) on a polycrystalline specimen showed that the normal phase, obtained by the application of a magnetic field of approximately 10 000 G, had a specific heat which could be represented by the usual sum of an electronic and lattice term, viz., $C_n=\gamma T+\text{const}(T/\Theta)^3$ with $\gamma=7.53$ mJ/mole deg.[2] The data indicated that in the range 12 to about 3°K, the value of Θ was constant and equal to 238°K. At lower temperatures the specific-heat values were larger than those given by the C_n relation, but the presence of 0.2% tantalum in the sample and the very high fields[4] required to suppress completely superconductivity in Nb alloys prompted the explanation of the larger values as a consequence of the appearance of the mixed phase in the material. Accordingly, the value of Θ appropriate to the normal phase over the whole interval to absolute zero was taken as constant and equal to 238°K. Previous measurements on annealed Nb made by Chou, White, and Johnston[5] gave values varying from about 250°K near the transition temperature to approximately 320 near 2°K. The precision of the latter values was apparently much less than those at the higher temperatures. Leupold and Boorse[2] using an annealed single crystal found a constant value equal to 241°K. Further evidence for a constant value of Θ approximately equal to that found in the previous researches reported from this laboratory has been given by Morin and Maita.[6] Using a field of 18 kG, they found Θ constant and equal to 230°K from above the transition to 1.5°K.

The superconducting-phase specific heat C_s in the HLB investigation was carefully measured in a number of separate trials because it was found that with $\Theta=238$°K, C_s below 1.7°K was smaller than the lattice specific heat in the normal phase. Although a similar anomaly had previously been found in indium by Bryant and Keesom,[7] the fact that Nb is a hard superconductor and likely to show significant variation in properties from sample to sample, prompted further measurements on a better specimen. Preliminary measurements[2] on a single-crystal rod, $\frac{3}{8}$ in. in diameter, obtained from Materials Research Corporation, Orangeburg, New York, did not show the anomaly. Accordingly, careful measurements were made again on both the polycrystal and on another piece of the same single-crystal rod mentioned above. The remeasurement of the polycrystal yielded identical results within the error of measurement with the originally published values.[3] In order to improve the superconducting properties of the second piece of the single-crystal rod, it was subjected to a zone-refining process. This operation was effected through the kindness of Dr. J. E. Kunzler and E. Buehler of the Bell Telephone Laboratories, Murray Hill, New Jersey, where the specimen was subjected to four passes in an electron-beam melting apparatus in high vacuum. The specimen, as subsequently analyzed, showed that as compared to the HLB polycrystalline

material,[3] the tantalum content was lower, being 750 parts per million as compared with 2000; N_2, 54 ppm as compared with 248; O_2 at 34 ppm, Fe at 25 ppm and Si at 75 ppm were all slightly higher. Otherwise, the analysis was the same. A series of x-ray photographs taken at intervals along the length of the specimen showed identical crystal structure.

II. APPARATUS AND PROCEDURE

The apparatus used to make the measurements on this single crystal was essentially the same as that used in the HLB investigation.[3] The principal change was the replacement of the inner He-4 bath in the cryostat with an He-3 reservoir in order to reach lower temperatures. In carrying out the investigation, additional precautions were taken to insure the reliability of the temperature measurements.

As in previous investigations, temperatures were determined by the use of resistance thermometers. To measure temperatures in the He-3 range, Allen-Bradley 0.1-W carbon composition resistors having a room temperature resistance of approximately 10 Ω were used. For the He-4 range and up to 20°K, Allen-Bradley 0.1-W resistors having an approximate room temperature resistance of 33 Ω were employed. After each run, a resistance-vapor pressure calibration of the thermometer was made so that any errors arising from cycling to nitrogen temperatures or higher were avoided. The vapor-pressure temperature conversions for He-3 were made using the 1962 scale of Roberts, Sydoriak, and Sherman,[8] for the He-4 region of the 1960 scale,[9] and for the hydrogen region the scale of Wooley, Scott, and Brickwedde.[10]

The resistance-temperature curve for the He-3 region joined smoothly to the curve for the He-4 region and in the range of overlapping temperatures gave indistinguishable values. A least-squares fit of the helium calibration date was obtained for each run with the aid of an IBM 1620 computer using the relation

$$T=\frac{B}{\ln R+K/\ln R-A}.$$

The temperatures calculated by means of this formula agreed with those determined experimentally from vapor pressure measurements to within 2 or 3 millidegrees.

For each run in which heat capacity data were taken above the helium temperature region, the thermometer was also calibrated against the vapor pressure of liquid hydrogen in the range between its normal boiling point (20.4°K) and triple point (13.957°K). The H_2 and He^4 points together were then fitted with the aid of a 1620 computer to the expression

$$\ln R=A+BT^{-1/2}+CT^{-1}.$$

The agreement between values of T calculated from this formula and those obtained by observed vapor pressures was excellent, the root-mean-square error amounting to about 6 millidegrees over both the helium and hydrogen ranges. This formula was used only in the specific heat calculation at the temperatures in the gap between the He and H_2 regions where a 6-millidegree error is only of the order of 0.1% of the measured temperature.

In the uncalibrated region between liquid helium and liquid hydrogen temperatures, it was essential that some checks be provided in order that the accuracy of the specific-heat determinations as well as that of the transition temperature could be estimated. To make such checks, gas thermometer measurements of the transition temperature of a highly purified lead wire were used. The gas thermometer measurements were made at Rutgers University through the kindness of Professor B. Serin. Two determinations of the transition temperature of the lead wire were made, yielding values of 7.210±0.005° and 7.209±0.005°K. Throughout the heat-capacity measurements, the lead wire was thermally bonded to the niobium sample and readings of the resistance thermometer on the sample determined when the lead changed from the superconducting to the normal phase or vice versa. In three separate comparisons, the reading of the resistance thermometer when placed in the $\ln R$ versus T formula above yielded the following temperatures: 7.19, 7.21, and 7.21°K. It was therefore concluded that the formula based on calibrations in the He-4 and hydrogen temperature ranged was not in error at 7.21°K by more than a few tenths percent. The adoption of 7.21°K as the lead transition

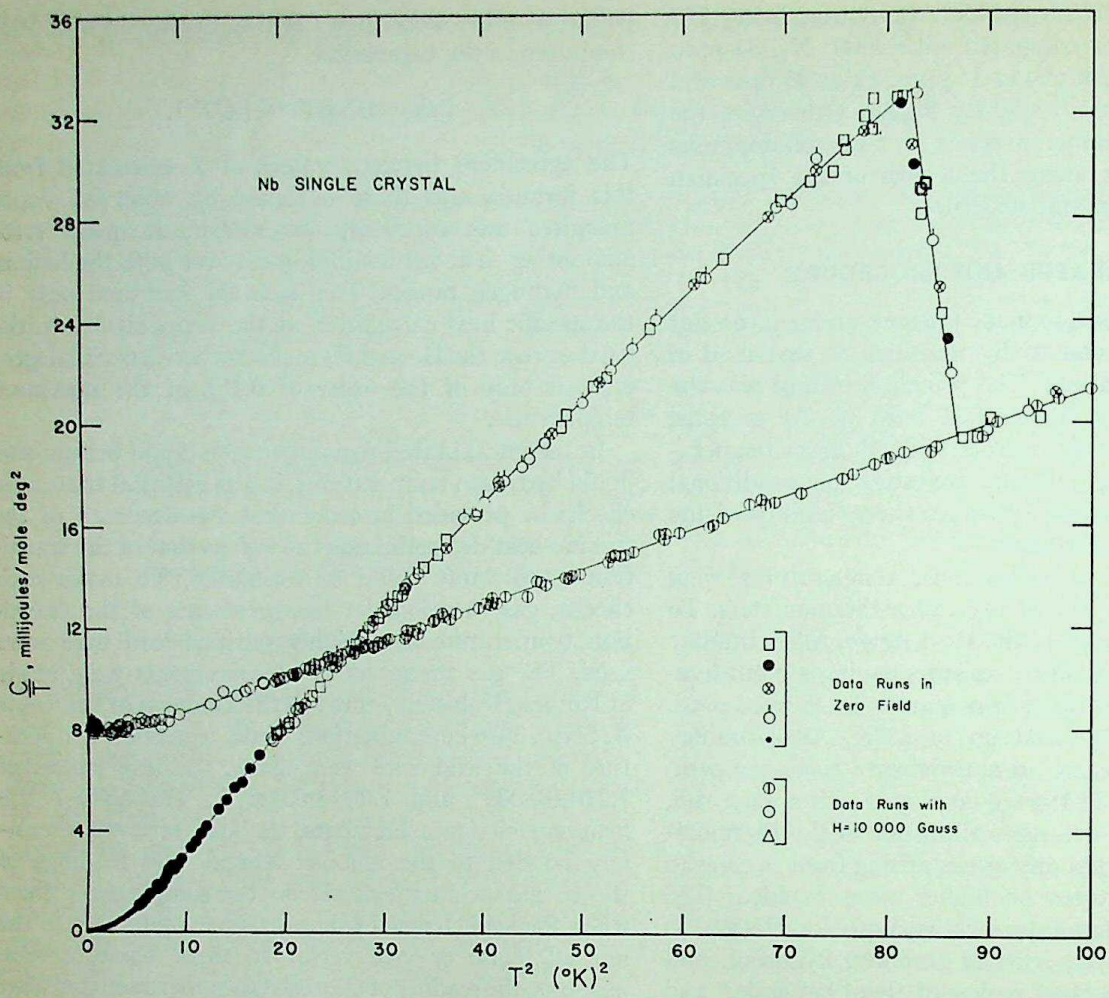

FIG. 1. C/T versus T^2 plot of the normal and superconducting specific heats of a single crystal of Nb. Full lines represent the mean values of the data.

temperature is 0.02°K higher than the latest determination[11] but more in line with the average of earlier measurements.[12]

III. RESULTS

The superconducting specific heat measured in zero field and the normal specific heat measured in a field of 10 000 G are shown in Fig. 1 and smoothed values for the data in the two phases are given in Table I. The normal data from the transition down to about 3°K can be calculated from the usual Debye-Sommerfeld relation with $\Theta = 241$°K and $\gamma = 7.38$ mJ/mole deg^2 obtained from the extrapolation of the $\Theta = 241$°K line to 0°K in substantial agreement with the values previously reported for the polycrystal. In the present data, however, starting at T^2 values between 10 and 9, the experimental points at decreasing temperatures rise gradually above the $\Theta = 241$°K normal line and fall on a new line whose Θ value was found to be 275°K with the corresponding value of γ equal to 7.80 mJ/mole deg^2. The uncertainty regarding the proper interpretation of this line suggested that the normal specific heat be determined in fields higher than the 10 000-G field available. Professor P. H. Keesom of Purdue University kindly agreed to measure the specific heat of the polycrystalline sample in a field of 17 kG in order to check the published data. The results of this investigation conducted by van der Hoeven and Keesom[13] (VK) and

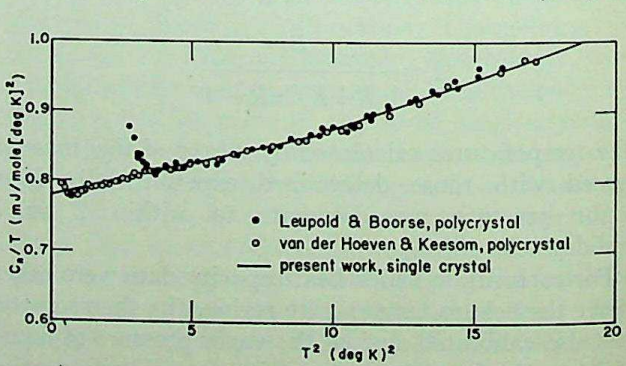

FIG. 2. C/T versus T^2 plot showing the experimental determinations of the normal specific heat below $T^2 = 20$. The data of van der Hoeven and Keesom is compared with polycrystal measurements in this laboratory, and the present data on a single crystal (full line) found in this investigation. The change in slope of the normal line just below $T^2 = 10$ should be noted.

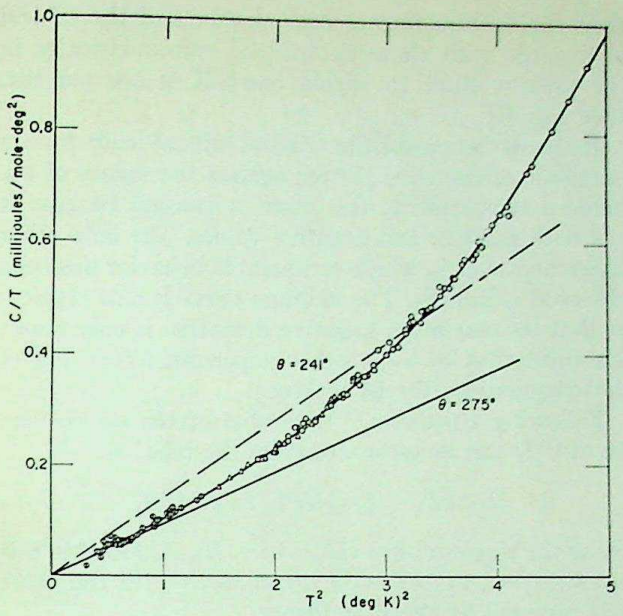

FIG. 3. C/T versus T^2 plot of the superconducting specific heat below $T^2=5$. The lines for Debye Θ values of 241° and 275° are shown for comparison.

published in this journal show clearly that the Θ = 275°K line is characteristic of the normal phase of niobium at the lowest temperatures and is not the result of the appearance of the superconducting phase.

In Fig. 2, the VK measurements are compared with those made in this laboratory on the same sample as well as with the smooth curve of the single-crystal measurements. All three sets of measurements agree within 1%. The measurements of VK show the same rise at 3° and follow the line Θ = 275 to about 0.7°K before undergoing an abrupt upward departure in the 17 000-G field. As can be seen from Fig. 2, the measurements made in this laboratory on the sample in a 10 000-G field rise sharply at about 1.8°K. This suggests that the gradual departure between $T^2=10$ and $T^2=9$ of the normal data from the line Θ = 241°K to the line Θ = 275°K reflects an inherent property of the crystal structure and not a consequence of an insufficient magnetic field as had been originally supposed. On this basis, the previously reported specific-heat anomaly disappears and the slope of the normal line corresponding to a Debye Θ of 275°K agrees with the limiting slope of the superconducting data close to the origin (see Fig. 3). It is interesting also that this value for Θ now agrees with the 277°K value found by Alers and Waldorf[14] from ultrasonic measurements at 4.2°K.

The transition temperature of the single-crystal sample was taken to be 9.19₅°K, the midpoint of the superconducting specific-heat discontinuity which extended from 9.07 to 9.32°K. A further confirmation for the view that the phonon spectrum of the metal changes in the neighborhood of 3°K is found in the experimentally determined entropy difference between the normal and superconducting phases. A plot of this difference versus temperature was found to vanish at 9.19₃°K. This value is in excellent agreement with the transition temperature taken as defined above, since the difference between 9.193° and 9.195° produces a disagreement in entropy between normal and superconducting phases of only 0.1%, less than the experimental error. If it is assumed that the change in Θ is an effect arising from imperfectly quenched superconductivity, the entropy difference vanishes at 9.13°K with the result that at 9.19₅°K the superconducting entropy exceeds the normal by about 3%. Thus an increase in Debye Θ seems to be the correct explanation for the change in slope of the normal line.

For a thermodynamically reversible superconductor, the critical field H_T at temperature T may be calculated from the relation

$$\int_T^{T_c}(S_n-S_s)dT=-(VH_T^2/8\pi). \qquad (1)$$

The entropy difference (S_n-S_s) for the single crystal was found by plotting a large scale graph of $(C_n/T-C_s/T)$ against the temperature and then measuring the appropriate areas with a planimeter. Using the values for the entropy difference thus obtained, Eq. (1) was integrated graphically and H_T could then be calculated after choosing $V=10.8$ cc/mole.[15] The resulting temperature dependence of H_T is shown on the graph in Fig. 4 and numerical values of H_T are given in Table II. The critical field H_0 at 0°K was found to

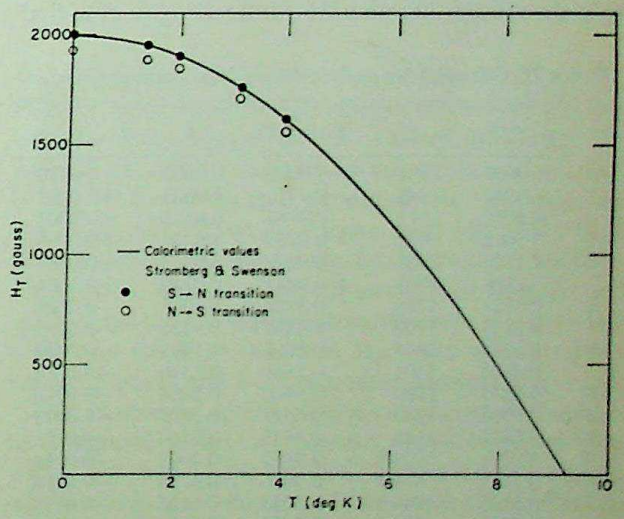

FIG. 4. Critical field versus temperature for the single-crystal specimen of Nb deduced from the specific-heat measurements, compared with critical-field measurements taken from the data of Stromberg and Swenson for transitions from normal to superconducting (open circles) and superconducting to normal (dots). The agreement of the latter data with the critical field deduced from these specific-heat measurements is obvious.

be 1994 G. This is in excellent agreement with the field deduced from calorimetric measurements by McConville and Serin[16] who found the value 1990 G. The value deduced from direct magnetic measurements by Stromberg and Swenson[17] was 1960±40 G. The critical-field values of the latter investigation were obtained by taking the average of values measured when going from the superconducting to the normal phase and when going in the reverse direction. It is interesting to note that their superconducting to normal values of the critical field agree with those determined calorimetrically in the present work to within one-half of one percent. (See Fig. 4.)

If the deviations of the reduced critical fields from a parabolic relation are plotted against the square of the reduced temperature, the curve is unusual because it has both positive and negative values. The only other superconductor in which comparable behavior has been observed is indium. The niobium curve is also atypical in that its maximum negative deviation is only about one-third that of most other superconductors and of that required by the BCS theory.

Following Goodman,[18] the value of the energy gap $2\epsilon_0$ at 0°K can be estimated from the relation:

$$2\epsilon_0/kT_c=(\tfrac{4}{3})\pi(H_0^2V/8\pi\gamma T_c^2)^{1/2}.$$

Using the single-crystal values of γ, H_0, T_c found in this investigation, $2\epsilon_0/kT_c=3.69$, compared with the value 3.52 required by the BCS theory.

The value obtained from ultrasonic measurements by Dobbs and Perez[19] depends on the propagation direction in the crystal; being 3.77 for the [100] direction, 3.74 for the [111], and 3.65 for the [110]. Levy, Kagiwada, and Rudnick,[20] using transverse waves, found 3.7 and 3.5, depending on the method of analysis. The value found from the tunneling experiments of Giaever[21] was 3.6, from Sherril and Edwards[22] 3.59, and from Townsend and Sutton[23] 3.84±0.06. A value of 3.8±0.2 has been found by Mendelssohn[24] from thermal conductivity measurements. The present value lies in the range of these determinations.

The BCS theory predicts an electronic specific heat at the transition C_{es} equal to $2.43\gamma T_c$. The value found for $C_{es}/\gamma T_c$ in these measurements is 2.87.

If the electronic specific heat C_{es} is calculated in the usual way, viz:

$$C_{es}=C_s-C_n+\gamma T;$$

using $\gamma=7.80$ mJ/mole deg^2, the plot of $\ln C_{es}/\gamma T_c$ versus T_c/T gives a straight line for values $5.5>T_c/T>1.7$, indicative of the relation

$$C_{es}/\gamma T_c=ae^{-bT_c/T}.$$

This is shown in Fig. 6. The data obtained from this plot yields $a=8.21$ and $b=1.52$ in fair agreement with the predicted BCS values of 8.5 and 1.44. At values of

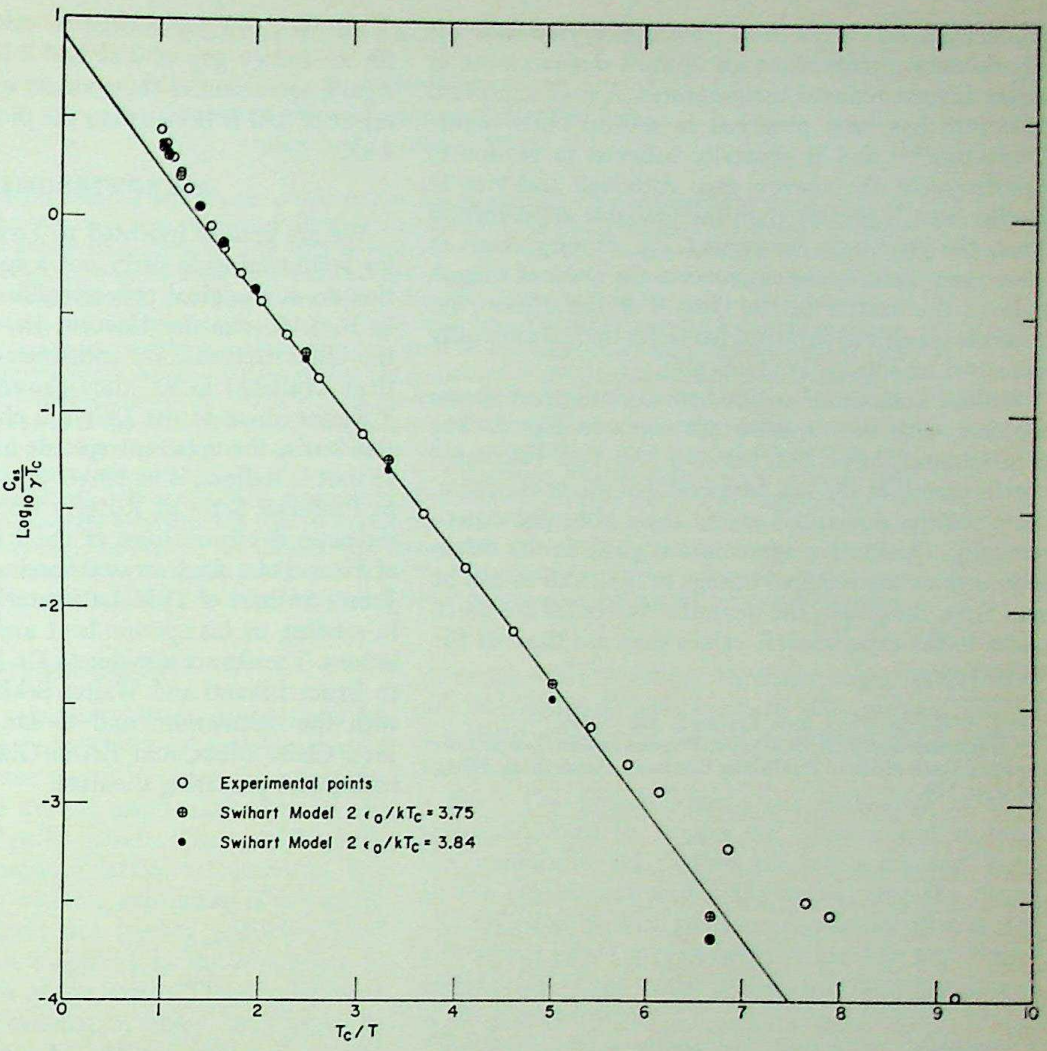

FIG. 6. The superconducting electronic specific heat C_{es} of a single-crystal specimen of Nb plotted on $\ln_{10}(C_{es}/\gamma T_c)$ versus T_c/T axes. Full line is the graph of $C_{es}/\gamma T_c = ae^{-bT_c/T}$, where $a=8.21$ and $b=1.52$. The dots and crossed circles show values computed from Swihart's model.

$T_c/T > 5.5$ the data departs from the exponential as will be discussed below.

Although the BCS theory gives fair agreement with the a and b values, the critical-field deviation curve, the value of the energy gap and the specific-heat jump at the transition all show significant disagreement. However, the BCS calculations were made under the assumption of weak coupling, i.e., that T_c/Θ is small, of the order of 0.003 or less, as for elements such as Zn, Al, and Ga. When T_c/Θ is an order of magnitude greater, however, as is the case for Nb (0.033 for $\Theta = 275°K$ and 0.039 for $\Theta = 241°K$) and In (0.039), the energy gap value increases to about 3.7 and the critical-field deviation has a minimum only about one-third to one-half as low. (See Fig. 5.) Moreover, the deviation actually is positive at the lowest temperatures as was mentioned above. For elements with still higher values of T_c/Θ, e.g., Hg (0.056) and Pb (0.075), the deviation becomes positive throughout the entire temperature range from 0°K to the transition temperature.

Calculations of these properties of superconductors which give closer agreement with the experimental data have been supplied by Swihart in a private communication. He assumed that the energy gap $\epsilon(T)/\epsilon(0)$ was the BCS function of reduced temperature and remained constant with energy out to a cut off of $13.7\epsilon(0)$ instead of to infinity as used in the weak-coupling case by BCS. The calculations were made for two cases, one assuming the ultrasonic energy gap $2\epsilon(0)/kT_c = 3.75$ and the other the value 3.84 obtained from tunneling. These cases correspond to values of T_c/Θ of 0.039 and 0.038, respectively, which are much closer to the values 0.033 and 0.038 for niobium than the weak-coupling values to which the BCS procedure is applicable.

The electronic specific heats calculated by Swihart are compared to the experimental values in Fig. 6. The values are seen to be relatively intensitive to the assumed energy gap values and both sets of calculations agree well with the experimental data for $T_c/T < 5.5$. In contrast to the specific-heat curve of BCS which is applicable only from inverse reduced temperatures greater than about 2.0, the Swihart model agrees well with experiment with T_c/T values almost to the transition temperature. For values of T_c/T greater than 5 or 6, both the BCS theory and Swihart's modification predict a downward displacement of $C_{es}/\gamma T_c$ from the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

exponential. As can be seen from Fig. 6, however, the experimental points show an upward displacement at higher inverse reduced temperatures. A similar upward departure has been observed in several other superconductors[25,26] and is generally believed to be due to anisotropy of the energy gap. Although this rise in specific heat is greater than the probable experimental error, the electronic component, C_{es}, is very small at these temperatures and approaches the order of magnitude of the scatter in the data. For this reason, no accurate quantitative comparison with the ultrasonically measured anisotropy is practicable.

Swihart's calculated critical field deviations are shown together with the experimental curve in Fig. 5. The experimental curve lies between the two calculated curves except at the low temperatures where the calculated positive deviations exceed those observed experimentally. Qualitative agreement is good as the calculations show the required change in sign, and as can be seen from the graph, the quantitative results are much closer to the experimental values than are those of the BCS theory.

For $(C_{es}/\gamma T_c)_{T_c}$ Swihart's calculations yield 2.89 for an energy gap of 3.84 and 2.76 for a gap of 3.75. Again, agreement of these values with the experimental result of 2.87 is better than the predicted BCS value of 2.43.

ACKNOWLEDGMENTS

We are greatly indebted to Professor P. H. Kessom for volunteering to carry out a specific-heat investigation on our original polycrystalline sample of Nb and to B. J. C. van der Hoeven, Jr., who collaborated in the measurements. By measurements at higher fields than available to us, they showed that below about 3°K, the value of the Debye Θ changed to 275°K. On this basis, the apparent specific-heat anomaly, similar to that in indium, is no longer present. We are indebted to Professor Serin at Rutgers University for gas thermometer determinations of the transition temperature of Pb and of a single-crystal specimen of Nb, and to Dr. James Swihart of IBM Laboratories for his generosity in sending us his specific heat and critical field calculations. Thanks are also due to Dr. Leon Schkolnick and to Bruce Biavati and Walter Schillinger for assistance with the calculations and to Dr. Robert Cotellessa, Mrs. Claire Metz, and Erwin Glück for assistance in taking and preparing the data.

PHYSICAL REVIEW VOLUME 134, NUMBER 5A 1 JUNE 1964

Interstitials and Vacancies in α Iron*

R. A. JOHNSON
Brookhaven National Laboratory, Upton, New York
(Received 13 January 1964)

The migration energies and atomic configurations for mono- and di-interstitials and mono- and di-vacancies in α iron have been calculated using a classical model. About 530 atoms surrounding the defect were treated as individual particles, each with three degrees of freedom, while the remainder of the crystal was treated as an elastic continuum with atoms imbedded in it. A two-body central force was devised which matched the elastic moduli, was sharply repulsive at close separation, and which went to zero midway between the second and third neighboring atoms. Configurations were found by choosing a starting configuration roughly approximating the situation under consideration and successively adjusting the value of each variable occurring in the energy equation so that the magnitude of the generalized force associated with it was zero until equilibrium was reached. The energy calculations include changes in bond energy in the discrete region, energy in the elastic field, and work done against cohesive forces, but neglect changes due to the redistribution of electrons. Calculated activation energies for motion of mono- and di-interstitials and mono- and di-vacancies were 0.33, 0.18, 0.68, and 0.66 eV, respectively, and binding energies of di-interstitials and di-vacancies were 1.08 and 0.20 eV, respectively. The stable interstitial was a "split" configuration in which two atoms were symmetrically split in a ⟨110⟩ direction about a vacant normal lattice site, and the stable di-interstitial consisted of two parallel split interstitials at nearest-neighbor lattice sites with their axes perpendicular to the line joining their centers. In the vacancy configuration an atom was missing from a normal lattice site, and the divacancy consisted of two vacancies at second-nearest-neighbor lattice sites.

INTRODUCTION

DETAILED and extensive lattice calculations for copper have been carried out for the dynamics of radiation damage events near the threshold energy for damage,[1] and for the atomic configuration[1–3] and the energy of motion[2,3] of point defects. These studies have used a similar approach to lattice calculations: The forces between atoms within a crystallite of anywhere from 50 to 1000 atoms are treated explicitly, and boundary conditions are applied to the crystallite to simulate the remainder of the lattice. The development of this method of calculation may be traced to Huntington[4] and Tewordt,[5] and a number of less extensive calculations using similar models have been performed.[6] Copper was chosen for investigation primarily because there were sufficient experimental data available, because it was felt that an appropriate and more reliable potential was available for copper than for other metals, and because the face-centered cubic structure is amenable to calculation.

The dynamic calculations[1] have recently been extended to α iron,[7] and the present research was undertaken in conjunction with that investigation. Iron was selected as the metal of greatest interest with a body-centered cubic structure. Pertinent experimental data are lacking for all body-centered cubic metals, but the threshold energy for radiation damage for α iron is known.[8]

Since the present calculation is similar to that previously used for copper by Johnson and Brown,[2] the rationale for this method will not be repeated here. In the present calculation the atoms near the defect are treated as classical particles interacting by means of a potential which applies between the first and second neighboring atoms in the lattice and which is matched to the elastic moduli.

Atomic configurations are found by choosing a starting configuration roughly approximating the situation under consideration, and then successively adjusting the value of each variable occurring in the equation for energy such that the magnitude of the generalized force associated with it is zero, and iterating this process many times. The energy in the lattice above that for a perfect lattice normally converges in the above process. Convergence is not ensured, but no difficulties have been encountered in this respect. The numerical calculations have been performed by using an IBM 7094 computer.

Iron interstitial atoms, di-interstitial pairs, vacancies, and divacancies have been studied, and the activation energy for motion as well as the atomic mechanisms of migration, as predicted by this model, have been determined for these defects. By the application of appropriate boundary conditions, the associated activation volumes for motion have also been found. Some preliminary results have been reported previously.[9]

Calculations are also being carried out for interstitial

impurities in α iron and these results will be reported elsewhere.

THEORY

Model

In the present calculation each atom within a spherical crystallite containing 531 atoms was treated as an independent particle. In the perfect lattice an atom was located at the center of the crystallite and the surrounding 530 atoms comprised 25 shells of symmetrically equivalent atoms.

The atoms outside the crystallite were treated as though they were imbedded in an elastic continuum. The displacement field $\mathbf{u}$ used in the present calculation for the elastic continuum is given by

$$\mathbf{u}=-C\nabla(1/r)=C(\mathbf{r}/r^3), \tag{1}$$

where C is the so-called "strength" of the displacement field. The displacement for a given atom i is given by

$$\mathbf{u}^i=C[\mathbf{r}_0{}^i/(r_0{}^i)^3],$$

where the subscript means that the term is to be evaluated at the perfect lattice position. Thus, C was used as the variable determining the displacement of all atoms outside the crystallite. Equation (1) gives rise to a spherically symmetric displacement field, for which the origin was taken as the center of the crystallite. The choice of the displacement field given by Eq. (1) is discussed in detail by Johnson and Brown.[2] This particular $\mathbf{u}$ is just one of an infinite number of solutions of the static, isotropic, elastic equation, but activation energies and atomic configurations near defects were found to be insensitive to other solutions. The effect of the displacement field given by Eq. (1) on the energies and configurations is relatively minor and this term could be eliminated from the calculation (i.e., the atoms outside the crystallite frozen at their perfect lattice positions) without introducing any serious changes in the results, but it was retained because it can be used to find activation volumes.

The energy of the crystallite is given by

$$E=\tfrac{1}{2}\sum_i\sum_j\varphi^{ij}+\sum_i\sum_k\varphi^{ik}+aC+bC^2, \tag{2}$$

where φ^{ij} is the interaction potential between atoms i and j, the i summation is over all atoms within the crystallite, the j summation is over all atoms within the crystallite which interact with the ith atom, and the k summation is over all atoms outside the crystallite which interact with the ith atom. The term aC accounts for the work done against the forces required to hold the perfect lattice in equilibrium, and the term bC^2 accounts for the energy stored within the elastic field. The energy for a particular configuration is given by $E-E_0$, where E_0 is the perfect lattice energy;

$$E_0=\tfrac{1}{2}\sum_i\sum_j\varphi_0{}^{ij}+\sum_i\sum_k\varphi_0{}^{ik}.$$

The derivation of the coefficients a and b will be given after the discussion of the potential.

The force on an atom i due to an atom j is given by

$$\mathbf{F}^{ij}=(\partial\varphi^{ij}/\partial r^{ij})(\mathbf{r}^{ij}/r^{ij}), \tag{3}$$

where $\mathbf{r}^{ij}=\mathbf{r}^j-\mathbf{r}^i$ (the vector from i to j). The total force on an atom i is then

$$\begin{aligned}\mathbf{F}^i&=-(\partial E/\partial\mathbf{r}^i)\\&=\sum_j\mathbf{F}^{ij}+\sum_k\mathbf{F}^{ik},\end{aligned} \tag{4}$$

where the summation indices have the same meaning as in Eq. (2). The generalized force on the crystallite arising for the elastic variable C is given by

$$\begin{aligned}F^c&=-(\partial E/\partial C)\\&=-\sum_i\sum_k\mathbf{F}^{ik}\cdot(\partial\mathbf{r}^k/\partial C)-a-2bC.\end{aligned} \tag{5}$$

The process for finding energy minima and saddle points was as follows: Initial vector positions of each atom within the crystallite were chosen to approximate the configuration of interest. Each coordinate of each atom within the crystallite was varied in turn until the corresponding force component became zero, and then the value of C was adjusted so that F^c was zero. Usually 10 to 20 such iterations were required for the energy and the configuration to converge sufficiently. The force on a given atom and the generalized elastic force are very nearly linear with displacement for small displacements. Thus, it was possible to find the force for a given variable at two values of the variable and use linear extrapolation to the value where the force is zero.

The volume expansion associated with a lattice configuration is easily calculated and is found to be linear with C, the elastic variable. Let $\Delta V'$ be the volume expansion of a hypothetical sphere around the defect.

$$\begin{aligned}\Delta V'&=\int\int\mathbf{u}\cdot d\mathbf{S}\\&=4\pi C.\end{aligned} \tag{6}$$

$\Delta V'$ is seen to be independent of the radius of the sphere. For a finite lattice, Eshelby[10] has shown that the boundary condition of zero stress at the surface of the lattice gives rise to an additional term in the volume expansion (the so-called "image force" correction). This correction may be written as

$$\Delta V=\Delta V'\{1+[4C_{44}{}^0/(3C_{12}{}^0+2C_{44}{}^0)]\}, \tag{7}$$

[10] J. D. Eshelby, J. Appl. Phys. 25, 255 (1954).

where the superscript indicates that the effective isotropic elastic constants, as given by Leibfried,[11] are to be used.

$$C_{12}^0=\tfrac{1}{5}(C_{11}+4C_{12}-2C_{44})$$
$$C_{44}^0=\tfrac{1}{5}(C_{11}-C_{12}+3C_{44}).$$

Applying these to Eq. (7) leads to

$$\Delta V=\Delta V'\left(1+\frac{4(C_{11}-C_{12})+12C_{44}}{15B}\right), \qquad (8)$$

where B, the bulk modulus, is given by $\frac{1}{3}(C_{11}+2C_{12})$.

Potential

Experimental elastic-constant data were used as a basis for obtaining an interatomic potential for the present calculation. The elastic constants of a metal may be thought of as arising primarily from two contributions: long-range electronic interactions and short range ionic interactions. The short-range interactions predominate for transition metals, but corrections were included for the long-range terms. Analytic expressions for the electronic contribution to the elastic constants of body-centered cubic metals have been derived by Fuchs[12] using the free-electron model. Since the long-range contributions are small and since the free-electron model is expected to be a rough approximation, the calculated values were used only as a guide. The elastic moduli of iron[13] and the long- and short-range contributions used in the present calculation, in units of eV/Å^3, are listed in Table I.

The simplest type of potential that can be used in a lattice calculation is one which gives rise to central forces between pairs of atoms. The ranges of the potential must not be so large as to give rise to an interaction between distant pairs or the calculation becomes too time consuming. For the body-centered cubic lattice, it is natural to cut off the potential between the second and third nearest neighbors, since the ratio of distances to the nearest, second nearest, and third nearest neighbors is $\sqrt{3}$: 2: $2\sqrt{2}$, respectively. Thus, the first and second nearest neighbor distances are comparable, while the third nearest neighbors are considerably more distant. The body-centered cubic structure is not stable with just a nearest-neighbor central force interacting between the lattice atoms, so the potential cannot be cut off between the nearest and second nearest neighbors. Since the potential is meant to describe the short-range ionic interactions, the inclusion of only nearest and second nearest-neighbor interactions is consistent with the division of the elastic-constant data into long-range and short-range contributions.

TABLE I. Elastic moduli of iron (units of eV/Å^3).

	$C_{11}-C_{12}$	C_{44}	B
Electronic contribution	0.057	0.162	0.281
Tonic contribution	0.600	0.600	0.800
Experimental values[a]	0.657	0.762	1.081

[a] See Ref. 13.

The conditions which a spherically symmetric potential $\varphi(r)$ extending through second neighbors must fulfill to match the short-range elastic moduli are

$$(C_{11}-C_{12})_{sr}=\frac{2}{3r_2}\left(\frac{6}{r_1}\varphi_1'+3\varphi_2''+\frac{3}{r_2}\varphi_2'\right), \qquad (9a)$$

$$(C_{44})_{sr}=\frac{2}{3r_2}\left(\varphi_1''+\frac{2}{r_1}\varphi_1'+\frac{3}{r_2}\varphi_2'\right), \qquad (9b)$$

$$(B)_{sr}=\frac{2}{3r_2}\left(\varphi_1''-\frac{2}{r_1}\varphi_1'+\varphi_2''-\frac{2}{r_2}\varphi_2'\right), \qquad (9c)$$

where the primes indicate differentiation with respect to r and the subscripts 1 or 2 mean that the term is to be evaluated at the nearest or second nearest-neighbor distance, respectively. There are three equations with four unknowns. Figure 1 indicates a family of possible curves of $\varphi'(r)$ which fit the conditions in Eq. (9) and which are zero midway between the second and third neighbor distances. The value and slope of $\varphi'(r)$ are determined at r_1 and r_2, and the value is determined at the cut off distance r_c, while the lines indicate how smooth curves might be fitted to these conditions. Curve II, which is roughly parabolic, is the "smoothest" of the family of curves, and no reason is seen to prefer any other to it. Indeed, it would be difficult to rationalize the choice of any of the other curves in preference to the parabolic one. Equation (9) contains

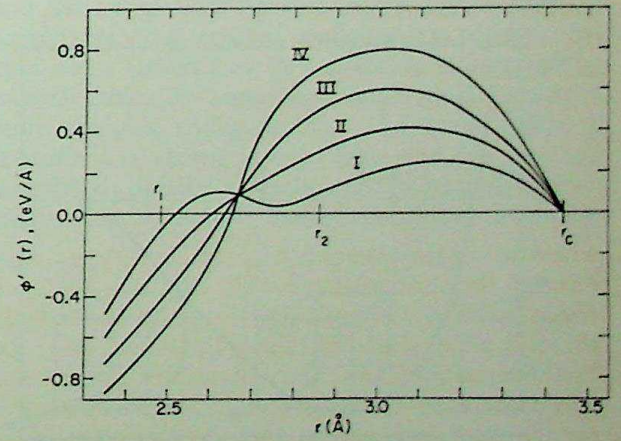

FIG. 1. A family of possible curves of the derivative of the potential, $\varphi'(r)$, which fit the short-range elastic constant conditions and which are zero midway between the second and third nearest neighbor distances.

TABLE II. Iron potential.

Range (Å)	Potential (eV)
1.9–2.4	$-2.195976(r-3.097910)^3+2.704060r-7.436448$
2.4–3.0	$-0.639230(r-3.115829)^3+0.477871r-1.581570$
3.0–3.44	$-1.115035(r-3.066403)^3+0.466892r-1.547967$

three conditions and a parabola has three coefficients, so there is one parabola which fits the elastic moduli exactly. This parabola does not have a zero value midway between the second and third nearest-neighbor distances and so, another parabola was joined to it just past the second neighbor distance with matching value and slope, and zero value midway between the second and third neighbors. These parabolas represent $\varphi'(r)$, the derivative of the potential, and the actual potential was found by integration. The constant of integration was determined by the condition that the value of the potential be zero at the cutoff distance r_c.

Gibson *et al.*[1] and Erginsoy *et al.*[7] have shown that the threshold energy for radiation damage is determined primarily by the form of the potential at separations considerably less than the nearest-neighbor distance; distances which do not enter into the present calculation. It was felt, however, that the potential used here should be matched to the radiation damage potential for iron,[7] and thus, a cubic equation was joined with matching value and slope to the potential derived above at a distance just less than the nearest-neighbor distance, and was joined with matching value and slope to the dynamically determined potential at a distance less than any equilibrium distances expected from the calculation. Thus, the potential was a composite of the three cubic equations given in Table II and is shown in Fig. 2. All distances are given in Å, the iron lattice constant was taken as 2.86 Å, and energies are given in eV.

The coefficients a and b occurring in Eq. (2) may now be easily evaluated. From elastic theory, the pressure required to hold the crystallite in the perfect lattice configuration is[14]

$$P=\tfrac{1}{2}(C_{12}-C_{44})_{sr}$$
$$=\tfrac{1}{2}[(B)_{sr}-(C_{44})_{sr}-\tfrac{1}{3}(C_{11}-C_{12})_{sr}]. \quad (10)$$

For the elastic constants given in Table I for iron, $P=0$ and thus, $a=0$. The value of a may also be found by an explicit bond calculation in which Eq. (5) is evaluated for the perfect lattice with the requirement that $F^c=0$, i.e., that the perfect lattice is in equilibrium. Using the iron potential given in Table II, this calculation yields

$$a=0.0134 \text{ eV/Å}^3,$$

which value was used in the calculations. The discrepancy between this value of a and the value derived from elastic theory is negligible when compared with the magnitude of the elastic moduli. It arises because there is not an exact ratio of 4:3 of nearest to second nearest-neighbor bonds crossing the boundary between the crystallite and the elastic region.

The coefficient b was calculated from elastic theory[14] by setting the energy due to a displacement field $\mathbf{u}$ stored in the elastic field outside the crystallite equal to bC^2. This leads to

$$b=(64\pi^2/5Nr_2^3)[(C_{44})_{sr}+\tfrac{1}{3}(C_{11}-C_{12})_{sr}], \quad (11)$$

where N is the number of atoms in the crystallite. The pressure term aC plays a somewhat more important role than the elastic term bC^2, but for iron both terms could have been eliminated from the calculations with no serious effect upon the results.

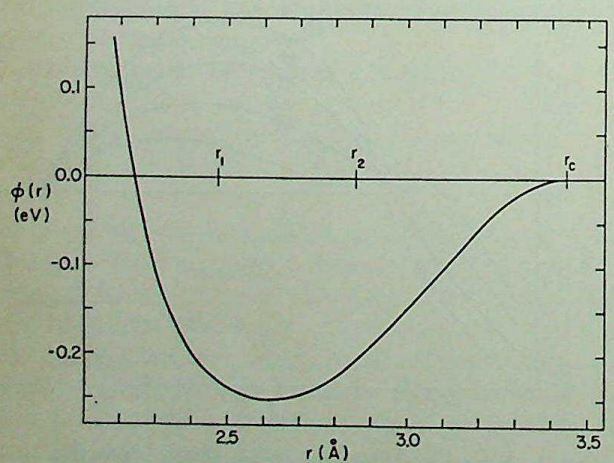

FIG. 2. The iron-iron interaction potential, $\varphi(r)$, which was used in the present calculation.

RESULTS

Interstitials

There are six interstitial configurations which must be equilibrium configurations because of symmetry, but only one of which is stable. These six configurations are denoted by the symbols I_1, $I_2 \cdots I_6$, and are described as follows: I_1 [⟨100⟩ split interstitial, Fig. 3(a)], two atoms are symmetrically split in a ⟨100⟩ direction about a vacant normal lattice site; I_2 [⟨110⟩ split interstitial, Fig. 3(b)], two atoms are symmetrically split in a ⟨110⟩ direction about a vacant normal lattice site; I_3 [⟨111⟩ split interstitial, or crowdion, Fig. 3(c)], two atoms are symmetrically split in a ⟨111⟩ direction about a vacant normal lattice site; I_4 [activated crowdion, Fig. 3(d)], an atom is located at the midpoint between two normal nearest-neighbor lattice sites; I_5 [octahedral interstitial, Fig. 3(e)], an atom is located at the midpoint between two normal second nearest-neighbor lattice sites; and I_6 [tetrahedral interstitial, Fig. 3(f)], an atom is located at the midpoint between two nearest octahedral interstitial sites.

In the three "split" cases the pairs of atoms are approximately 1.5 a_0 apart (a_0=half-lattice constant).

Configuration I_2, the ⟨110⟩ split interstitial, is the minimum energy configuration and is, therefore, stable, in agreement with the results of Erginsoy *et al.*,[7] while I_3, the ⟨111⟩ split interstitial, is just barely a local minimum, i.e., metastable. The energy and volume expansion for the various interstitial configurations are given in Table III. I_7 is the saddle-point configuration for motion of the interstitial, and is somewhat awkward to describe because it does not have much symmetry. If the initial configuration is a [110] split interstitial centered at (0,0,0), the next equilibrium configuration after one jump might be a [101] split interstitial centered at (1,1,1) a_0. The saddle point for this step is at (0.50, 0.69, 0.31) a_0. The migration sequence $I_2 \rightarrow I_7 \rightarrow I_2$ is shown in Fig. 4., and the activation energy for this process was found to be 0.33 eV. The calculation also gave an activation volume for motion of 0.1 atomic volume.

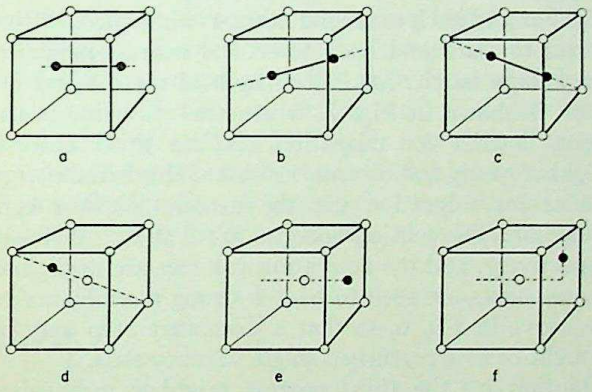

FIG. 3. Six iron interstitial configurations: (a) I_1 or ⟨100⟩ split interstitial; (b) I_2 or ⟨110⟩ split interstitials; (c) I_3, ⟨111⟩ split interstitial or crowdion; (d) I_4 or activated crowdion; (e) I_5 or octahedral interstitial; and (f) I_6 or tetrahedral interstitial.

The crowdion configuration I_3 is metastable, but by less than 0.01 eV, and the crowdion migration sequence $I_3 \rightarrow I_4 \rightarrow I_3$ has an activation energy for motion of 0.04 eV. The activation energy for rotation of a split interstitial, holding the center fixed, was found to be 0.33 eV, the same as the motion energy.

In order to make a complete study of interstitials it was necessary to check for the possible existence of other equilibrium configurations. In a manner similar to that used for copper[2] it was found to be possible to define a configuration by three coordinates. The iron calculations show that no two atoms ever approach each other closer than 1.5 a_0, and that there is always one atom within a radius of 0.75 a_0 from each normal lattice site. Thus, there is always one atom outside a bcc lattice of spheres of radius 0.75 a_0, which atom is defined as the interstitial. If the remaining atoms are at equilibrium positions consistent with the interstitial position, the crystal energy may be considered as a function of just the interstitial coordinates. If two atoms are on opposite ends of a sphere diameter, each is considered half in and half out of the sphere. These are the "split" configurations, and if one atom of a split pair enters the sphere, the other moves away from the sphere and becomes the interstitial. The volume available to the interstitial that must be studied is greatly reduced by symmetry. The volume in which the interstitial coordinates have no symmetrically equivalent position is 1/48 atomic volume, and only about half of this volume is outside the spheres, so, in effect, only about 0.01 atomic volumes must be investigated.

TABLE III. Interstitial configurations (Ω=atomic volume).

Configuration	Energy above I_2(eV)	$\Delta V(\Omega)$
I_1	1.29	1.7
I_2	...	1.6
I_3	0.32	1.7
I_4	0.36	1.7
I_5	1.12	1.4
I_6	0.85	1.5
I_7	0.33	1.7

No further equilibrium configurations of interest were found. The general pattern of the interstitial energy contours was as follows: low energy pockets at I_2 sites; a plateau region containing I_3, I_4, and I_7; and high energies elsewhere. The plateau region is roughly an oblate spheroid with its axis along the line joining two nearest neighbors. It is centered at an I_4 site, has two I_3 sites on its surface where the axis pierces the surface and has six I_7 sites on its outer rim. Not only are the configurations within this region at about the same energy, but there are no steep contours between them.

Di-Interstitials

There are many possible di-interstitial configurations and the calculations showed that many of them are metastable. Di-interstitial configurations consist of two split-single interstitials in reasonably close proximity to each other: No cases were found which resulted in more complex configurations. The most stable di-interstitial is shown in Fig. 5(a), and has two split interstitials parallel to each other at nearest-neighbor lattice sites, with their axes perpendicular to the line

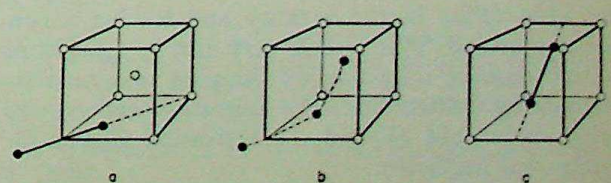

FIG. 4. The iron interstitial migration process. Configurations (a) and (c) are both I_2 configurations, and (b) is I_7, the saddle point configuration.

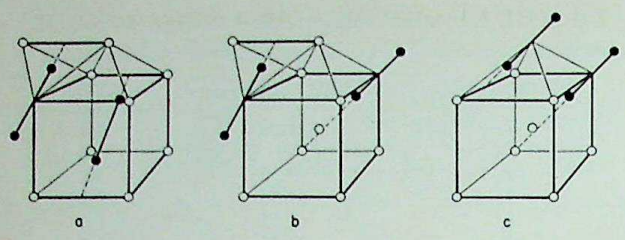

FIG. 5. The iron di-interstitial migration process. Configurations (a) and (c) are both stable di-interstitial configurations, and (b) is the intermediate step between (a) and (c).

joining their centers. The binding energy for this configuration relative to two separated interstitials was 1.08 eV and the associated volume relaxation was 0.3 atomic volumes.

The migration of di-interstitials is by a stepping process in which the two split interstitials partially dissociate. If the initial di-interstitial configuration is an interstitial split in the [110] direction at (0,0,0) a_0 and an interstitial split in the [110] direction at $(1,\bar{1},1)$ a_0, the intermediate configuration might be an interstitial split in the [110] direction at (0,0,0) a_0 and an interstitial split in the [011] direction at (2,0,2) a_0, and the final configuration would then be an interstitial split in the [011] direction at (1,1,1) a_0 and an interstitial split in the [011] direction at (2,0,2) a_0. This two step process is shown in Fig. 5, and it should be noted that the interstitial moving in each step follows a single interstitial migration path. The di-interstitial motion energy was 0.18 eV and the activation volume for motion was 0.3 atomic volumes.

The separation distance at which two split interstitials are bound as a di-interstitial did not have a well defined cutoff, but was calculated to be about 4.4 a_0. This is an average since the value depends upon the direction between the interstitials as well as their individual orientations. This range corresponds to a region of roughly 88 atomic volumes in which split interstitials have positive binding energy.

Vacancies and Di-Vacancies

The vacancy problem was straightforward compared to the interstitial calculations. The stable vacancy was the configuration in which an atom was missing from a normal lattice site, and the migration process consisted of a nearest-neighbor atom to the vacancy jumping from its normal lattice site to the vacancy site, thus filling in the vacancy and leaving a new vacancy behind. This process may also be thought of as the vacancy migrating by jumping to a nearest-neighboring lattice site. The migration energy was found to be 0.68 eV and the activation volume for motion was negligible.

The potential barrier for vacancy motion had a slight depression at the midpoint, i.e., the symmetric configuration at the midpoint of the process was not the saddle point but a local minimum. A single migration jump, therefore, had two saddle points as is shown in Fig. 6, where the energy of the configuration is plotted as a function of the position of the migrating atom. The existence of this metastable configuration should have little physical significance, however, since it is metastable by only about 0.04 eV.

A di-vacancy consists of two single vacancies in close proximity to each other. The most stable di-vacancy was that in which two vacancies were at second nearest-neighboring lattice sites, and the binding energy was 0.20 eV. The binding volume, or volume decrease of the lattice upon formation of a di-vacancy, was 0.1 atomic volumes. Vacancies at nearest neighboring sites were bound by 0.13 eV and vacancies at fourth nearest-neighboring sites were bound by 0.05 eV. No other pairs had an appreciable binding energy.

Di-vacancy migration was by a stepping process, in each step of which one of the vacancies of a di-vacancy pair moved as a single vacancy. Two possible migration processes were important; where the configuration changes from second nearest neighbor to nearest neighbor and back to second nearest neighbor, and from second to third and back to second nearest neighbor. The energy barrier for half of each of these migration paths is shown in Fig. 7, where the solid line is the energy barrier for migration via the third nearest-neighbor configuration and the dashed line is the energy barrier for migration via the nearest-neighbor configuration. The motion energies are 0.66 and 0.78 eV, respectively, and the activation volumes are negligible. These curves are seen to bear a strong resemblance to the curve in Fig. 6, so that a divacancy step may be thought of as a perturbed single vacancy step.

Motion by the third nearest neighbor mechanism always leaves the orientation of the divacancy un-

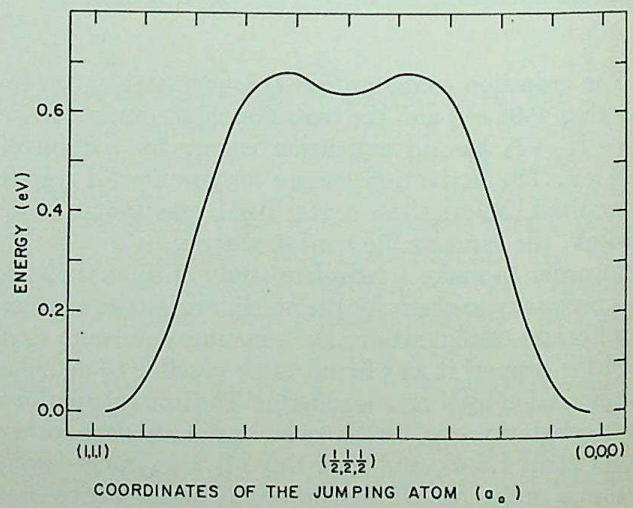

FIG. 6. The vacancy migration energy barrier. The energy of the configuration is shown as a function of the position of the jumping atom, as the vacancy migrates from (0,0,0) at the left to (1,1,1) at the right. The curve does not extend to (1,1,1) and (0,0,0) because the atom relaxes towards the vacancy.

altered, while the orientation may be changed by a nearest neighbor process. The nearest-neighbor configuration also may act as a trap, since 0.71 eV are required for the nearest neighbor to second nearest-neighbor divacancy transition.

A summary of these results is given in Table IV. Interstitial motion is not by the same mechanism as interstitial reorientation, although the energy and volume are the same. The corresponding di-interstitial processes are the same. Vacancies have the symmetry of the lattice and therefore do not have any reorientation process associated with them.

TABLE IV. Summary of results (energy in eV, volume in atomic volumes).

	Motion energy	Motion volume	Binding energy	Binding volume
Interstitial	0.33	0.1		
Crowdion	0.04	0.0		
Di-interstitial	0.18	0.3	1.08	0.3
Vacancy	0.68	0.0		
Di-interstitial	0.66	0.0	0.20	0.1
Interstitial	0.33	0.1	Reorientation	
Di-interstitial	0.18	0.3		
Divacancy	0.78	0.0		

DISCUSSION

Results

Very little experimental data are available pertaining to the results reported in the present paper, but some comparisons may be made for interstitial migration. Lucasson and Walker[8] have obtained isochronal resistivity annealing curves for iron and copper after irradiation with electrons at energies slightly above threshold. They also found that the stage I iron and copper annealing curves can be superposed if the iron temperature scale is reduced by a factor of 2.5.[15] Corbett, Smith, and Walker[16] have found an energy value of 0.12 eV for annealing of stages I_d and I_e in copper and have ascribed this annealing to interstitial migration. Assuming that the corresponding annealing stages in iron are also due to interstitial migration, and assuming that the pre-exponential factor associated with the migration processes of the iron and copper interstitials are roughly the same, then the iron interstitial migration energy is 0.30 eV. The calculated value was 0.33 eV, in very good agreement.

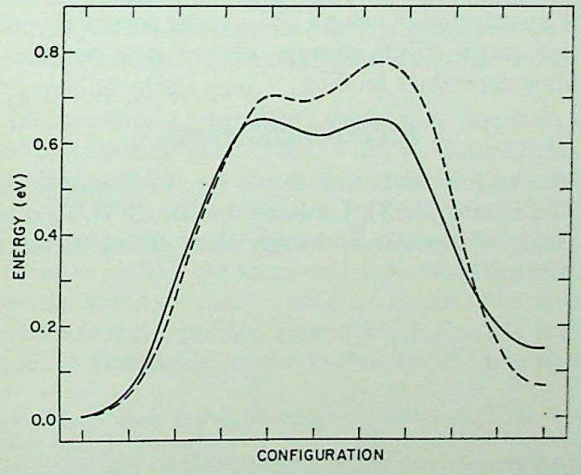

FIG. 7. The divacancy migration energy barrier. The energy of the configuration is plotted as a function of a configuration coordinate (similar to the coordinate of the jumping atom) as the divacancy transforms from a second nearest neighbor configuration on the left to a third nearest neighbor configuration along the solid line and a first nearest-neighbor configuration along the dashed line. Both curves have a mirror image repeat to the right of the drawn curves by which the migration process is completed.

In an internal fraction experiment by Wagenblast and Damask,[17] which searched for a relaxation associated with the interstitial in irradiated iron, the irradiation was performed at 140°K and the relaxation was looked for at higher temperatures, with negative results. Using the interpretation that interstitials anneal in stage I, the work of Lucasson and Walker just discussed shows that the iron interstitial anneals out of iron in ten minutes at 120°K. Thus, this interpretation is consistent with the Wagenblast and Damask findings.

Another interpretation of annealing in copper is that crowdions migrate in stages I_d and I_e and interstitials migrate in stage III.[18] The present calculations of crowdion stability and motion energy do not support this interpretation for iron. The Wagenblast and Damask experiment also does not support this interpretation since they found no indication of an oriented defect over a wide temperature range (140° to 385°K) in iron.

No direct experimental evidence is available for the motion energy of vacancies in iron. The activation energy for self-diffusion in α iron is 2.6 eV,[19] which is the sum of formation and motion energies. Theoretical estimates by Brooks[20] and by Mehl, Swanson, and Pound[21] indicate that the vacancy formation energy is considerably larger than the vacancy motion energy for bcc crystals, so that the motion energy of 0.68 eV reported in the present paper is not unreasonable compared to the self-diffusion energy. However, Damask

et al.,[22] in an extensive study of carbon in α iron did not find a vacancy annealing stage at temperatures which would correspond to a motion energy of 0.68 eV, and the model which they proposed to explain their results assumes that vacancies move at a temperature corresponding to a motion energy of greater than about 1.0 eV.

The present results indicate that none of the defects studied are amenable to internal friction studies. Vacancies have the symmetry of the lattice and are, therefore, eliminated from consideration. The energy to reorient di-vacancies is greater than their motion energy, and so they will anneal before being able to reorient. Both interstitials and di-interstitials require the same energy to migrate as to reorient (migration and reorientation are the same process for di-interstitials), and thus, internal friction experiments would be very difficult to perform as the concentration of defects would be decreasing at a temperature where internal friction would be large. This does not take into account the possibility that the relaxation strength associated with these defects might be sufficiently small so that internal friction could not be measured at experimentally obtainable concentrations. A detailed calculation of this effect was made for copper[23] for an oriented interstitial with the result that even if the defect were present in heavy concentrations, it would be very difficult to detect by internal friction.

Model

The results of the present calculations are considered to accurately represent the model: Increasing the size of the region in which the atoms are allowed full freedom to relax, using greater precision within the calculation, using a different relaxation scheme, etc., would not sensibly affect the results. The important question is whether or not the model satisfactorily represents the real crystal so that the results are meaningful.

This model completely neglects any contribution from the so-called electron redistribution energy, i.e., it does not account for the drastic alteration of the electron wave functions near the defect. The author knows of no method currently available to obtain any sensible estimate of how this term enters into the differences in energy between various configurations. It is felt, however, that in all probability the calculated vacancy migration energy would be increased. It is also felt that the configurations are determined primarily by the close repulsions, so that the electron redistribution would have very little affect upon the configurations.

The energy in this model is not a sensitive function of the volume, and thus, the volume changes for the various configurations should only be considered as a rough approximation.

The choice of a potential is a critical part of any calculation, and it is felt that the potential used in the present calculation is as good an approximation as may be made. It matches the experimental elastic moduli and is fitted to a number of other not unreasonable criteria. A major objection might be that it is cut off after the second nearest neighbor. Aside from the fact that increasing the range of the potential would greatly increase the complexity of the calculation, it is desirable to test the simplest reasonable model first and only incorporate more complex features where necessary. The assumption in using a short range potential is that longer range effects average out to give rise to the volume-dependent binding.

Electronic Spectra of Crystalline Germanium and Silicon*†

DAVID BRUST‡
Argonne National Laboratory, Argonne, Illinois
(Received 9 December 1963)

A detailed calculation of the energy bands of germanium and silicon has been performed by use of the pseudopotential method. The first three potential coefficients have been determined empirically, and all higher ones set equal to zero. This potential was used to compute the energy eigenvalues at ~50 000 points throughout the Brillouin zone. By use of this sample, we calculated the imaginary part of the dielectric constant in the optical and near ultraviolet where direct transitions between the valence and low-lying conduction bands dominate the response. Photoelectric yield curves were obtained for comparison with recent experiments. In all cases agreement of theory and experiment was reasonable. Energy contours were constructed in several of the principal symmetry planes. These were used to explain the structure in the optical properties of Ge and Si in terms of transitions near certain important critical points. Effective masses and the static dielectric constant were also computed.

I. INTRODUCTION

RECENTLY, very precise reflectivity measurements have been taken on[1] Ge and[2] Si in the optical and near ultraviolet region of the electromagnetic spectrum. When the reflectance, $|r(\omega)|^2$, is plotted as a function of ω, the resulting curves show detailed structure. The energies involved ($1.5\ \text{eV}<\hbar\omega<10\ \text{eV}$) are such that direct interband transitions between states lying near to the forbidden gap are expected to dominate the dielectric properties of these materials.

Before attempting an explanation of the observed data, it is necessary to know the behavior of the valence and low-lying conduction bands throughout the Brillouin zone. Prior theoretical work on the energy bands of[3–5] Ge and[6–9] Si has been confined to calculations at points and along lines of particularly high symmetry. This is inadequate for our purposes; we find it necessary to extend the energy-band calculations so as to sample all of the zone.

The previous energy-band work will, however, be used as a starting point. First of all, we shall employ a simplified version of the orthogonalized plane-wave method (OPW method) utilized in Refs. 3–9. Secondly, we shall make use of the eigenvalues at symmetry points in order to deduce the numerical values of the pseudopotential matrix elements used as computational parameters in this simplified approach (see Sec. III of this paper). A reasonably precise knowledge of these eigenvalues (or rather the differences between them) is necessary to undertake the present computations.

For our purposes the energy levels can be put into two categories: levels which are sensitive to small changes in the crystal potential and those which are not. The former have, in the past, been computed *ab initio* with an uncertainty of order 3 eV,[10] while the latter were obtained to within $\sim\frac{1}{2}$ eV. The principal features (peaks and edges) of the optical curves are separated by less than 1 eV. It is necessary, therefore, to know the levels with a considerably greater accuracy than the current *a priori* calculations permit. Fortunately, a good deal of very fine experimental information is available which, when combined with the results of band theory, allows a sharp definition of both the sensitive and insensitive levels. Ehrenreich, Philipp, and Phillips[11] have given a good account of most of the main energy gaps at the symmetry points. Table I is largely taken from their work.

TABLE I. Some of the major energy gaps at the symmetry points $\Gamma=(2\pi/a)(0,0,0)$, $L=(2\pi/a)(\frac{1}{2},\frac{1}{2},\frac{1}{2})$, and $X=(2\pi/a)(1,0,0)$. The labeling of states is after Bouckaert, Smoluchowski, and Wigner.[a] The experimental reference list is by no means exhaustive. Furthermore, energy-band calculations, not included in the table, played an important role in making the identifications.

It should be emphasized at this point that Ehrenreich *et al.* have deduced some of the energy gaps of Table I with the aid of several natural assumptions. They assume, for example, that the main features of the optical curves can be associated with direct transitions between levels at symmetry points. One of the primary purposes of the present work is to attempt a justification of such assumptions and working hypotheses. In order to illustrate further, Ehrenreich *et al.*[11] make use of certain characteristic properties of the reflectivity, as discussed by Phillips,[12] in order to make their assignments in a definite way. For example, the edge near 2.2 eV in Ge has been resolved into a doublet[13] (see Table I). This corresponds to the expected 0.2 eV spin-orbit splitting of the $L_{3'}$ level[14] provided the optical edge is taken as arising from transitions near $L_{3'} \rightarrow L_1$. This assignment was considered as reasonable since both band theory and g-factor information[15,16] indicate an $L_{3'} \rightarrow L_1$ splitting ~ 2 eV.

With the $L_{3'} \rightarrow L_1$ gap determined in Ge it was possible to deduce it in Si.[12] This was done by extrapolating the indirect gap ($\Gamma_{25'} \rightarrow L_1$) in Ge-rich Ge-Si alloys[17,18] to its value in pure Si, and also by extrapolating the $L_{3'} \rightarrow L_1$ optical edge[19] to give a value for the $L_{3'} \rightarrow L_1$ splitting in Si.

The $\Gamma_{25'} \rightarrow \Gamma_{2'}$ splitting was found in Ge by observing the threshold for direct optical transitions.[17,20] Its value could be deduced in Si by the extrapolation of alloy data[17] and also (see Ref. 12) by cyclotron resonance measurements in strained p-type Si.[21] The last-mentioned experiments as well as optical reflectivity were used to find a value for $\Gamma_{25'} \rightarrow \Gamma_{15'}$ in Si. Again cyclotron resonance[22] and extrapolation techniques[19] were used to get $\Gamma_{25'} \rightarrow \Gamma_{15}$ in Ge.[11,12] Finally, $X_4 \rightarrow X_1$ and $L_{3'} \rightarrow L_3$ were determined by comparing band-theory results (these two gaps are both insensitive to the potential) with reflectivity data.

To sum up, the energy levels of Table I provide a model on the basis of which we can begin our detailed calculations. Hopefully we will be able to explain the frequency dependence of the optical properties. This will enable us to establish the validity of Table I and provide us with a much broader understanding of the band structure than has heretofore been possible. Furthermore, the present work in the course of checking the level assignments of Ehrenreich *et al.*[11] and Phillips[12] will confirm or redefine their diagnostic techniques.

Spin-orbit effects will not be accounted for in this paper. They are observable in Ge, as mentioned, but are $<10\%$ of the band separations. These effects, if desired, can be treated as a perturbation, and their influence on the line shape determined.

II. OPTICAL PROPERTIES

A. General Discussion

If $\epsilon_2(\omega)$ is used to denote the imaginary part of the complex dielectric constant, we have from Eq. (9) of Ref. 23

$$\epsilon_2(\omega)=\frac{4\pi^2e^2\hbar}{3m^2\omega^2}\sum_{n,s}\int_{\text{B.Z.}}\frac{2}{(2\pi)^3}\times\delta(\omega_{n,s}(\mathbf{k})-\omega)\,|M_{n,s}(\mathbf{k})|^2d^3k. \quad (1)$$

The subscripts n and s refer to filled and unfilled bands, respectively, and $\omega_{n,s}(\mathbf{k})=(E_s(\mathbf{k})-E_n(\mathbf{k}))/\hbar$. $|M_{n,s}(\mathbf{k})|^2=|(U_{\mathbf{k},n}|\nabla|U_{\mathbf{k},s})|^2$, where $U_{\mathbf{k},n}$ and $U_{\mathbf{k},s}$ represent the periodic parts of Bloch functions. Expression (1) neglects lifetime broadening effects such as those resulting from phonon and impurity scattering. If we ignore for a moment the matrix element in the integral (and the factor $4\pi^2e^2\hbar/3m^2\omega^2$) then the contribution from a given pair of bands to $\epsilon_2(\omega)$ is simply

$$J_{n,s}(\omega)=\int_{\text{B.Z.}}\frac{2}{(2\pi)^3}\delta(\omega_{n,s}(\mathbf{k})-\omega)d^3k. \quad (2)$$

The quantity $J_{n,s}(\omega)$ is the joint density of states for the two bands indexed by n and s. $J_{n,s}(\omega)\Delta\omega$ is equal to the number of pairs of states in bands n and s with $\hbar(\omega-\Delta\omega/2)\leqslant(E_s(\mathbf{k})-E_n(\mathbf{k}))<\hbar(\omega+\Delta\omega/2)$. Later in our discussion of momentum matrix elements we shall see that $|M_{n,s}(\mathbf{k})|^2$ can, to a good approximation, be treated as a constant. This implies that a knowledge of the relevant $J_{n,s}(\omega)$ is all that one requires to understand the properties of $\epsilon_2(\omega)$.

In the Introduction it was stated that the reflectivity data were used as an aid in establishing the model term scheme of Table I. Actually the reflectance is a function of both $\epsilon_1(\omega)$ and $\epsilon_2(\omega)$. However, by examining the figures of Refs. 1 and 2 and comparing them with $\epsilon_2(\omega)$ for Ge and Si presented in Sec. VIII of this paper one sees that $R(\omega)\sim\epsilon_2(\omega)$. All of the principal features in $|r(\omega)|^2$ are reproduced at the same energies in $\epsilon_2(\omega)$.

B. Theory of Optical Structure

At this point it is clear that to understand $\epsilon_2(\omega)$ (we shall direct our attention to the imaginary part of the dielectric constant hereafter), we must carefully examine the functions $J_{n,s}(\omega)$. Expression (2) can be

transformed to

$$J_{n,s}(\omega)=\frac{2}{(2\pi)^3}\int_{\omega_{n,s}(\mathbf{k})=\omega} ds/|\nabla_k\omega_{n,s}(\mathbf{k})|\,, \qquad (3)$$

where the integral extends over the surface defined by $\omega_{n,s}(\mathbf{k})=\omega$ and ds is an infinitesimal element of area on that surface. The points $\mathbf{k}_0$ where $|\nabla_k\omega_{n,s}(\mathbf{k})|_{\mathbf{k}=\mathbf{k}_0}=0$ are significant and are called critical points (c.p.). Van Hove[24] wrote the following expansion, valid about a normal c.p.,

$$\omega_{n,s}(\mathbf{k})=\omega_c+\sum_{\alpha=1}^{3} a_\alpha\epsilon_\alpha\Delta\mathbf{k}_\alpha^2\,, \qquad (4)$$

where $\epsilon_\alpha=\pm1$, $\Delta\mathbf{k}=\mathbf{k}-\mathbf{k}_0$. Here $\omega_c=\omega_{n,s}(\mathbf{k}_0)$, and a coordinate transformation which preserves d^3k has been made so as to get the functional dependence expressed by (4). He found that the critical points produce analytic singularities in what we call $J_{n,s}(\omega)$. The mathematical behavior of $J_{n,s}(\omega)$ near the "Van Hove" singularities is described by the following list:

M_0 $\quad\epsilon_1=\epsilon_2=\epsilon_3=1\,,$

$$J_{n,s}(\omega)=\begin{cases}C+O(\omega-\omega_c) & \text{when } \omega<\omega_c\\ C+A(\omega-\omega_c)^{1/2}+O(\omega-\omega_c) & \text{when } \omega>\omega_c\,,\end{cases} \qquad (5)$$

M_1 $\quad\epsilon_1=\epsilon_2=-\epsilon_3=1\,,$

$$J_{n,s}(\omega)=\begin{cases}C-A(\omega_c-\omega)^{1/2}+O(\omega_c-\omega) & \text{when } \omega<\omega_c\\ C+O(\omega-\omega_c) & \text{when } \omega>\omega_c\,,\end{cases} \qquad (6)$$

M_2 $\quad\epsilon_1=\epsilon_2=-\epsilon_3=-1\,,$

$$J_{n,s}(\omega)=\begin{cases}C+O(\omega-\omega_c) & \text{when } \omega<\omega_c\\ C-A(\omega-\omega_c)^{1/2}+O(\omega-\omega_c) & \text{when } \omega>\omega_c\,,\end{cases} \qquad (7)$$

M_3 $\quad\epsilon_1=\epsilon_2=\epsilon_3=-1\,,$

$$J_{n,s}(\omega)=\begin{cases}C+A(\omega_c-\omega)^{1/2}+O(\omega-\omega_c) & \text{when } \omega<\omega_c\\ C+O(\omega-\omega_c) & \text{when } \omega>\omega_c\,.\end{cases} \qquad (8)$$

In each of these expressions C and A represent constants. The symbol M_0 designates a minimum in $\omega_{n,s}(\mathbf{k})$, M_3 denotes a maximum, and M_1 and M_2 refer to saddle points. In Figs. 1(a)–1(d) we plot the behavior of $J_{n,s}(\omega)$ near the Van Hove singularities. One can already see the way in which a critical point can produce *edges* in the joint density of states and hence in $\epsilon_2(\omega)$. In Fig. 1(e) we show the possibility of two nearly degenerate critical points of the M_1 and M_2 type producing a peak-like structure in $J_{n,s}(\omega)$. Later work by Phillips[25] showed that the periodicity of the energy bands requires the existence of a minimal set of critical points. From group theoretical arguments he demonstrated that

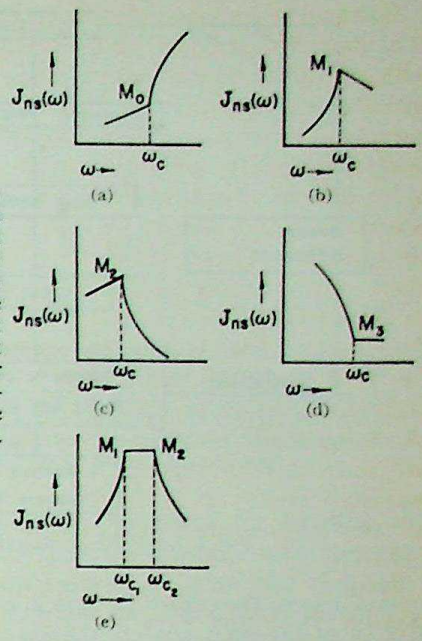

FIG. 1. Joint density of states near a normal critical point (a) M_0, (b) M_1, (c) M_2, (d) M_3, (e) a nearly degenerate pair M_1 and M_2. It should be noted that the slope of the linear portion is not determined by the nature of the critical point.

critical points occur at symmetry points. In the simplest cases (e.g., lattice vibration spectra), almost all the critical points may occur at symmetry points. In the absence of detailed information about $E(\mathbf{k})$ throughout the Brillouin zone, the empirical analysis of the previous section was confined to symmetry points. For the complicated band structures of Ge and Si this simplification (which has also been made in order to interpret the ultraviolet spectra of the noble metals) is certainly not valid. Moreover, the constants in (5)–(8) which indicate the strength of a given edge can only be obtained from values of $E(\mathbf{k})$ throughout the Brillouin zone.

C. Band-Structure Approach to Optical Properties

We now wish to do a band-structure calculation with the view of deriving $\epsilon_2(\omega)$. A description of the logical framework to be employed is the following. First a method of computing the bands will be proposed. The method should have a small number of disposable parameters. In order to determine these parameters, the term scheme discussed in Sec. I will be used as a starting point. Having set the parameters, we shall then proceed to find the bands throughout the Brillouin zone. From the band structure $\epsilon_2(\omega)$ can be computed. If the dielectric function agrees with experiment, we shall conclude that both the model of Sec. I and the computed band structure are correct. Should there be substantial disagreement then a consistent alternate to the starting term scheme will be tried, and a corrected band structure found. A schematic diagram of this is shown in Fig. 2.

Since the optical structure is associated with critical points, we must find them in the computed bands. Of course, we know that they will appear at the symmetry points, and they will have energies which correspond to

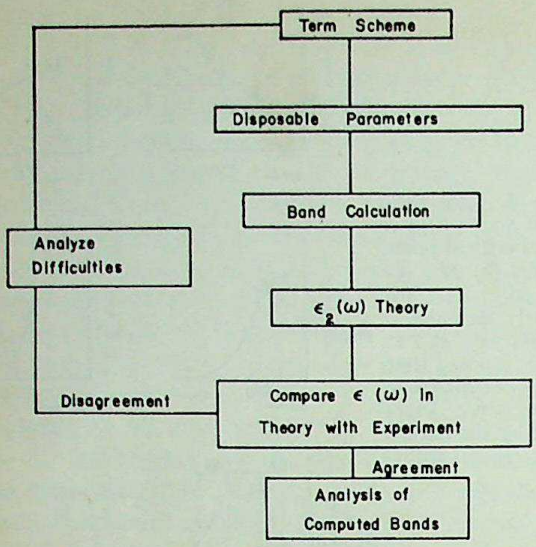

FIG. 2. Logical flow diagram.

optical edges. We cannot be sure in advance that they will be of the right analytical class or will contribute edges of the correct strength. Furthermore, there may be critical points away from the principal symmetry points, in which case they will have to be located.

III. PSEUDOPOTENTIAL METHOD

We mentioned earlier that for certain levels the OPW technique is only accurate to ~ 3 eV.[10] Furthermore, the unwieldy nature of the orthogonalization terms makes it unsuitable for extensive calculations. These considerations imply that the OPW method is unsuited for our needs.

Research workers using the OPW method noticed that the effect of orthogonalizing the plane waves to core orbitals was to greatly diminish the magnitude of the off-diagonal matrix elements in the secular equation. This led Phillips and Kleinman[26] to write the wave functions in the form

$$\psi_{n,\mathbf{k}}(\mathbf{r})=\phi_{n,\mathbf{k}}(\mathbf{r})-\sum_l \langle\theta_{l,\mathbf{k}}(\mathbf{r})|\phi_{n,\mathbf{k}}(\mathbf{r})\rangle\theta_{l,\mathbf{k}}(\mathbf{r}). \quad (9)$$

Here $\theta_{l,\mathbf{k}}$ is the core function constructed from the lth core orbital, and $\phi_{n,\mathbf{k}}$ is a smooth wave function satisfying the wave equation

$$(P^2/2m+V_c+V_R)\phi_{n,\mathbf{k}}=E_n(\mathbf{k})\phi_{n,\mathbf{k}}, \quad (10)$$

where V_c is the crystal potential. The operator V_R has the character of a repulsive potential. Cohen and Heine[27] show that $\phi_{n,\mathbf{k}}$ and V_R are not unique. By a variational argument they demonstrated that the latter can be chosen so as to minimize

$$V_{\text{eff}}=V_c+V_R, \quad (11)$$

in which case V_R has the form

$$V_R\phi_{n,\mathbf{k}}=-\sum_l(\theta_{l,\mathbf{k}}|V_c\phi_{n,\mathbf{k}})\theta_{l,\mathbf{k}}. \quad (12)$$

[26] J. C. Phillips and L. Kleinman, Phys. Rev. **116**, 287 (1959).
[27] M. H. Cohen and V. Heine, Phys. Rev. **122**, 1821 (1961); also, see Ref. 30.

From (11) it is apparent that if the set of core orbitals were complete, perfect cancellation of $(V_c\phi_{n,\mathbf{k}})$ by $(V_R\phi_{n,\mathbf{k}})$ would result (the bands would then be completely free electron). The core orbitals form a surprisingly good basis set in the core region. This implies that the Fourier coefficients of $V_{\text{eff}}^{\mathbf{G}_i}=V_c^{\mathbf{G}_i}+V_R^{\mathbf{G}_i}$ are small for large values of $\mathbf{G}_i=(a/2\pi)\mathbf{K}_i$ where $\mathbf{K}_i$ is a reciprocal lattice vector.[28] This suggests introducing a pseudopotential with Fourier coefficients $V_p^{\mathbf{G}_i}\simeq V_{\text{eff}}^{\mathbf{G}_i}$ which are zero for $|\mathbf{G}_i|$ greater than the first two or three values.[29] A pseudopotential of this form was first introduced by Phillips.[30] He, however, chose $V_p^{\mathbf{G}_i}$ = const for large $\mathbf{G}_i$. Bassani and Celli,[31] on the other hand, took $V_p^{\mathbf{G}_i}=0$ for $\mathbf{G}_i$ such that $|\mathbf{G}_i|^2>11$ which materially improved the convergence in agreement with the variational arguments of Cohen and Heine.

In this paper we shall adopt a pseudopotential having the form used by Bassani and Celli. For both Ge and Si this will be of the form

$$V_p=\sum_j V_p^{\mathbf{G}_j}\exp[(2\pi i/a)\mathbf{G}_j\cdot\mathbf{r}],$$

$$V_p^{\mathbf{G}_j}=V_p(3)\cos\left[(\mathbf{G}_{j,1}+\mathbf{G}_{j,2}+\mathbf{G}_{j,3})\frac{\pi}{4}\right] \quad \text{if} \quad |\mathbf{G}_j|^2=3,$$

$$=V_p(8)\cos\left[(\mathbf{G}_{j,1}+\mathbf{G}_{j,2}+\mathbf{G}_{j,3})\frac{\pi}{4}\right] \quad \text{if} \quad |\mathbf{G}_j|^2=8,$$

$$=V_p(11)\cos\left[(\mathbf{G}_{j,1}+\mathbf{G}_{j,2}+\mathbf{G}_{j,3})\frac{\pi}{4}\right] \quad \text{if} \quad |\mathbf{G}_j|^2=11,$$

$$=0 \quad \text{if} \quad |\mathbf{G}_j|^2>11.$$

Here $\mathbf{G}_{j,1}$ is the projection of $\mathbf{G}_j$ on the (1,0,0) direction (direction normal to a square face). There are then three adjustable parameters $V_p(3)$, $V_p(8)$, and $V_p(11)$. We should point out that V_{eff} is both l and $\mathbf{k}$ dependent. That is, it is different depending on whether $\phi_{n,\mathbf{k}}$ has s or p symmetry, and also varies throughout the Brillouin zone. This nonlocal character is a consequence of the OPW method. We notice, however, that V_p is a local (function of $\mathbf{r}$ only) potential. This simplifying feature cannot be regarded as deleterious. The energy eigenvalues which result from using V_p are generally within 2 eV of those deriving from the use of V_{eff}. The latter, one remembers, gives energies certain to only 3 eV furthermore, V_p will be adjusted at the outset to agree with what we believe to be a large number of symmetry term values. We would then expect V_p to give eigenvalues at other points of the zone with an error much

[28] In these units the center of the hexagonal face is located at $(\frac{1}{2},\frac{1}{2},\frac{1}{2})$ and the shortest nonzero $\mathbf{G}_i$ has length $=\sqrt{3}$.
[29] We are here distinguishing between V_{eff} which is uniquely defined by (7) and (8) and V_p which is an approximation to V_{eff}. Inserting V_{eff} into (6) gives exactly the same results as the OPW method from which it is derived, whereas V_p does not.
[30] J. C. Phillips, Phys. Rev. **112**, 685 (1958).
[31] F. Bassani and V. Celli, Phys. Chem. Solids **20**, 64 (1961).

less than the OPW method. The pseudopotential in a sense circumvents the task of finding a crystal potential replete with a correct exchange interaction, Coulomb interaction, etc. It fits, instead, the most important terms in the potential to experiment.

One more point should be made. Bassani and Celli do distinguish between s- and p-like states by allowing $V_s(0)$ to differ from $V_p(0)$. In this way they can raise s-like states with respect to p-like states. We have found that this is not necessary to get an adequate fit to the experimental interpretation of the levels.

IV. DIAGONALIZATION PROCEDURE

We seek to determine the energy eigenvalues of our model wave equation

$$H_p\phi_{n,\mathbf{k}}=E_{n,\mathbf{k}}\phi_{n,\mathbf{k}}, \tag{13}$$

where $H_p=(-\hbar^2/2m)\nabla^2+V_p$. To do this we must in principle solve the infinite secular equation

$$|H_p{}^{i,j}-E\delta_{i,j}|=0. \tag{14}$$

Here $H_p{}^{i,j}=\langle\phi_{\mathbf{k}+\mathbf{K}_i}|H_p|\phi_{\mathbf{k}+\mathbf{K}_j}\rangle$ and $\phi_{\mathbf{k}+\mathbf{K}_i}=e^{i(\mathbf{k}+\mathbf{K}_i)\cdot\mathbf{r}}$. That is, we use a plane-wave representation in which to expand the $\phi_{n,\mathbf{k}}$. The lowest four levels will represent valence states and the higher one's conduction states (one remembers that the core levels have been eliminated from the problem by the orthogonalization procedure). Only the low-lying conduction levels are of interest so that we shall ask for only the first eight eigenvalues of H_p (four valence and four conduction).

Assuming that the $\phi_{\mathbf{k}+\mathbf{K}_i}$ have been ordered so that for $i>j$, $|\mathbf{k}+\mathbf{K}_i|^2\geq|\mathbf{k}+\mathbf{K}_j|^2$, we may truncate the secular Eq. (14) so as to include contributions from only those plane waves for which $i,\ j\leq N$ (N some integer). We expect the low-lying levels to converge to their final values as N is made large. If we take as our convergence criterion that $|E_{n,\mathbf{k}}{}^{N=N_0}-E_{n,\mathbf{k}}{}^{N=\infty}|<0.1$ eV then N_0 would have to be $\sim$50. The time required by the IBM 704 to diagonalize a 50×50 matrix at a large number of points was judged as too great to make this approach feasible. By augmenting the calculation with perturbation theory it is possible, however, to reduce greatly the computing time.

A form of perturbation theory, e.g., Löwdin[32] was used instead of the Rayleigh-Schrödinger method. We seek the eigenvalues of the secular equation

$$|U_p{}^{n,m}-E\delta_{n,m}|=0, \tag{15}$$

$$U_p{}^{n,m}=H_p{}^{n,m}+\sum_{\gamma=N+1}^{\Gamma}\frac{H_p{}^{n,\gamma}H_p{}^{\gamma,m}}{E-H_p{}^{\gamma,\gamma}}, \tag{16}$$

with $n,\ m\leq N$ and $\gamma>N$ but $\leq\Gamma$ where N and Γ are integers. The indexes n and m refer to plane waves being treated exactly; whereas Γ refers to higher plane waves being treated only through perturbation theory. This procedure is especially convenient for handling degenerate and quasidegenerate cases as it is not necessary to find linear combinations of zero-order degenerate states as in the standard method. This is particularly advantageous when automatic computing machinery is employed.

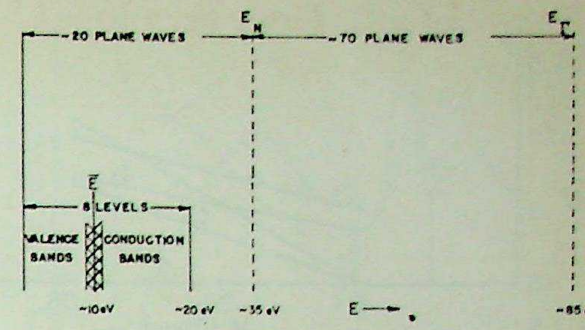

FIG. 3. The approximate relationship of the quantities entering the band calculation. $\bar{E}$ represents an average energy for the valence and conduction bands. E_N is a cutoff energy such that all plane waves with kinetic energy $(\hbar^2/2m)|\mathbf{k}+\mathbf{K}_i|^2\leq E_N$ are treated exactly, whereas those having a kinetic energy between E_N and E_Γ are accounted for by perturbation theory.

Before proceeding it was necessary to eliminate the eigenvalue dependence of the matrix elements in (15). If this were not done, we should have to solve for each of the eigenvalues separately and to use an iteration procedure for each of them. We wished, instead, to diagonalize (15), and obtain all eight interesting levels at once.

In handling the matrix elements the following substitutions were made: off the diagonal $\sum_\gamma(H_p{}^{n,\gamma}H_p{}^{\gamma,m})/(E-H_p{}^{\gamma,\gamma})\rightarrow\sum_\gamma(H_p{}^{n,\gamma}H_p{}^{\gamma,m})/(E-H_p{}^{\gamma,\gamma})$, that is, $E\rightarrow\bar{E}$. Here $\bar{E}$ is an average of the eight energy levels at each point in the reduced zone. On the diagonal $\sum_\gamma(H_p{}^{n,\gamma}H_p{}^{\gamma,n})/(E-H_p{}^{\gamma,\gamma})\rightarrow\sum_\gamma(H_p{}^{n,\gamma}H_p{}^{\gamma,n})/(H_p{}^{n,n}-H_p{}^{\gamma,\gamma})$, i.e., $E\rightarrow H_p{}^{n,n}=(\hbar^2/2m)|\mathbf{k}+\mathbf{K}_n|^2$.

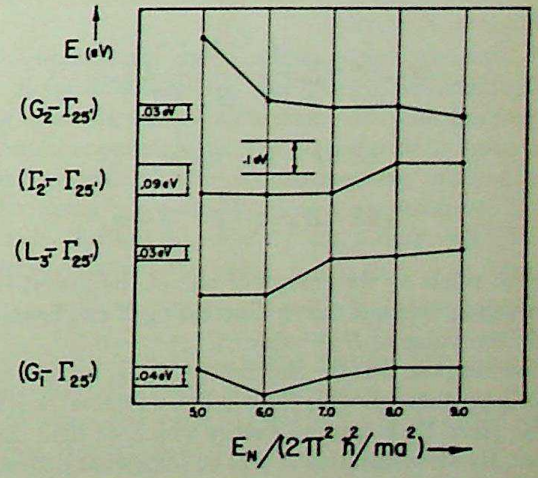

FIG. 4. Shows the convergence properties of the worst cases among those tested. G_1 and G_2 refer to states at the general point of the zone with $\mathbf{k}=(0.60,0.35,0.10)$. The energies (in eV) at the left are an estimate of the convergence for $E_N=7.0$ (the value actually used). They were gotten by comparing with the results for $E_N=9.0$.

[32] P. Löwdin, J. Chem. Phys. 19, 1396 (1951).

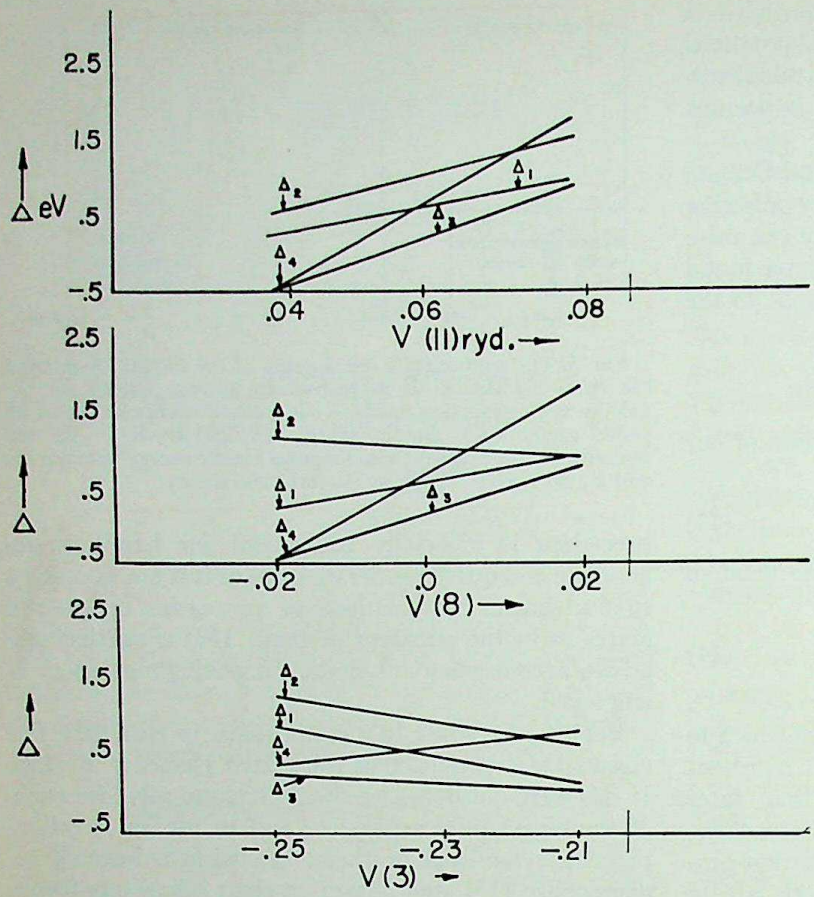

FIG. 5. Variation of some of the principal band gaps with the potential coefficients. In eV: $\Delta_1=(X_1-X_4)-3.0$, $\Delta_2=(L_3-L_{3'})-4.5$, $\Delta_3=(L_1-L_{3'})-1.5$, $\Delta_4=(\Gamma_{2'}-\Gamma_{25'})$; (a) $V(3)=-0.21$ Ry, $V(8)=0.0$ Ry; (b) $V(3)=-0.23$ Ry, $V(11)=0.06$ Ry; (c) $V(8)=0.0$ Ry, $V(11)=0.06$ Ry.

We here, in essence, replace E by the kinetic energy of the principal plane waves making up the expansion of $\phi_{n,\mathbf{k}}$. This allows a closer representation of E than any one choice of $\bar{E}$ permits. It was felt that the more accurate representation of the diagonal matrix elements would improve the convergence.

The error $\Delta U_p{}^{n,m}$ in a matrix element resulting from these approximations is

$$\Delta U_p{}^{n,m}\approx\sum_\gamma \frac{H_p{}^{n,\gamma}H_p{}^{\gamma,m}}{(E-H_{\gamma,\gamma}{}^p)^2}\delta E,$$
$$\delta E=\bar{E}-E, \quad n\neq m, \tag{17}$$
$$\delta E=H_p{}^{n,m}-E, \quad n=m.$$

Since E refers to the energy of one of the lowest eight eigenvalues, one sees that by increasing N and hence the minimum value of $H_p{}^{\gamma,\gamma}$ that $\Delta U_p{}^{n,m}\to 0$.

Now suppose that the plane waves $\phi_{\mathbf{k}+\mathbf{K}_n}$ being treated exactly are those obeying the condition $(\hbar^2/2m)|\mathbf{k}+\mathbf{K}_n|^2 \leqslant E_N$. Here E_N is a cutoff energy which we shall choose below. By this definition N will be somewhat dependent on $\mathbf{k}$. In a like manner the plane waves $\phi_{\mathbf{k}+\mathbf{K}_\gamma}$ entering the calculation through perturbation theory satisfy $E_N<(\hbar^2/2m)|\mathbf{k}+\mathbf{K}_\gamma|^2\leqslant E_\Gamma$.

The actual choice of E_N, E_Γ, and $\bar{E}$ depend on an intelligent use of trial and error. The values ultimately chosen were

$$E_N=7.0(2\pi^2\hbar^2/ma^2)\sim 35 \text{ eV},$$
$$E_\Gamma=19.0(2\pi^2\hbar^2/ma^2)\sim 85 \text{ eV},$$
$$\bar{E}=2.0(2\pi^2\hbar^2/ma^2)\sim 10 \text{ eV}.$$

With this choice N was $\sim$20 and $\Gamma\sim$90. In Fig. 3 we show these values in comparison with the band energies.

The question of convergence was examined by observing the change in the eigenvalues as E_N was increased. In Fig. 4 the levels showing the poorest convergence among the test cases are plotted as a function of E_N. One should note that convergence is good to $\sim$0.05 eV which is within the limits of the accuracy being sought.

V. PSEUDOPOTENTIAL PARAMETERS

We now turn to a brief discussion concerning the choice of the pseudopotential coefficients. The work of Bassani and Celli[31] on Ge was found to be a convenient starting point. Since the present work makes no distinction between s and p symmetry, it was necessary to redefine their potential slightly. In determining the Fourier coefficients particular emphasis was placed on getting good agreement with the proposed interpretation of the optical experiments. That means we sought to make the direct splittings such as $L_{3'}\to L_3$, $L_{3'}\to L_1$, etc., come as close as possible to the experimental

TABLE II. Energy of principal gaps (in eV).

Gap	Bassani (Ge)	Brust (Ge)	Brust (Si)
$\Gamma_{25'} \rightarrow \Gamma_{2'}$	0.8	0.6	3.8
$\Gamma_{25'} \rightarrow \Gamma_{15}$	3.4	3.6	3.4
$L_{3'} \rightarrow L_1$	2.0	1.8	3.1
$L_{3'} \rightarrow L_3$	5.4	5.4	5.4
$X_4 \rightarrow X_1$	4.4	3.6	4.0

identification. Since at our first trial we sought to test the proposed energy model by attempting to get the correct structure in the optical properties, it was natural to make the splittings agree as closely as possible with the model.

In order to reduce the labor required to get a good set of pseudopotential parameters the graph shown in Fig. 5 was prepared. This indicates how the principal band gaps vary with changes in the potential coefficients. By using this a good fit could be obtained with only one or two trials for both Ge and Si. In this way we found for Ge: $V(3)=-0.23$ Ry, $V(8)=0.0$ Ry, and $V(11)=0.06$ Ry; while for Si: $V(3)=-0.21$ Ry, $V(8)=0.04$ Ry, and $V(11)=0.08$ Ry. The term values resulting from these choices are given in Table II where our Ge results are compared with those of Bassani and Celli.

The values of Table II are somewhat different from those of Table I. It is not possible to get an exact fit with a three-parameter potential. If one required a better set of values, additional coefficients would have to be introduced into the potential.

It was of interest to compute the energy bands along symmetry directions. These are shown in Fig. 6, and should be compared with earlier results obtained by Herman on Ge and by Kleinman and Phillips for Si. We should point out that the good behavior of our bands was used as an indication of both the convergence of our computational procedure and of the correctness of the pseudopotential approach.

We are now in a position to go on to a calculation of $\epsilon_2(\omega)$. Before doing this, however, we shall examine the result of computing effective masses according to the present scheme.

VI. EFFECTIVE MASSES

We wish to determine the effective masses of the conduction electrons within the framework of the pseudopotential method. Doing this for Ge by the formulas of $\mathbf{k}\cdot\mathbf{p}$ perturbation theory we have for Ge, e.g., Liu[14]

$$\left(\frac{m_e}{m_t^*}\right)=1+\frac{2}{m}\frac{|\langle L_1|P_{y'}|L_{3'}{}^{y'}\rangle|^2}{(E_{L_1}-E_{L_{3'}})}. \qquad (18)$$

Here $P_{y'}$ is a momentum operator in a direction transverse to the (1,1,1) direction. Using our pseudopotential

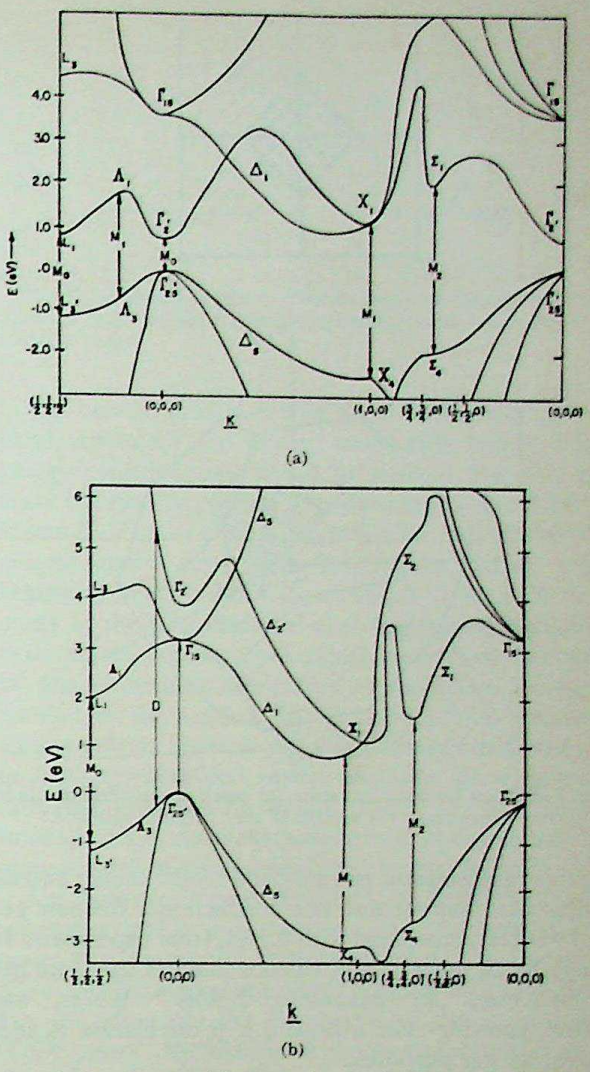

FIG. 6. Pseudopotential energy bands along Δ, Λ, and Σ symmetry directions. Some of the principal transitions have been marked.

wave functions the momentum matrix element was found to be $0.73\hbar^2(2\pi/a)^2$. The energy denominator is 1.8 eV. Putting these values into (18) one finds $m_t^*=0.12m_e$ compared with the experimental value of $0.082m_e$. Considering the approximations, used to get m_t^* the result is reasonably close to experiment. This value was checked by directly computing $E(\mathbf{k})$ in a transverse direction and using

$$m_e/(m_t^*)=[2m_e(E(\Delta\mathbf{k}+\mathbf{k}_L)-E(\mathbf{k}_L))]/\hbar^2(\Delta\mathbf{k})^2.$$

This also gave us $0.12m_e$, which justifies the use of a two-band model in the $\mathbf{k}\cdot\mathbf{p}$ calculation.

For Si where the minima correspond to Δ_1 states, we have from Dresselhaus[33]

$$\left(\frac{m_e}{m_t^*}\right)=1+\sum_1\frac{|\langle\Delta_1|P_y|\Delta_5{}^1\rangle|^2}{(E_{\Delta_1}-E_{\Delta_5{}^1})}. \qquad (19)$$

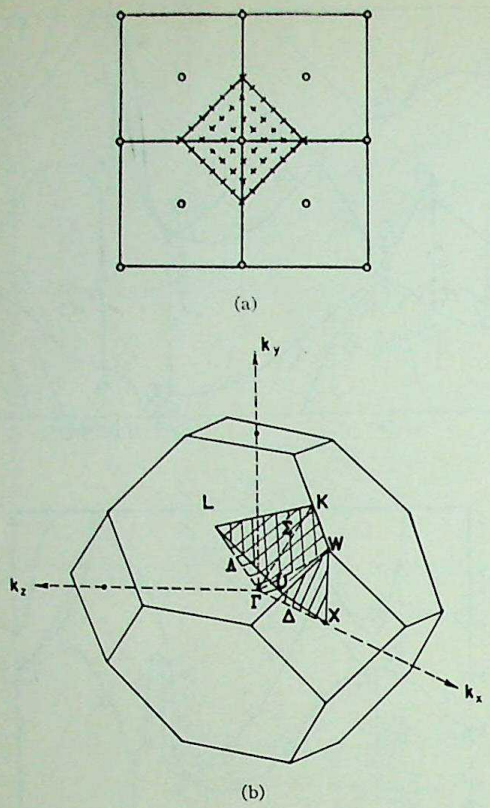

FIG. 7. Scheme for sampling zone (a) mesh of sampling points in two dimensions, (b) section of zone actually sampled.

In this case we must use a 3-band model taking two Δ_5 states (one valence and one conduction). We now get $m_t^*=0.17m_e$ compared with $0.19m_e$ from experiment. If only the Δ_5 state in the valence band is used, we get $m_t^*=0.14m_e$. By examining $E(\mathbf{k})m_t^*=0.17m_e$ was found, showing that a 3-band $\mathbf{k}\cdot\mathbf{p}$ calculation is adequate for our purposes.

VII. SAMPLING PROCEDURES

With a view toward finding $\epsilon_2(\omega)$ we discuss the calculation of the joint density-of-states functions $J_{ns}(\omega)$ defined by Eq. (2). Since in practice it is possible to solve for the eigenvalues of H_p at only a finite number of points in the reduced zone, we must replace the integral in (2) by a finite sum. This was done by defining the quantity

$$K_{ns}(\omega_i)=\sum_{\mathbf{k}_l}\delta^{\Delta\omega}(\omega_{ns}(\mathbf{k}_l)-\omega_i). \tag{20}$$

Here $\mathbf{k}_l$ is a set of uniformly spaced sampling points lying within the first Brillouin zone. The delta function is defined by

$$\delta^{\Delta\omega}(\omega_{ns}-\omega_0)=1 \quad \text{if} \quad |\omega_{ns}-\omega_0|\leqslant(\Delta\omega/2)=0 \text{ otherwise.} \tag{21}$$

The function $K_{ns}(\omega_i)$ is then defined for a set of values ω_i such that $\omega_{i+1}=\omega_i+\Delta\omega$. The meaning of $K_{ns}(\omega_i)$ is clear. It measures the number of pairs of states in bands n and s with direct energy gap $\hbar\omega_{ns}=\hbar\omega_i\pm\hbar(\Delta\omega/2)$ as found in the sample. The relationship between $K_{n,s}(\omega_i)$ and $J_{ns}(\omega)$ is

$$K_{ns}(\omega_i)=\frac{\Delta\omega}{\Delta^3k}\frac{(2\pi)^3}{2}J_{ns}(\omega=\omega_i), \tag{22}$$

where Δ^3k is the elementary volume surrounding the sampling points.

In making a choice for $\Delta\omega$ we were guided by the consideration that most of the experimental structure in $\epsilon_2(\omega)$ has a half-peak width $\sim\frac{1}{2}$ eV. We consequently took $\Delta\omega=0.1$ eV$/\hbar$ as a reasonable value.

The reciprocal lattice vectors of the diamond structure form a bcc lattice. The most natural choice for the sampling vectors $\mathbf{k}_l$ is a mesh of points forming a bcc array. This was reduced in size from the host lattice by a scaling factor of 36. That is, the $\mathbf{k}_l$ are determined by $\mathbf{k}_l=\mathbf{K}_l/36$ where $\mathbf{K}_l$ are reciprocal lattice vectors. This idea is demonstrated for a two-dimensional body centered structure in Fig. 7(a). With this reduction in scale the calculation gives results for $36^3=46\,656$ $\sim 50\,000$ points in the reduced zone.

Advantage was taken of the 48-fold symmetry of the Brillouin zone of the diamond structure. It is then necessary to examine only that 1/48th part of the zone indicated in Fig. 7(b). This region is defined by the conditions

$$0\leqslant(\mathbf{k}_l)_z\leqslant(\mathbf{k}_l)_y\leqslant(\mathbf{k}_l)_x, \tag{23}$$

and $\mathbf{k}_l$ contained within the first Brillouin zone. The contribution to $K_{ns}(\omega_i)$ from a point $\mathbf{k}_l$, in the interior of the sampling region is then taken to be 48. The number 48 is referred to as the weighting factor W of the point $\mathbf{k}_l$.

For points not in the interior of the sampling region W is easily found. We simply find the number of regions between which the point $\mathbf{k}_l$ is shared. If we call this number C, then $W=48/C$. For points not on the Brillouin zone surface C is found as follows:

$$\begin{aligned}
C&=\left\{\begin{matrix}1\\2\end{matrix}\right\}, \quad \text{if} \quad (\mathbf{k}_l)_x\neq(\mathbf{k}_l)_y\neq(\mathbf{k}_l)_z\begin{matrix}\neq0\\=0\end{matrix}\Big\},\\
C&=\left\{\begin{matrix}2\\8\end{matrix}\right\}, \quad \text{if} \quad (\mathbf{k}_l)_x\neq(\mathbf{k}_l)_y=(\mathbf{k}_l)_z\begin{matrix}\neq0\\=0\end{matrix}\Big\},\\
C&=\left\{\begin{matrix}2\\4\end{matrix}\right\}, \quad \text{if} \quad (\mathbf{k}_l)_x=(\mathbf{k}_l)_y\neq(\mathbf{k}_l)_z\begin{matrix}\neq0\\=0\end{matrix}\Big\},\\
C&=\left\{\begin{matrix}6\\48\end{matrix}\right\}, \quad \text{if} \quad (\mathbf{k}_l)_x=(\mathbf{k}_l)_y=(\mathbf{k}_l)_z\begin{matrix}\neq0\\=0\end{matrix}\Big\}.
\end{aligned} \tag{24}$$

If $\mathbf{k}_l$ lies on the first Brillouin zone surface then it is shared with adjoining zones, and the above value of C is multiplied by 2, 3, or 4 according to whether $\mathbf{k}_l$ is on a face, edge, or corner. For example, for the point Γ, $C=48$ and $W=1$. With this technique H_p had only to be diagonalized at ~ 1200 points.

Digitized by Arya Samaj Foundation Chennai and eGangotri

When the data first came from the computer, it was observed that the scatter in the 0.1-eV histograms, $K_{ns}(\omega_i)$, was excessive. We found, however, that by smoothing $K_{ns}(\omega_i)$ according to

$$\bar{K}_{ns}(\omega_i)=\tfrac{1}{3}[K_{ns}(\omega_{i+1})+K_{ns}(\omega_i)+K_{ns}(\omega_{i-1})]; \quad (25)$$

the scatter was materially reduced. This method is discussed by Hartree.[34] When the smoothing procedure is combined with the results of critical point analysis as in the next section, excellent results are achieved. In the Appendix we examine the effects of smoothing as well as the sources of the statistical noise.

VIII. DISCUSSION OF LINE SHAPES

In discussing the results we shall begin by examining the histogram for bands 4 and 5 (the bands are ordered in the conventional way with $n=4$ the highest valence band, and $s=5$ the lowest conduction band). From energy considerations it can be guessed that this will make the most important contribution to $\epsilon_2(\omega)$. Figure 8 shows $\bar{K}_{4,5}(\omega)$ for both Ge and Si. One notices that the graphs show a group of periodic peaks (dashed lines) beginning at 4.5 eV in Ge and at 5.6 eV in Si. A close study of the data disclosed that these arise in an artificial way as boundary sampling errors. Near the point W one finds that the planes of sampling points lie parallel to the surfaces on which $E_{4,5}(\mathbf{k})$ is constant. This condition is drawn for a two-dimensional example in Fig. 9, where one easily sees how these artificial sampling peaks can be formed. Since they were judged to be spurious, the peaks have been eliminated from the joint density of states (solid lines in Fig. 8).

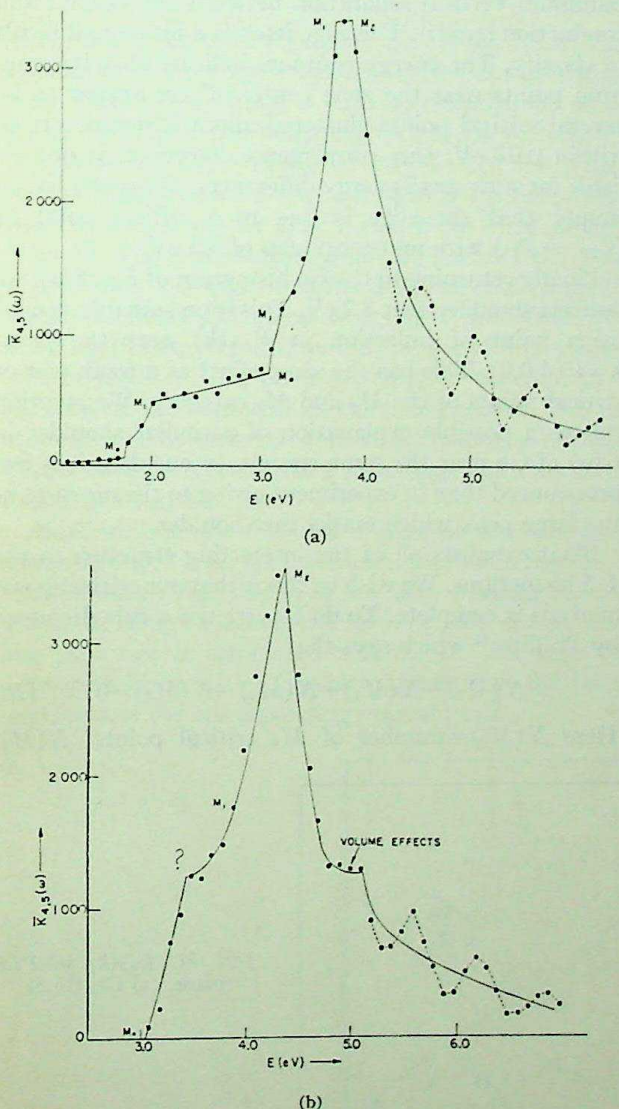

FIG. 8. 4–5 histograms. Volume effects refer to structure which could not be traced to critical points. (a) Ge, (b) Si.

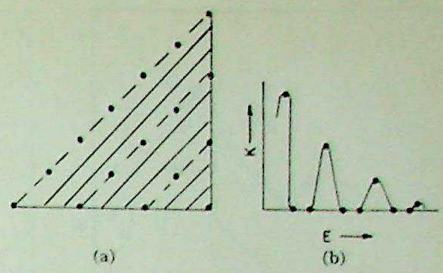

FIG. 9. (a) Sampling planes (dashed lines) are parallel to energy contours (solid lines); (b) resulting density of states showing the spurious peaks.

The most striking result is the large central peak. We remember that in our starting model the large optical peak was associated with transitions of the type $X_4 \rightarrow X_1$. To understand how it arises in $\bar{K}_{4,5}$ we inspect Fig. 10 where $E_{4,5}(\mathbf{k})$ is plotted in the basal plane (ΓKX plane). By looking at the energy contours near the point X in Fig. 10(b), one discovers that there exists a critical point of the M_1 class with a direct energy gap of 3.6 eV. Furthermore, on the Σ axis near the point $\mathbf{k}=(0.6,0.6,0.0)$ there occurs another critical point. This belongs to the M_2 class, and has an energy gap of 3.8 eV. The large peak in $\bar{K}_{4,5}$ of Ge, results then from these two nearly degenerate critical points corresponding to $X_4 \rightarrow X_1$ and $\Sigma_4 \rightarrow \Sigma_1$ transitions. This idea has been demonstrated previously in Fig. 1(e). The occurrence of a critical point on Σ is a new result.

The analysis of Fig. 10(b) for Si leads to the same general conclusions. At the point X there again occurs an M_1 critical point with energy of 4.0 eV. On the Σ axis near $\mathbf{k}=(0.4,0.4,0.0)$ we find an M_2 critical point this time with an energy gap of 4.4 eV.

In Fig. 8 the reader may notice that sharp corners have been drawn into the data. The analysis discussed earlier indicates that this is the correct behavior near a critical point.

Returning to Fig. 8(a), we see a sharp corner of the M_1 type in $\bar{K}_{4,5}$ of Ge at 2.0 eV. It is clear that this is identifiable with the spin-orbit split optical edge at 2.2 eV. Figure 11(a) shows the contours of $E_{4,5}(\mathbf{k})$ in the

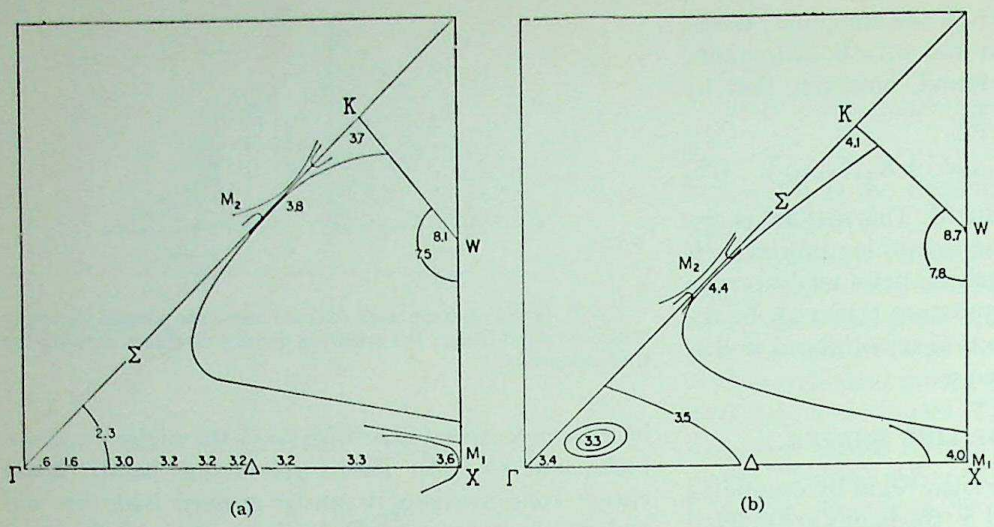

FIG. 10. $E_{4,5}(\mathbf{k})$ contours in ΓKX plane. The energies indicated on graph are all in eV. A few of the principal contours are drawn showing behavior near critical points. (a) Ge, (b) Si.

plane defined by ΓKL. At L there is an M_0 critical point with a gap of 1.8 eV. Looking along Λ, we detect another critical point near $\mathbf{k}=(0.17,0.17,0.17)$. This one is classified as an M_1 with an energy of 2.0 eV. The edge results from $\Lambda_3 \rightarrow \Lambda_1$ transitions, while the threshold is produced by $L_{3'} \rightarrow L_1$ transitions. This interpretation is again a new one.

Both $\Lambda_3 \rightarrow \Lambda_1$ and $L_{3'} \rightarrow L_1$ are spin-orbit split by approximately the same amount. Although the predicted breadth of the 2-eV edge given by the separation of the M_0 and M_1 singularities (0.2 eV) is in good agreement with experiment, more decisive confirmation of the predicted M_0 threshold can be obtained in materials where the spin-orbit splitting and the M_1 peak are somewhat larger. This is the case for GaAs[35] and still more clearly ZnTe.[36] The M_0 thresholds are well resolved approximately 0.2 eV below the M_1 edges. It is striking that such fine details appear to carry over not only to slightly ionic crystals such as GaAs but also to strongly ionic ones such as ZnTe.

In the 4–5 histogram of Si there is an edge at 3.5 eV. This is identified with the peak at 3.5 eV in $\epsilon_2(\omega)$. Figure 11(b) shows that the threshold for this edge is once more an M_0 critical point at L. The energy of the $L_{3'} \rightarrow L_1$ gap is here 3.1 eV (in Si this appears to be the minimum vertical separation between the valence and conduction bands). The edge itself is a bit more difficult to classify. The energy contours indicate that it comes from points near the zone center. There appear to be several critical points clustered about Γ degenerate to within 0.04 eV. Our convergence, however, is not reliable for such small energy differences. We prefer to say simply that the edge is due to a critical point at $(\Gamma_{25'} \rightarrow \Gamma_{15})$ with an energy gap of 3.5 eV.

Finally returning to the Ge histogram of Fig. 8(a), we notice a shoulder near 3.2 eV. This is presumably caused by a point of inflection in $E_{4,5}(\mathbf{k})$ near the point $\mathbf{k}=(0.4,0,0)$. This has the same effect as a weak pair of critical points of the M_0 and M_1 category. We mention this as a possible explanation of a similar shoulder in $\epsilon_2(\omega)$ of Ge near the same energy. In our data it is less pronounced than in experiment owing to the nearness of the large peak which masks the shoulder.

That exhausts all of the interesting structure in the 4–5 histograms. We wish to check that our critical-point analysis is complete. To do this we use a rule discussed by Phillips,[25] which says that

$$N(M_0)-N(M_1)+N(M_2)-N(M_3)=0. \qquad (26)$$

Here $N(M_0)$=number of M_0 critical points; $N(M_1)$

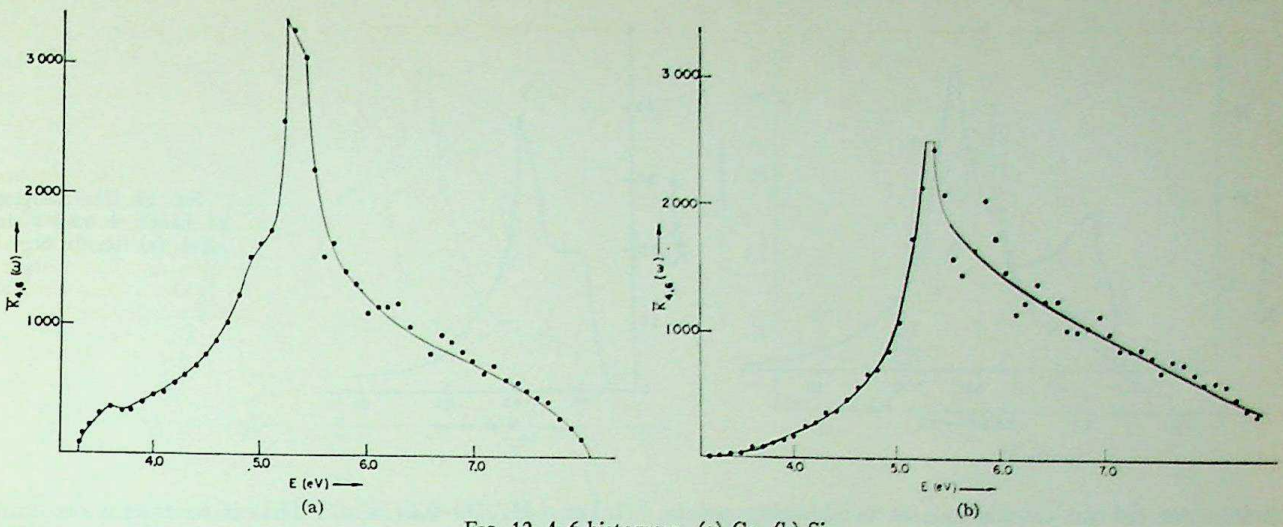

FIG. 12. 4–6 histogram. (a) Ge, (b) Si.

=number of M_1 critical points; etc. In Ge, $N(M_0)$ has contributions from three sources: Γ (the absolute minimum $\Gamma_{25'} \rightarrow \Gamma_{2'}$), L, and Δ (the M_0 contribution of the kink). Putting in the weighting factors (W) for each of the points we have $N(M_0)=1+4+6=11$. For $N(M_1)$ the contributions are from Λ, X, and Δ (the M_1 saddle point arising from the kink). This gives $N(M_1)=8+3+6=17$. The contributions to $N(M_2)$ are all from Σ and $N(M_2)=12$. The contributions to M_3 all come from the maximum in $E_{4,5}(\mathbf{k})$ which occurs at W and $N(M_3)=6$. Forming the sum implied by (26) we get $11-17+12-6=0$ as required. We have not applied the rule to Si because of the complexities discussed earlier. We can nevertheless, be confident that all the important critical points have been found since the energy contours in Ge and Si are very similar.

Next we examine the contribution of the 4–6 histogram. In Fig. 12, $\bar{K}_{4,6}(\omega)$ is drawn. The main feature in the Ge data [Fig. 12(a)] is the large peak at 5.3 eV. From the energy contours of Fig. 13(a), one can see that the structure is associated with L. In this case the transition being $L_{3'} \rightarrow L_3$ which agrees with the interpretation of the corresponding optical peak.

The Si data are understood similarly. The $L_{3'} \rightarrow L_3$ transition is responsible for the peak at 5.3 eV. The somewhat large peak at 5.8 eV is apparently a boundary sampling error of the type discussed in connection with the 4–5 histogram. After matrix elements are accounted for, the remaining structure in $\bar{K}_{4,6}$ is too weak to make an observable contribution to the optical properties. For the same reason the remaining histograms contribute nothing to $\epsilon_2(\omega)$.

We are now in a position to use these results to construct $\epsilon_2(\omega)$. First we shall give a very brief discussion of how the matrix elements were determined.

In order to develop a reasonable way of handling $|M_{n,s}(\mathbf{k})|^2$ we computed matrix elements for $n=4$, $s=5$, and for $n=4$, $s=6$, at a number of points in the reduced zone. These were gotten by using the pseudopotential wave functions $\phi_{n,\mathbf{k}}$. Such a procedure corresponds to using the smooth part of the OPW wave functions which according to Ref. 37 gives accuracy of better than 20%.[38] The results are shown in Table III. The Si wave functions were used; however, we would get almost identical results with the Ge wave functions. In obtaining the matrix elements for the symmetry

[37] L. Kleinman and J. C. Phillips, Phys. Rev. 118, 1153 (1960).
[38] The effective masses are determined by momentum matrix elements. Since our computed values for the effective masses agree well with experiment, we naturally expect the computed matrix elements also to be correct.

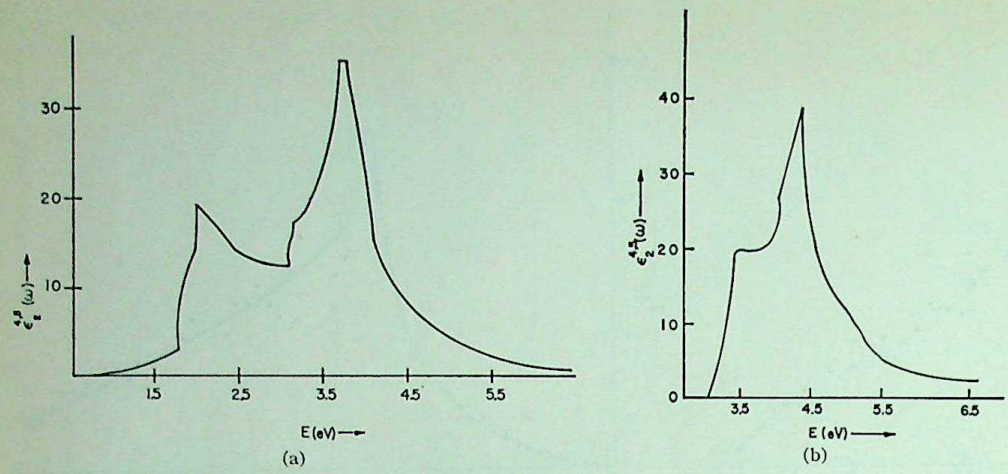

FIG. 14. Contribution of bands 4 and 5 to $\epsilon_2(\omega)$. (a) Ge, (b) Si.

points, we did the calculations at neighboring points. This was done so that degeneracies would be lifted, and the resulting matrix elements would be those of the bands being studied. If this were not done then, for example, the wave functions of bands 5 and 6 would mix at X.[39]

Looking at the values for $|M_{4,5}(\mathbf{k})|^2$ in Table III we see that it is roughly constant throughout the zone

TABLE III. Matrix elements in units of $(2\pi/a)^2$.

k	$\lvert M_{4,5}(\mathbf{k})\rvert^2$	$\lvert M_{4,6}(\mathbf{k})\rvert^2$
(0.04,0.04,0.02)	0.90	0.01
(1.00,0.04,0.04)	1.51	0.00
(0.72,0.39,0.33)	1.33	0.09
(0.6,0.6,0.0)	1.41	0.00
(0.58,0.25,0.14)	0.94	0.22
(0.50,0.48,0.52)	0.85	0.63

varying by less than a factor of 2. We could then replace the matrix element in Eq. (1) by a $\mathbf{k}$-independent quantity $|M_{4,5}|^2$. To determine this value we took the weighted average of the values in Table III. Then $|M_{4,5}|^2=1.2(2\pi/a)^2$. As Table III points out, $|M_{4,6}(\mathbf{k})|^2$ is small except near the point L, precisely where the 4–6 peak originates. It is a bit difficult to settle on a way to handle the matrix element. We have taken $|M_{4,6}|^2=0.6(2\pi/a)^2$. That is we take a constant value equal to $|M_{4,6}(\mathbf{k}=(\frac{1}{2},\frac{1}{2},\frac{1}{2}))|^2$. In Figs. 14 and 15 we show the contributions to $\epsilon_2(\omega)$ of the 4–5 and 4–6 histograms. In Fig. 16 we take $\epsilon_2(\omega)=\epsilon_2^{4,5}(\omega)+\epsilon_2^{4,6}(\omega)$, that is, as the sum of the contributions from the 4–5 and 4–6 histograms, and compare with experiment. In previous work (see Refs. 40 and 41) $\epsilon_2(\omega)$ was also taken as $=\epsilon_2^{4,5}(\omega)+\epsilon_2^{4,6}(\omega)$. Figure 6 shows our energy bands with the principal transitions marked.

To check our hypothesis regarding matrix elements it was decided to do Si with matrix elements included. $|M_{n,s}(\mathbf{k})|^2$ was computed along with the energy eigenvalues at each point of the zone, and put in Eq. (1). This added about 3 h of machine time to a total of about 15 h. The result for $\epsilon_2(\omega)$ shown in Fig. 16(b) includes all of the separate histograms.

As Fig. 16 indicates, our line shapes appear satisfactory. The two exceptions are the $L_{3'}\rightarrow L_3$ peaks in Ge and Si, as well as the $\Gamma_{25'}\rightarrow\Gamma_{15}$ peak in Si. The main difficulty in the first case centers around the strength. We have seen that our treatment probably overestimates the matrix element so that it is not surprising that the computed strength is too large. In Fig. 17 we examine the experimental line shape derived by taking the shaded portion of $\epsilon_2(\omega)$ as shown by the inset. With suitable magnification the theoretical and experimental line shapes are in good agreement. The $\Gamma_{25'}\rightarrow\Gamma_{15}$ peak is not well understood. Since it is so narrow, there is a

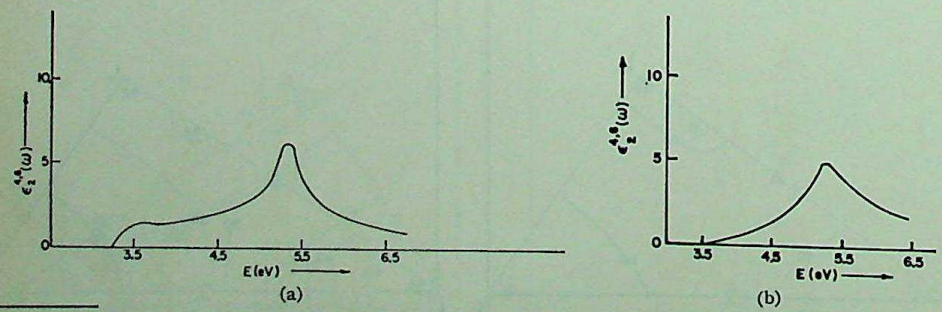

FIG. 15. Contribution of bands 4 and 6 to $\epsilon_2(\omega)$. (a) Ge, (b) Si.

[39] The program did not construct symmetrized combinations of plane waves as it was a general one designed to handle all points of the zone on an equal footing.

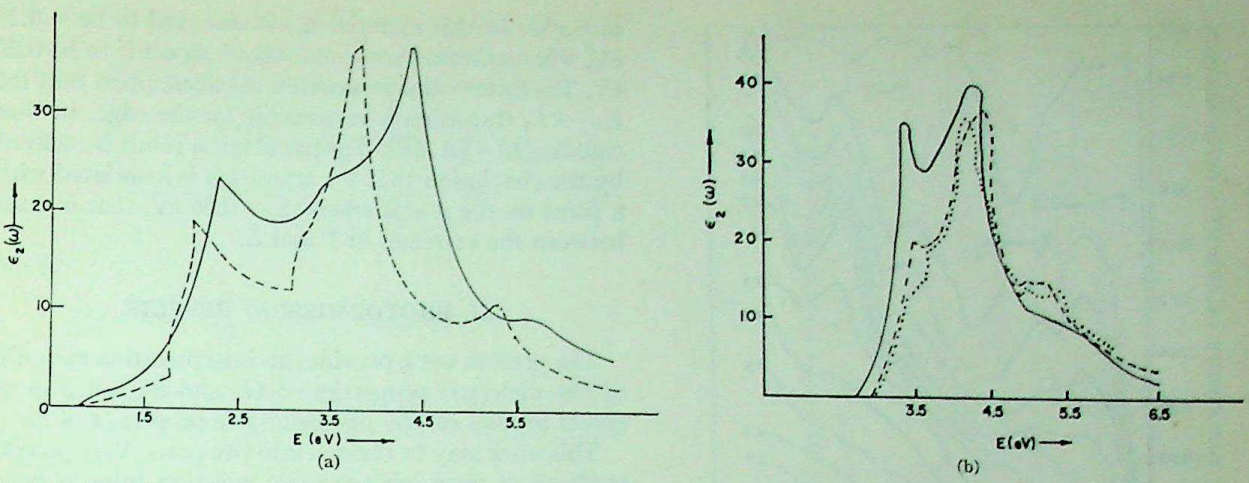

FIG. 16. Experimental result for $\epsilon_2(\omega)$ (solid line) compared with our computed value (a) Ge $\epsilon_2(\omega)=\epsilon_2^{4,5}(\omega)+\epsilon_2^{4,6}(\omega)$ (dashed line, with edges emphasized to account for critical points), (b) Si $\epsilon_2(\omega)=\epsilon_2^{4,5}(\omega)+\epsilon_2^{4,6}(\omega)$ (dashed line), $\epsilon_2(\omega)$ taken as sum of contribution from all bands with dipole matrix elements included (dotted line).

chance that it is a density-of-states effect which we did not detect. The reader should see a further discussion concerning this point by Phillips.[42]

The results of this section are summarized in Table IV.

IX. STATIC DIELECTRIC CONSTANT

From a knowledge of $\epsilon_2(\omega)$ it is possible to calculate the real part of the dielectric constant $\epsilon_1(\omega)$ in the limit $\omega \rightarrow 0$. From the Kramers-Kronig relation the following expression can be obtained[43]

$$\epsilon_1(0)=1+\frac{2}{\pi}\int_0^\infty \frac{\epsilon_2(\omega)}{\omega}d\omega.$$

[43] T. S. Moss, Proc. Phys. Soc. (London) **B66**, 141 (1953).

Using our results for $\epsilon_2(\omega)$, we can now derive $\epsilon_1(0)$. It is realized, however, that the value calculated in this way is directly proportional to the choice of matrix elements. In the case of the 4–5 bands we took this as $1.2(2\pi/a)^2$ with an assigned error ~25%. For the other pairs of bands where the matrix element is considerably smaller we do not have a sufficiently reliable value for this purpose. Therefore, only the contribution from $\epsilon_2^{4,5}(\omega)$

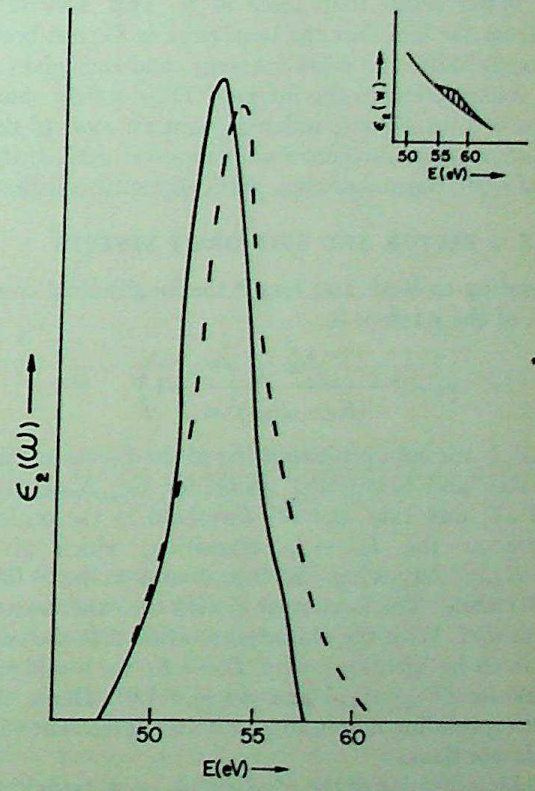

FIG. 17. Comparison of the theoretical and experimental line shapes for the $L_{3'}\rightarrow L_3$ transition in Ge. The solid line is the shaded portion of the experimental curve indicated by the inset. The shaded region has been moved 0.5 eV to the left and magnified seven times. The dashed line is a similar region under the theoretical curve.

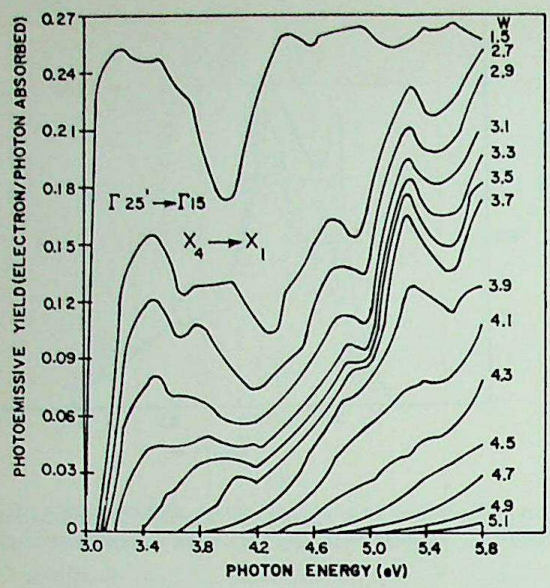

FIG. 18. Photoemissive yield: electrons/absorbed photons, as a function of photon energy, with vacuum W, eV, above the top of the valence band, as computed in present work.

was evaluated. For Ge this gave $\epsilon_1^{4,5}(0)=12.4$ and for Si $\epsilon_1^{4,5}(0)=7.6$, which are to be compared with the experimental values of 16.0 and 12.0, respectively. As expected $\epsilon_1^{4,5}(0)<\epsilon_1(0)$ due to the neglect of the higher bands. The 4–5 bands of Ge appear from these values to give a better result than those of Si. This, however, arises from the fact that the large peak in Ge has been erroneously shifted to a lower energy, and thus gives a bigger contribution to the integral. These values show that the 4–5 transitions, which account for most of the structure in $\epsilon_2(\omega)$, also contribute more than 50% of the value of $\epsilon_1(0)$, the macroscopic static dielectric constant.

X. g FACTOR AND SPIN-ORBIT EFFECTS

According to Roth and Lax,[15] the longitudinal component of the g tensor is

$$g_{11}=2-\frac{\Delta_{s0}}{\langle E_{L_1}-E_{L_3'}\rangle}\left(\frac{m_0}{m_t}-1\right).$$

Here Δ_{s0} is the spin-orbit splitting of the $L_{3'}$ states. We use Lukěs and Schmidt's[44] value for Ge, $\Delta_{s0}=0.195\pm0.02$ eV, and take the M_0 threshold in the optical response as the $L_{3'}\rightarrow L_1$ transition, which gives $\langle E_{L_1}-E_{L_3'}\rangle=2.1$ eV. g_{11} is then found to be $=0.96$ ($m_t=0.082m_0$). This is compared with the experimental value of 0.87. With the old interpretation that the edge itself is to be identified with $L_{3'}\rightarrow L_1$ we would use 2.35 eV for $\langle E_{L_1}-E_{L_3'}\rangle$ and get $g_{11}=1.07$. Hence the new interpretation is seen to give better agreement with the g-factor data.

The identification of the edge with $\Lambda_3\rightarrow\Lambda_1$ transitions allows us to resolve a problem in the spin-orbit splitting of GaAs. In this material Δ_{s0} is observed to be $=0.26$ eV, whereas from theory one would expect it to be 0.20 eV. The latter value is based on the assumption that the $L_{3'}\rightarrow L_1$ transition is responsible for the edge. In that case $\Delta_{s0}(L)=\frac{2}{3}\Delta_{s0}(\Gamma)$. The paradoxical result is resolved by the conclusion that the transition is associated with a point on the Λ axis where $\Delta_{s0}=0.26$ eV, that is, falls between the extremes at Γ and L.

XI. PHOTOEMISSION RESULTS

The present work provides an interpretation not only of the dielectric properties of Ge and Si, but also of recent studies on the photoemissive properties of Si.

This work may be divided into two parts. Very precise studies[45] of weak photoelectric emission from Si near threshold on atomically clean surfaces reveal direct and indirect thresholds similar to the infrared absorption edges discussed by Hall, Bardeen, and Blatt.[46] The indirect threshold is at 5.15 eV, the direct threshold at 5.45 eV. The crystal surface is a (111) plane, and the thresholds, according to Kane,[47] are associated with the symmetry line Λ, where V is directed normal to the (111) plane. The direct transition responsible for the direct threshold therefore starts *from* Λ_3 at an energy 0.3 eV below $\Gamma_{25'}$. The transition marked D in Fig. 6(b) starts from $\mathbf{k}=(0.12,0.12,0.12)$ and requires $E=5.5$ eV. The agreement with Kane's theory and Allen and Gobelli's experiment is satisfying. It should be emphasized that this agreement is a by-product of our calculations for the ultraviolet absorption.

The second part of the photoelectric data concerns the broad yield curves obtained when the effective work function is reduced by covering the surface with up to one monolayer of Cs. In doing the analysis we assume that electrons which are excited into the conduction bands have an escape probability $P_s^W(\mathbf{k})$. Then $P_s^W(\mathbf{k})=0$ if $E_s(\mathbf{k})<W$ and $P_s^W=P$ if $E_s(\mathbf{k})>W$. Here $E_s(\mathbf{k})$ is the energy of the electron state with respect to the top of the valence band and W is the vacuum energy also measured relative to $\Gamma_{25'}$. With these assumptions the photoemissive yield function (number of electrons emitted/number of photons absorbed) is given by

$$Y_W(\omega)=\frac{\sum_{n,s}\int_{\text{B.Z.}} d^3k P_s^W(\mathbf{k})\delta(\omega_{n,s}(\mathbf{k})-\omega)\,|M_{n,s}(\mathbf{k})|^2}{\sum_{n,s}\int_{\text{B.Z.}} d^3k\,\delta(\omega_{n,s}(\mathbf{k})-\omega)\,|M_{n,s}(\mathbf{k})|^2},\tag{27}$$

in which it is assumed that the electron escapes with a negligible loss of energy.

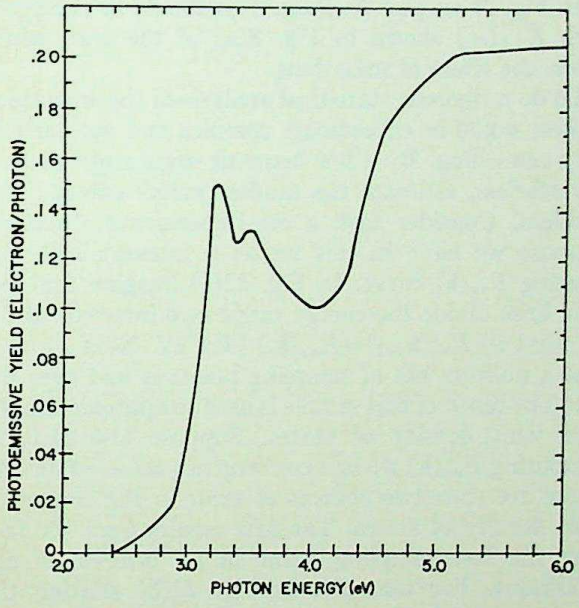
CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

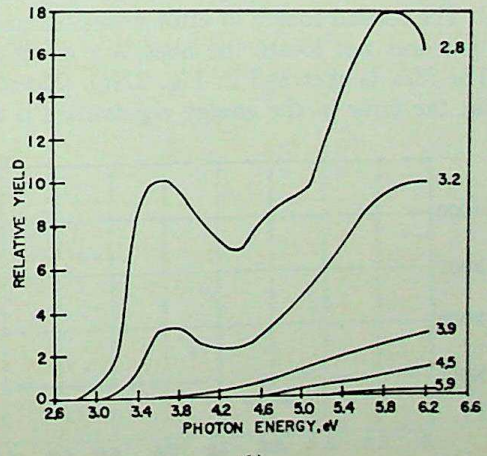
Digitized by Arya Samaj Foundation Chennai and eGangotri

In performing the calculations we arbitrarily set $P=0.26$. Then, again, taking constant matrix elements we have after making a finite sample of the zone



$$Y_W(\omega_i)=\frac{\sum_{n,s} K_{n,s}{}^W(\omega_i)\,|M_{n,s}|^2}{\sum_{n,s} K_{n,s}(\omega_i)\,|M_{n,s}|^2}, \qquad (28)$$

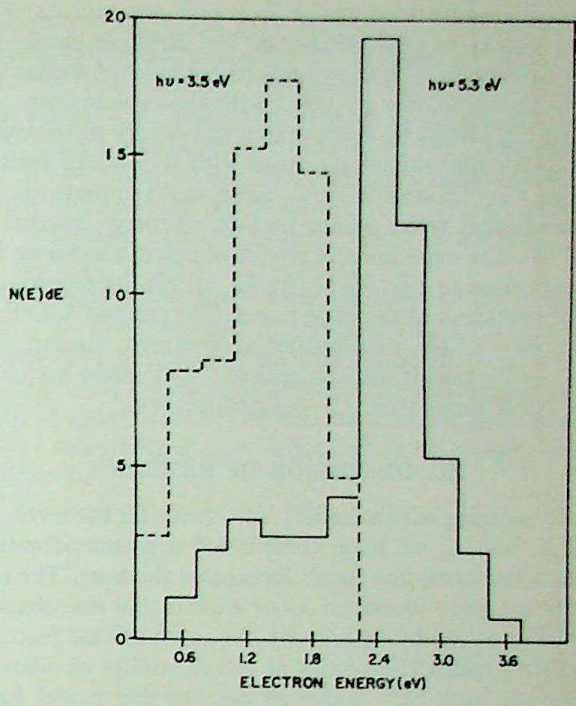
where



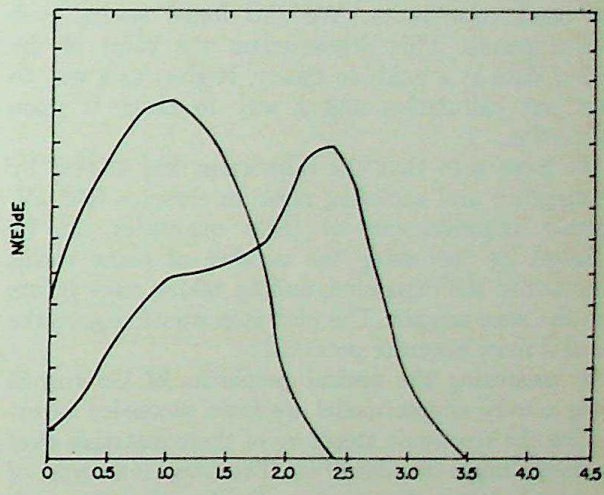
$$K_{n,s}{}^W(\omega_i)=\sum_{\mathbf{k}_l} P_s{}^W(\mathbf{k}_l)\hat{\delta}^{\Delta\omega}(\omega_{n,s}(\mathbf{k}_l)-\omega_i). \qquad (29)$$

Again we replace the quantities $K_{n,s}(\omega_i)$ and $K_{n,s}{}^W(\omega_i)$ by the three point smoothed quantities $\bar{K}_{n,s}(\omega_i)$ and $\bar{K}_{n,s}{}^W(\omega_i)$.

In Fig. 18 we have plotted the results for $Y_W(\omega)$ with ω varied between 1.5 and 5.1 eV. This is to be compared



(a)



(b)

FIG. 19. Experimental results for the photoemissive yield (a) Spicer; (b) Gobeli and Allen.

(a)

(b)

FIG. 20. (a) The energy distribution of electrons emitted from Si for $\hbar\omega=3.6\pm0.1$ eV and 5.3 ± 0.1 eV with $W=1.5$ eV, as computed; (b) Spicer's results for $P(E)$, $W=1.5$ eV.

with the experimental results obtained by Spicer[48] and by Gobeli and Allen[49] as shown in Fig. 19. The value of ω is experimentally varied, as we said, by covering the Si surface with a fraction of a monolayer of Cs. The over-all agreement appears satisfactory. The principal features in the $W=2.7$-eV plot are the peaks at 3.4 and 5.3 eV due to $\Gamma_{25'}\rightarrow\Gamma_{15}$ and $L_{3'}\rightarrow L_3$ transitions. The $X_4\rightarrow X_1$ dip at 4.3 eV arises since $E(X_1)-E(\Gamma_{25'})=1.1$ eV $<W$. The secondary peaks at 3.8 and 4.8 eV

have been identified as due to transitions near $\Lambda_3 \rightarrow \Lambda_1$ and points in the volume of the Brillouin zone, respectively. As W is increased the behavior of the curves is in quantitative agreement with the experiments.

In Fig. 20(a) we have drawn the energy distribution $P(E)$ for the emitted electrons with $W=1.5$ eV for the cases $\hbar\omega=3.5$ and 5.3 eV. Since our sample includes considerably fewer points, we take an energy interval of 0.3 eV. The experimental results of Spicer are drawn for comparison in Fig. 20(b). Again our results provide an interpretation of the experiment. The peak at 1.2 eV in the $\hbar\omega=3.5$-eV distribution is centered around the $\Gamma_{25'} \rightarrow \Gamma_{15}$ transition. The peak at 2.4 eV in the $\hbar\omega=5.3$-eV curve arises from $L_{3'} \rightarrow L_3$ transitions.

XII. DISCUSSION OF RESULTS

By starting with a model term scheme for the levels at Γ, X, and L, we have constructed a pseudopotential which has given the bands *throughout* the zone. The results we have found for $\epsilon_2(\omega)$ explain the line shapes which are seen in experiment. As an additional feature we can explain the results of recent studies on photoemission from Si.[50] Although our starting model had errors in it, they were subsequently straightened out by the band calculations. We also found several new critical points. This demonstrates the value of the optical data as a guide to theory. It gives us a way to start our calculation and a way to check it upon completion.

We have seen that the calculation was limited by convergence and sampling noise to errors $\sim$0.05 eV. Further improvements of these quantities can be achieved by increasing the number of plane waves admitted to the expansion, and by taking more points into the zone sample. The next step would require the use of a more accurate potential.

By analyzing the optical properties of Ge and Si using a very simple model we have succeeded in exploring the electronic structure of these materials over an energy range of order 10 eV. This range is an order of magnitude larger than that studied by infrared experiments. The precision of our study enables us not only to explain all the observed structure but also to predict new features, such as M_0 thresholds.

Comparing the results for Ge and Si we find that alterations in the crystal potential are small and lead to much smaller changes in the over-all band structure than might have been supposed from infrared data. This agrees with the ultraviolet experimental results. One may say that in Ge and Si the energy surfaces in k space are determined primarily by the shape of the Brillouin zone, i.e., by symmetry considerations, and by $V(3)$, which measures the strength of the covalent bond.

[50] A further application has allowed us to explain some of the properties of Ge-Si alloys as well as high-pressure effects on the band structure [F. Bassani and D. Brust, Phys. Rev. 131, 1524 (1963)].

ACKNOWLEDGMENTS

The author wishes to express his gratitude to Professor J. C. Phillips for suggesting this problem and for guidance throughout the work, Dr. F. Bassani for valuable discussions, M. Yoshimine for assistance in checking the program, Professor M. H. Cohen for helpful discussions. He further wishes to thank Dr. O. C. Simpson for his hospitality during the author's stay at the Argonne and to the staff of the IBM 704 for aiding the author whenever possible. He also wishes to acknowledge Dr. H. Ehrenreich and Dr. H. Philipp for communicating their results on the imaginary part of the dielectric constant, Marvin L. Cohen for assistance with the data reduction and useful conversations, and his thesis committee for a critical reading of the manuscript.

APPENDIX

In Fig. 21 we plot $K_{4,5}(\omega_i)$. This should be compared with $\bar{K}_{4,5}(\omega_i)$ shown in Fig. 8(a) of the text, which shows the effect of smoothing.

To do a rigorous statistical analysis of the smoothing process would be exceedingly complex and not particularly rewarding. By a few heuristic arguments we can, nevertheless, estimate the random errors entering the problem. Consider first a one-dimensional situation. Suppose we have in this model a monotonically increasing $E_{ns}(\mathbf{k})$ curve. In Fig. 22(a) imagine that the solid lines divide the energy range into intervals of 0.1 eV, that is, $E_{ns}(\mathbf{k}_{i+1})=E_{ns}(\mathbf{k}_i)+0.1$ eV. Next suppose that a uniform net of sampling points is laid over the line. The result of this sample is used to approximate the true joint density of states. Suppose also that in computing $E_{ns}(\mathbf{k})$ we had convergence noise $\sim$0.05 eV. There are then two sources of error in the computed joint density of states. The first results from the fact that the last sampling point in an interval is not significant. For example, in Fig. 22(b) shifting the boundary at 0.2 eV very slightly to the left will, put the last point in the 0.1–0.2 eV interval into the 0.2–0.3 eV interval. The second source of error arises because our calculation does not locate the boundary energies exactly. The idea is sketched in Fig. 22(c). One should note that the error in the energy eigenvalues is a dis-

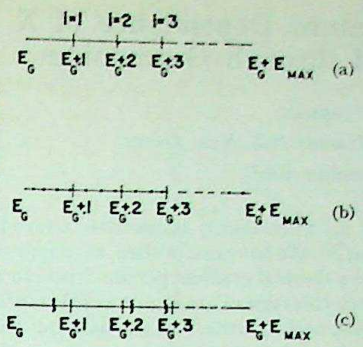

FIG. 22. Monotonically increasing $E_{ns}(\mathbf{k})$ in one dimension (a) energy divided into intervals of 0.1 eV, (b) uniform sampling net used to determine joint density of states, (c) wavy lines indicate erroneous boundaries of intervals arising from convergence noise.

continuous function of $\mathbf{k}$. This occurs because the number of plane waves in our expansion depends on $\mathbf{k}$.

If we take a sampling mesh of 1000 points and suppose that $E_{ns}(\mathbf{k})_{max}=5$ eV, then our one-dimensional sample contains $\sim$20 points per interval. These numbers roughly correspond to those of the actual problem. Then the error from boundary corrections is about 1 point per interval or 5%. The error arising from convergence noise can be $\sim$10 points per interval or 50%. The effect of the smoothing is clear. We take three times as many points while leaving the absolute error constant. Hence the dominant error is reduced from about 50% to about 20%.

The situation in three dimensions is not so readily analyzed. The same sort of arguments ought to apply, however, we now have a two-dimensional surface for the boundaries of the energy intervals. The scatter resulting from boundary corrections and from convergence noise before smoothing is now estimated to be $\sim$20%, and after, $\sim$10%.

Redetermination of the Temperature Dependence of X Rays Anomalously Transmitted through Germanium

Boris W. Batterman
Bell Telephone Laboratories, Murray Hill, New Jersey
(Received 2 December 1963)

We have redetermined the temperature dependence of the anomalously transmitted x rays through single crystals of germanium of effective thicknesses, $\mu_0 t = 20$ and 30. We have established, as suggested by Okkerse, that the earlier measurements were subject to error due to a thermal gradient perpendicular to the diffracting planes. By suitable rearrangement of the heating geometry this type of gradient was substantially removed. The current results are in agreement with those of Okkerse and indicate that the data can be explained by allowing the imaginary part of the scattering factor to depend on temperature as $\exp(-M)$ where M is based on a Debye temperature of 291°K. It is felt that there is insufficient evidence at present to conclude in general that the temperature dependence in dynamical diffraction is $\exp(-M)$.

In a previous publication[1] we reported measurements on the temperature dependence of the anomalous transmission of x rays in germanium single crystals. We obtained a linear dependence of the logarithm of the integrated intensity with temperature ranging over an order of magnitude in intensity. [Reference to this work will be abbreviated as (I).] The data in (I) were fitted to theory assuming that $\epsilon(=F_H''/F_0'')$, the normalized angular dependence of the imaginary part of the scattering factor, could be expressed as $\epsilon = \epsilon_0 \exp[-(\alpha M)]$ where ϵ_0 is the static value, M is the exponent in the usual Debye-Waller factor e^{-M} and α is an adjustable constant. It was found that the data for the (220) and (400) reflections were consistent with a single $\alpha = 1.32$.

In a symposium associated with the 50th anniversary celebration of the discovery of x-ray diffraction, Okkerse[2] presented experimental data indicating a similar logarithmic dependence but with an α value of 1.0 based upon a Debye temperature of 291°K.

To resolve the experimental discrepancy, we repeated our past measurements with several variations. In the first series of experiments the crystals were mounted in the same manner as before (crystal in the shape of the letter T, held by the vertical arm) as in (I), Fig. 4, but with the crystal extended in the furnace so that both the forward diffracted (anomalously transmitted) and diffracted beams could be measured. (Previously only the diffracted beam was measured.) The experiment was repeated with the x-ray beam striking different portions of the surface of the crystal. The results of these measurements were: (1) the slopes of log intensity versus temperature of the diffracted beams were constant for different points on the crystal surface to within 5%, but did not agree in value with the previous measurements for a crystal of the same thickness, (2) the curves of the forward diffracted beam were not linear but curved toward lower intensities at higher temperatures such that at sufficiently high temperatures, the forward beam had less intensity than the diffracted beam. The amount of curvature depended upon where the beam struck the crystal surface.

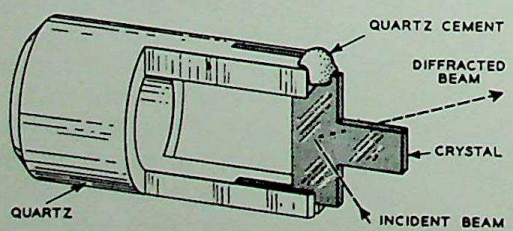

FIG. 1. Details of crystal mount. The crystal is attached on only one arm of the yoke.

These results strongly indicated the presence of thermal gradients even though the slopes of the diffracted beam curves (which were measured in our previous paper) did not vary with beam position on the crystal.

We subsequently repeated our previously reported measurements on the (400) reflection on the same crystal and experimental setup as in (I). The results reproduced those in Fig. 4, Ref. 1, i.e., they showed the curvature when the beam was near the supported part of the crystal, and a linear plot of the same slope as before, when the beam was at the center of the tee-shaped crystal. However, when the beam was moved still further from the support, the plot remained linear, but had a progressively smaller slope the further the beam was from the quartz-supporting rod. This definitely proved that the results in (I) were in error because of a thermal gradient due to heat flow down the supporting rod. This substantiates Okkerse's[2] hypothesis concerning the results in (I) that a linear dependence of the log of intensity versus temperature is not the correct criterion for a strain gradient-free crystal. In this arrangement heat flow down the quartz-support rod produced a gradient perpendicular to the diffracting planes which strongly affected the integrated intensities.

To avoid this difficulty we now mounted the crystal as in Fig. 1. Any gradient caused by heat flow down the supporting rod would now be parallel to the diffracting planes and should have a minimal effect on the integrated intensity. As before, the germanium (220) and

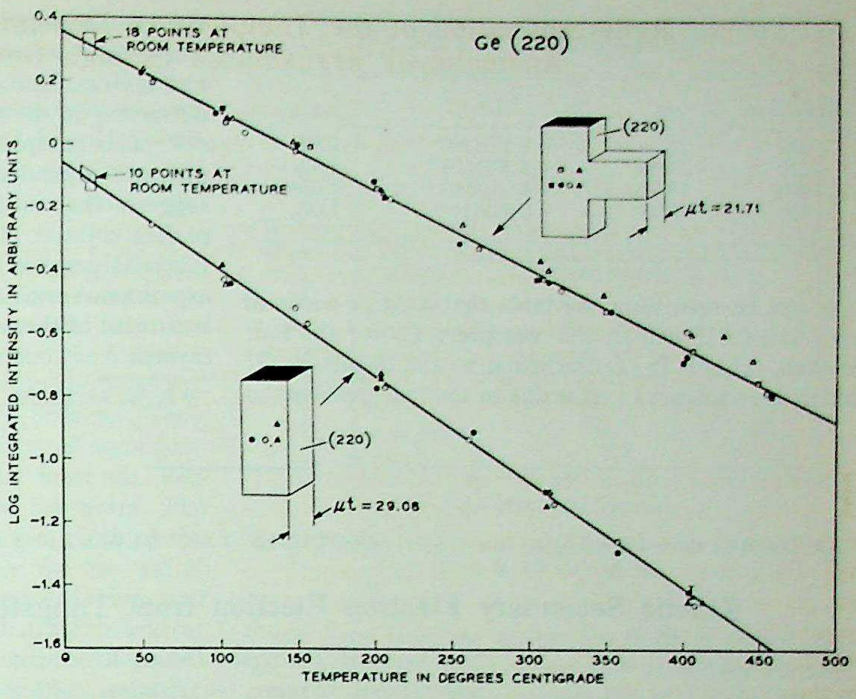

FIG. 2. (220) temperature dependence for two crystals of $\mu_0 t = 21.71$ and 29.08. The insets show the crystal shape and beam position. The shading indicates the mounting face of the crystal.

(400) anomalously diffracted beams were investigated using Cu K_α radiation. Two new specimens oriented for (220) and one new specimen for the (400) were prepared as described in (I). The (400) used in (I) was still available and made the fourth sample. The crystal thicknesses were such that for each reflection we investigated the region of $\mu_0 t \approx 20$ and ≈ 30.

The quantitative measurements were performed in the same manner as in (I), the only variation being the new manner in which the crystals were held (Fig. 1). The data for the two reflections are presented graphically in Figs. 2 and 3. The insets show the positions of the intersection of the primary beam with the crystal surface. This beam had a rectangular cross section of 0.5×0.5 mm^2. The intensity values for the various positions are included in the same plot. The intensities for the different points were taken generally in a random sequence. After measurements at several temperatures for any one crystal position, a room temperature check was made.

The internal consistency of the data for the many beam positions for each crystal gives strong evidence that thermal gradients are not affecting the measurements.

The slope of the curves is related to α of the assumed Debye-Waller factor, $e^{-\alpha M}$, by Eq. (9) in (I) which is repeated below for convenience:

$$\text{slope} = -(1-\alpha/2)k - \mu_0 t \epsilon_0 \alpha k e^{-\alpha M},$$

where $k = M/T$ and M is based on an x-ray Debye temperature for germanium of 291°K.[3] Table I gives the parameters and resulting values for α. The static values, ϵ_0, are very close to unity. For the computation we took Wagenfeld's[4] theoretical values, $\epsilon_0(220) = 0.993$ and $\epsilon_0(400) = 0.985$.

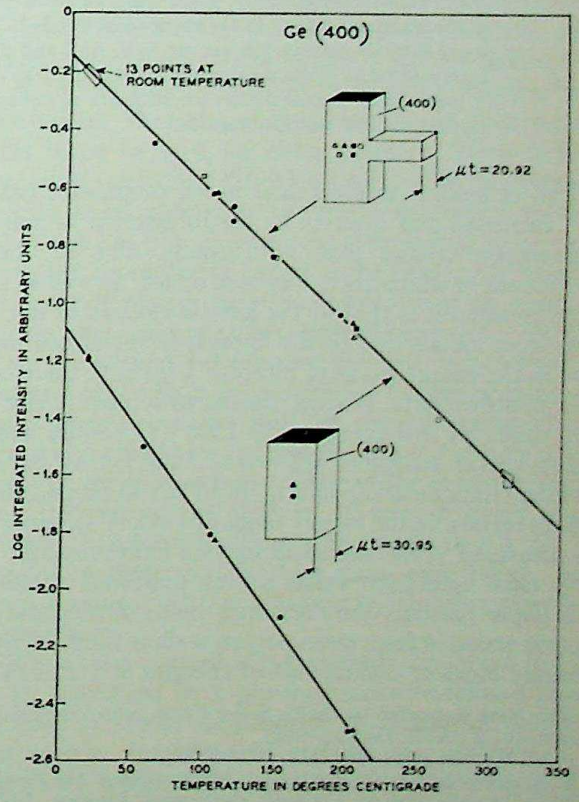

FIG. 3. (400) temperature dependence for two crystals of $\mu_0 t = 20.92$ and 30.95. Details as in Fig. 2.

TABLE I. Experimental slopes from Figs. 2 and 3 and corresponding values of α.

Reflection	μt	Slope	α
220	21.71	-2.48×10^{-3}	0.99_9
220	29.08	$-3.39_5\times10^{-3}$	1.02_7
400	20.92	$-4.65_6\times10^{-3}$	1.02_7
400	30.95	-6.85×10^{-3}	1.01_8

It can be seen from the table that a single value of $\alpha=1.01\pm0.015$ will fit the measurements for the four crystals. This is in contradiction to the results in (I) which were subject to error due to thermal gradients in the specimens perpendicular to the diffracting planes. These results now substantially agree with Okkerse's and indicate that Debye-Waller factor for germanium diffracting in the symmetric Laue case is very close to e^{-M}. This, coupled with the same experimental temperature dependence for symmetric Bragg reflection,[5] suggests that in general the Debye-Waller factor for perfect crystals is e^{-M}. This should not, however, be taken as proof of its general validity without further experiments and the development of a sound theoretical treatment of thermal vibrations in an absorbing perfect crystal.

PHYSICAL REVIEW VOLUME 134, NUMBER 5A 1 JUNE 1964

Kinetic Secondary Electron Ejection from Tungsten by Cesium Ions*

SAMUEL H. BOSCH AND GUNTIS KUSKEVICS
Electro-Optical Systems, Inc., Pasadena, California
(Received 23 December 1963)

Initial measurements of the number of electrons ejected per incident ion, γ_i, have been made for medium-energy (1–21 keV) cesium ions at normal incidence on a clean polycrystalline tungsten surface. The residual gas pressure was $\leq5\times10^{-9}$ Torr. The tungsten surface was cleaned by prolonged bakeouts and by flashing before each measurement. A dc ion-beam pulse method of measurement was used to prevent cesium coverage of the tungsten surface. In the energy range of 3–21 keV γ_i is a linear function of the ion kinetic energy with $\partial\gamma_i/\partial E\simeq0.04$ electron per ion per keV. At 3 and 21 keV γ_i is 0.02 and 0.74, respectively. If the data are extrapolated to $\gamma_i=0$, a threshold energy of 2.5 keV is obtained. Below this energy the measured values of γ_i were equal to zero within the accuracy of the measurement. The change of γ_i with cesium adsorption on the tungsten was also recorded.

USE of cesium as propellant in ion propulsion has increased the interest in the interaction of medium-energy cesium ions with solids. One of the interactions in which there has been a basic as well as a practical interest is that of the kinetic ejection of electrons from metals due to the bombardment of cesium ions. In the energy range of interest, 1–20 keV, there is little published data. Waters,[1] measured secondary electron yields for low-energy (150–1500 eV) cesium and lithium ions on tungsten. Arifov *et al.*,[2] and Petrov[3] have published data for alkali ions up to 10 keV impinging on various metals. In the energy range of 1–4 keV Brunnee[4] has measured γ_i for the alkali ions on molybdenum.

No close agreement exists among published values. This paper presents the measured yields of secondary electron emission from clean polycrystalline tungsten by normally incident cesium ions of energies of 1–21 keV. Since the ionization energy of cesium, 3.87 eV, is less than the work function of clean tungsten, about 4.5 eV, the electron yields presented are due to the kinetic ejection process only and not to the Auger or potential-ejection[5] process. The apparatus used is shown in Fig. 1.

The vacuum chamber is a stainless-steel cylinder, 3 ft in length with a diameter of 1 ft. It is pumped by a liquid-nitrogen trapped, 6-in. silicon oil diffusion pump. The chamber can be baked to 300°C with either an oven or strap heaters. Copper gaskets are used for all flanges. Within the tank a liquid-nitrogen liner is used to freeze out all condensibles. It can be baked out by passing hot gas through it. Pressure is measured with a Bayard-Alpert type ionization gauge. The system is capable of pressures lower than 1×10^{-9} Torr if proper care and technique are used.

The cesium ions are produced by a surface-ionization ion source using a porous tungsten ionizer operating at 1000–1200°C.[6] This source can generate up to 5 mA of cesium ion current with a maximum current density at the target of approximately 1–2 mA/cm². The fraction of neutral cesium atoms for the currents used in this

experiment was less than 0.01. This represents neutral cesium incidence rates corresponding to monolayer adsorption times of greater than five hours. All measurements were taken with low ion-current densities of approximately 10 μA/cm^2. The singly charged cesium ions, accelerated by the three electrode structures are monoenergetic except for their thermal velocity distribution.

The secondary electron emission detector consists of the target made of 0.003-in.-thick tungsten filament, and a cylinder collector with slits in front and rear. The latter allows higher pumping speed around the filament. The target can be flashed by direct resistance heating. Biased slits are situated in front of the collector. They collimate the beam, prevent the escape of secondary electrons that are ejected toward the front slit, and extract electrons that may be in the ion beam. The edges of the slits are chamfered and the width of the slits becomes progressingly larger from the first slit to the collector. The values of the incident ion and secondary electron currents are obtained by measuring the voltage drop across precision resistors. These are read out on a Westronic two-channel chart recorder. The collector potential is provided by a dc voltage supply in conjunction with a polarity switch.

During the bakeout and pump down of the vacuum system to the 10^{-9} Torr range (approximately 24 h) the tungsten filament is heated continuously at about 1600°K. The procedure used in measuring is a modification of Petrov's dc pulse method.[3] With the ion beam deflected off of the detector the target is flashed for 15 sec at approximately 2300°K with the collector at a negative potential so that it collects any positive ions evaporated from the surface. Three to four seconds after flashing when the target has cooled below thermionic emission temperatures, the collector potential is changed to a +45 V and the chart recorder is started.

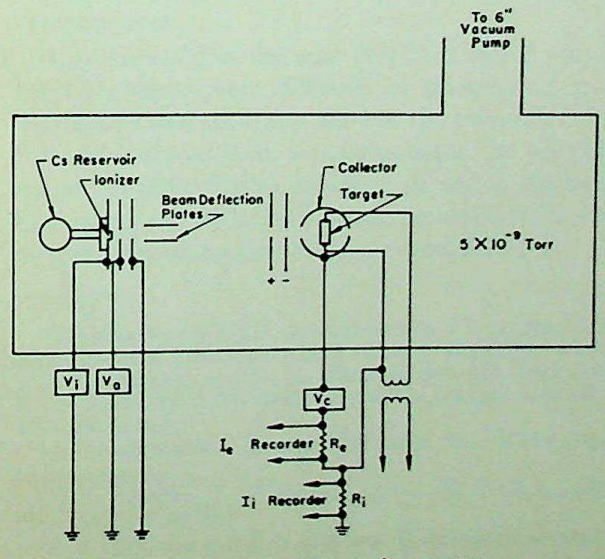

FIG. 1. Schematic diagram of apparatus.

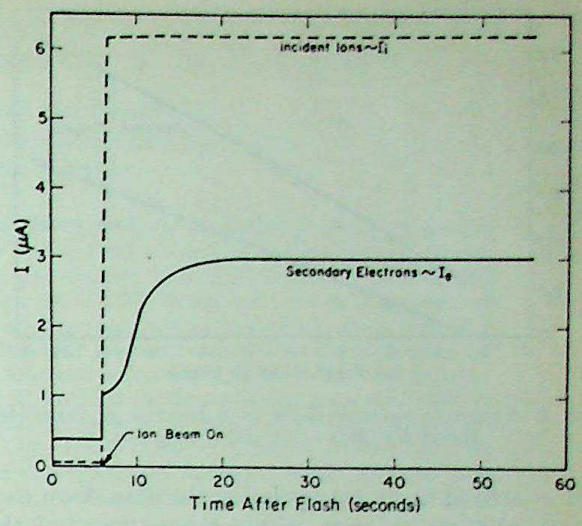

FIG. 2. Typical primary and secondary currents as functions of time. 6 keV Cs^+ on W.

About 2 sec later the cesium-ion beam is pulsed onto the target. The primary ion and secondary electron currents are recorded continuously. If desired, the ion beam can periodically be deflected off of the target to insure the zeros of the ion and electron currents have not shifted.

The instant the beam strikes the target the values of I_i and I_e rise from their zero values to their initial values. These incident ion and secondary electron zero-value currents are due to insulator leakage caused by a cesium film which builds up on them as measurements are taken. The ratio of these initial value increments was taken to be γ_i for clean tungsten. There is little observed variation of I_i with time but I_e immediately begins to increase steadily until a saturation value is obtained (see Fig. 2). Not only is the initial γ_i for clean tungsten reproducible but so is the final γ_i for cesiated tungsten if enough time is allowed. Since all measurements were taken with background pressures $\leq 5\times10^{-9}$ Torr the authors believe that the 5–10 sec delay from the end of the flash to the time of the initial measurement does not allow time for ambient gases to appreciably adsorb on the target. Exact monolayer adsorption times have been measured for these pressures[7] and they are of the order of 10 min. A quick check showed the adsorption time to be greater than 5 min for conditions under which these data were taken. This gives a value of surface coverage by ambient gases less than 3%.

The results of these measurements are shown in Fig. 3. In agreement with previous measurements a linear increase in γ_i was obtained for an increase in incident ion energy, $\partial\gamma_i/\partial E \simeq 0.04$ electron/ion per keV. But contrarily, a higher kinetic ejection threshold energy for cesium on tungsten was obtained. This threshold, 2.5

keV is arrived at by extrapolating the data down to a $\gamma_i=0$. Also, γ_i was zero within the accuracy of the measurement below this energy for what the authors believe to be clean tungsten. The equipment and method of detection used would be capable of detecting a γ_i down to about 0.005. For cesiated tungsten, nonzero values of γ_i were observed for energies down to 1 keV.

In Fig. 4 the data presented in this paper are shown in comparison with other measurements. Because of the measurement of a threshold energy for γ_i for cesium on tungsten and because of the lower values of γ_i obtained, the authors believe the previous measurements of Waters and Petrov are in error. This error is probably due to cesium or adsorbed gas coverage on the target. In the energy range common to both measurements, the values of Brunnee agree very well with those presented here. There is a difference in the $\partial\gamma_i/\partial E$'s and also in the threshold energy. This could be due in part to the difference in properties of tungsten and molybdenum. The threshold energy of 2.5 keV corresponds to a cesium-ion velocity of approximately 0.6×10^7 cm/sec. This is in excellent agreement with the theoretical value of the velocity threshold for kinetic ejection of electrons calculated by Parilis and Kishinevskii.[8]

Defects in Irradiated Silicon: Electron Paramagnetic Resonance and Electron-Nuclear Double Resonance of the Si-E Center

G. D. Watkins and J. W. Corbett
General Electric Research Laboratory, Schenectady, New York
(Received 7 January 1964)

The Si-E center is one of the dominant defects produced by electron irradiation in phosphorus-doped vacuum floating zone silicon. It introduces an acceptor level at $\sim(E_c-0.4)$eV and gives rise to an electron paramagnetic resonance when this level does not contain an electron. As a result of electron paramagnetic resonance (EPR) and electron-nuclear double resonance (ENDOR) studies described in this paper, we conclude that the defect is a lattice vacancy trapped next to a substitutional phosphorus atom, with EPR arising from the neutral charge state. The observed hyperfine interactions with P^{31} and neighboring Si^{29} nuclei, as well as the observed g-tensor anisotropy, are discussed in terms of a simple linear combination of atomic orbitals (LCAO) molecular orbital treatment. In addition to the anisotropy associated with the phosphorus-vacancy direction in the lattice, an additional distortion of the defect occurs which is identified in the LCAO treatment as a manifestation of the Jahn-Teller effect. Thermally activated reorientation from one Jahn-Teller distortion to another causes motional broadening and narrowing effects upon the EPR spectrum in the temperature region 60–150°K. The motion is also studied by stress-induced alignment at lower temperatures and the activation energy for this process is determined to be $\sim$0.06 eV. Alignment of the phosphorus-vacancy direction in the lattice is also achieved by stressing at elevated temperatures. The activation energy for this motion is 0.93 ± 0.05 eV. The magnitude and sense of the alignment in both kinds of stress experiments are consistent with the microscopic model of the defect. The role of the phosphorus-vacancy interaction in the diffusion of phosphorus in unirradiated silicon is discussed. Using the published value for the diffusion activation energy for phosphorus in silicon, we estimate the appropriate value for silicon self-diffusion to be 3.94 ± 0.33 eV and the formation energy for the lattice vacancy in silicon to be 3.6 ± 0.5 eV. These are quantities for which no direct experimental values are available. Also included is an appendix which gives estimates of $|\psi_{3s}(0)|^2$ and $\langle r_{3p}^{-3}\rangle$ for the $3p$ atoms aluminum through chlorine.

I. INTRODUCTION

THIS is the third[1] in a series giving detailed descriptions of defects produced by irradiation in silicon. In this paper, we describe electron paramagnetic resonance (EPR) studies of the Si-E center.[2] This center has been discussed briefly in previous publications[3,4] where it was tentatively identified as a phosphorus-vacancy pair. In this paper the arguments leading to this identification are presented, and a model of the microscopic configuration of the defect as well as its electronic structure is presented. Such physical properties as its activation energy for diffusion, its binding energy, etc., are estimated.

Also discussed is the role that this defect plays in the high-temperature diffusion of phosphorus in unirradiated material. From some of the properties of the E center deduced here, we can estimate the activation energy for self-diffusion in silicon as well as the formation energy for the lattice vacancy, quantities for which no direct experimental values are available.

II. EXPERIMENTAL PROCEDURE

The silicon samples[5] studied were n type (phosphorus $\approx10^{15}-10^{16}/cm^{-3}$) which had been grown in vacuum by the floating zone technique. The samples were approximately 0.1 in.$\times$0.1 in.$\times$0.5 in. and were irradiated equally on opposite sides at room temperature by 1.5 MeV electrons from a resonant transformer accelerator. The bombardment current was ≈2.5 $\mu A/cm^2$, the maximum temperature rise in the sample being about 25°C.

The samples were mounted with their long dimension along the axis of a TE_{011} microwave cavity and EPR was studied using a balanced bolometer spectrometer at 20 kMc/sec. Magnetic field modulation and lock-in detection at 94 cps were employed. Most measurements were made in dispersion. At $\lesssim$20°K, relaxation times are long and rapid passage effects[6] gave absorption-like spectra, 180 deg out of phase with respect to the modulation. Studies at higher temperatures gave the usual derivative of dispersion curves.

For electron-nuclear double resonance (ENDOR)[7] studies, a single turn coil on the end of a coaxial line was introduced into the resonance cavity, as shown in Fig. 1, the open loop at the bottom of the coil allowing it to slip over the previously mounted sample. The coil was driven by a General Radio 1211B Unit Oscillator

and supplied the radio-frequency magnetic field necessary for the nuclear transitions. ENDOR studies were made at 4.2°K by observing a strongly saturated electronic transition in dispersion under normal conditions of magnetic field modulation. The nuclear transition frequencies were detected as a transient change in the electron resonance signal as the radio-frequency oscillator was swept through the nuclear resonance frequency.

The method for applying uniaxial stress to the crystal has been previously described in (I). Briefly, a simple lever and weights outside the cryostat supplies a force to a stainless-steel rod (inserted into the entry tube in place of the ENDOR coaxial line) which in turn transmits this force directly to the end of the crystal, thus compressing it along its long dimension.

Studies versus temperature were made below 77°K by first cooling to 20°K, expelling the liquid H_2 coolant, and observing as the cavity plus crystal warmed up to the 77°K of the cryostat heat shield. For higher temperatures, a heater connected to the wave guide approximately 6 in. above the cavity was used. Temperature was monitored by a copper-constantan thermocouple on the cavity.

III. GENERAL RESULTS AND DISCUSSION

A. Experimental Results

1. Summary of Previous Work

Previous studies[3] have shown the following:

(a) The E center is the dominant spin-resonance center produced in phosphorus-doped *vacuum floating zone* silicon by 1.5 MeV electron irradiation at room temperature. It does not appear in the initial stages of the irradiation but only after the Fermi level has receded to $\approx(E_c-0.4)$eV as a result of the irradiation. The E center is thus associated with a net acceptor level at $\approx(E_c-0.4)$eV[8] and *is observed only when this level does not contain an electron.*

[8] We found this level to be at 0.43 eV. Other investigators have reported the dominant acceptor level in phosphorus-doped floating zone silicon to be at (i) 0.38 eV [G. K. Wertheim and D. E. Buchanan, J. Appl. Phys. **30**, 1232 (1959)], (ii) 0.4 eV [H. Saito, M. Hirata, and T. Horiuchi, J. Phys. Soc. Japan **10**, Suppl. III, 246 (1963)], and (iii) 0.47 eV [E. Sonder and L. C. Templeton, J. Appl. Phys. **34**, 3295 (1963)]. These discrepancies may reflect the presence of other defects with energies near to that of the E center (see Ref. 4).

(b) Hyperfine interaction with 4.7% abundant Si^{29} has shown that the E-center resonance arises from an unpaired electron that is highly localized on one silicon atom. An additional hyperfine interaction with an impurity atom with a 100% abundant nuclear isotope of $I=\frac{1}{2}$ is also observed. This was suggested to be due to a neighboring phosphorus atom.

(c) The E center has not been observed in *pulled* n-type silicon (containing oxygen $\approx10^{18}$ cm^{-3}). Instead in this material the dominant defect observed is the Si-A center,[1] which we have identified as a substitutional oxygen atom, presumably formed when a mobile lattice vacancy is trapped by an interstitial oxygen impurity. This reciprocal behavior between Si-A and Si-E centers, depending upon the concentration of oxygen, led us to suggest that the E center also results from a trapped vacancy, in this case trapped by a phosphorus atom.

2. EPR Spectrum

Figure 2 shows a recording of the E-center spectrum. There is a strong central group made up of doublets and, at higher gain, satellites are observed showing the same doublet structure. Figure 3(a) shows the angular variation of the central group. The satellites are found to be composed of pairs symmetrically located around each of the central lines and with intensity (per pair) $\approx5\%$ of the corresponding central component.

The complete spectrum can be described as arising from several identical defects, but differently oriented in the lattice, each with the spin Hamiltonian

$$\mathcal{H}=\beta\mathbf{H}\cdot\mathbf{g}\cdot\mathbf{S}+\sum_j \mathbf{I}_j\cdot[\mathbf{A}_j\cdot\mathbf{S}-(\mu_j/I_j)\mathbf{H}], \qquad (1)$$

with $S=\frac{1}{2}$.

The second term describes magnetic hyperfine interactions with nuclei neighboring the defect. In these

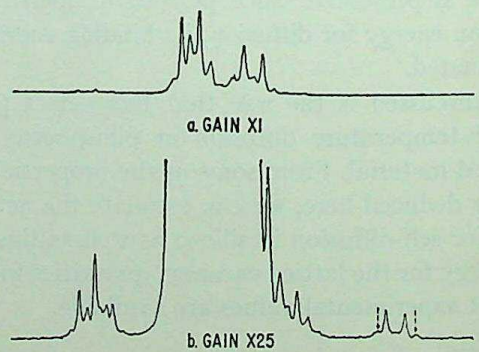

FIG. 2. E-center spectrum at two gain settings with $\mathbf{H}\|\langle111\rangle$. The arrows indicate weak shoulders on the satellite lines, which are referred to in the text.

interactions, there are two distinct nuclear species involved. One is a nucleus with a 100% abundant isotope of $I=\frac{1}{2}$. (We will demonstrate in the next section that this nucleus is that of a phosphorus atom near the defect, hence we will refer to it here as phosphorus.) There is always one and only one such phosphorus nucleus near the defect, giving rise to the doublet structure on all lines shown in Figs. 2 and 3. The other nuclear species is Si^{29} (4.7% abundant, $I=\frac{1}{2}$) associated with neighboring silicon atoms. The satellites of Fig. 2 arise from strong interaction with the Si^{29} nucleus of *one* nearby silicon atom, their amplitudes relative to the central lines reflecting the isotopic abundance of Si^{29}. Hyperfine interactions with other silicon atoms in the vicinty of the defect are an order of magnitude smaller and are only partially resolved, contributing mainly to the breadth of the central lines.

Equation (1) gives for the energy levels

$$E=g\beta HM+\sum_j E_{hf}{}^j(M,m_j)\,, \qquad (2)$$

with

$$g^2=g_1{}^2n_1{}^2+g_2{}^2n_2{}^2+g_3{}^2n_3{}^2\,, \qquad (3)$$

where n_1, n_2, n_3 are the direction cosines of the principal axes of the g tensor with respect to **H**. Ignoring the small anisotropy in g, the hyperfine energy terms in (2) are given to first order in $A/g\beta H$, $\mu/g\beta I$ by

$$E_{hf}{}^j(M,m_j)=\frac{M}{|M|}m_j\{\sum_\alpha[MA_{j\alpha}-(\mu_j/I_j)H]^2n_{j\alpha}{}^2\}^{1/2}. \qquad (4)$$

Here $n_{j\alpha}$ are the direction cosines of the $\alpha=1,\ 2,\ 3$ principal axes of the $\mathbf{A}_j$ tensor with respect to **H**. Equation (4) has been written in a form convenient for use when $|MA_{j\alpha}|>|\mu_j/I_j|H$, the case for the hyperfine interactions studied here. In so doing, the selection rules for the allowed EPR transitions are the usual $\Delta M=\pm1$, $\Delta m_j=0$,[9] giving

$$g\beta H=h\nu_0-\sum_j[E_{hf}{}^j(\tfrac{1}{2},m_j)-E_{hf}{}^j(-\tfrac{1}{2},m_j)]. \qquad (5)$$

The analysis is summarized in Fig. 4, where the principal values of the **g** and **A** tensors are given along with their principal axes for one of the possible defect orientations.[10] From Fig. 4, it is seen that there must be 24 equivalent orientations available for the defect in the cubic silicon lattice. That is, for each of the twelve possible ⟨110⟩ axes for g_2, there are two equivalent

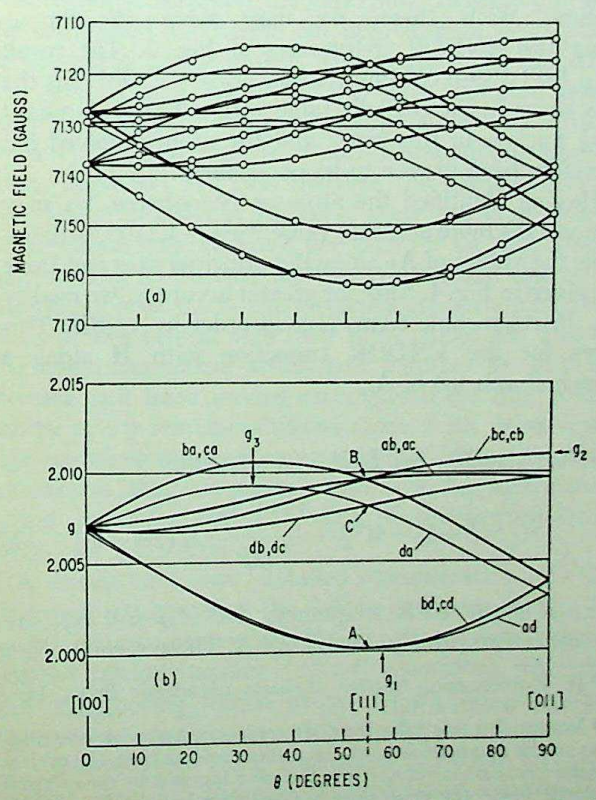

FIG. 3. (a) Angular dependence of the central lines in the E-center spectrum with **H** in the (0$\bar{1}$1) plane (see Fig. 4). The microwave frequency was 20.029 kMc/sec. (b) Corresponding g values. The labeling scheme is described in the text.

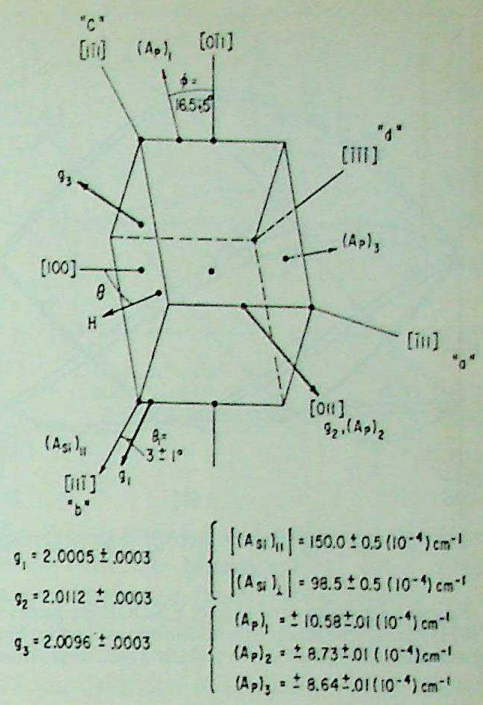

FIG. 4. Spin Hamiltonian constants for the E center with axes indicated for one of the twelve equivalent defect orientations in the lattice. With the magnetic field **H** in the (0$\bar{1}$1) plane as shown, this set of axes gives rise to the g values given by cb in Fig. 3(b).

[9] If $|MA_{j\alpha}|<|\mu_j/I_j|H$, omission of the term $M/|M|$ in Eq. (5) will allow the use of the same selection rules.

[10] These values for A_P were determined also by ENDOR measurements to be described in the next section. They are therefore more accurate than the values determined by analysis of the doublet splitting in the EPR alone. These results are within the stated error of our previously published results (Refs. 3, 4) but reveal in addition the tilting of the $(A_P)_1$ axis by $\varphi=16.5$ deg away from [0$\bar{1}$1], a fact not previously noted.

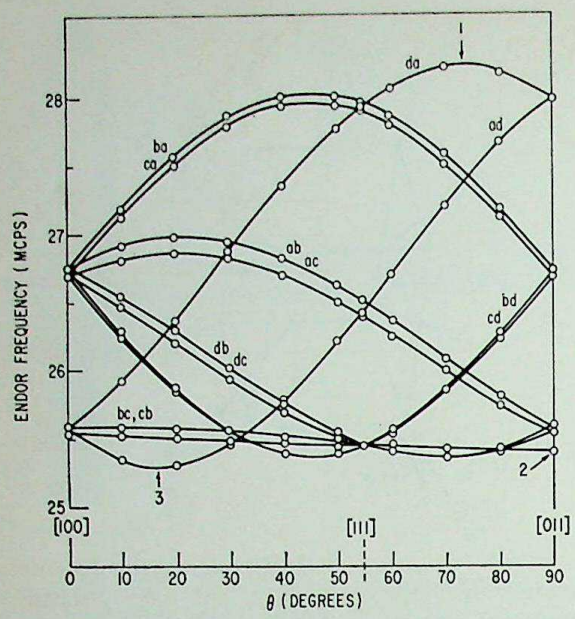

FIG. 5. Angular dependence of the P^{31} ENDOR frequencies with H in the $(0\bar{1}1)$ plane. The labels denote the corresponding branches of the spectrum in Fig. 3(b) for which these transitions are observed.

choices for g_1, one being generated from the other by a 180-deg rotation around g_2. In the EPR spectrum, such a rotation, or inversion, of coordinates cannot be distinguished and the number of distinguishable spectra is reduced to twelve. For most of the studies described here, the spectra were studied with H in a {110} plane (i.e., crystal rotated around the corresponding ⟨110⟩ axis). In this case ten of the spectra become equivalent by pairs, giving only seven distinct spectra as shown in Fig. 3, five of double intensity, and two of unit intensity.

We label (for later use) the transitions of Fig. 3 as referring to a specific defect orientation. This has been done as follows: In Fig. 4, the four ⟨111⟩ axes are labeled "*a*," "*b*," "*c*," and "*d*." (We do not distinguish here the *sign* of the axis direction.) We label a defect by two letters. The first letter specifies the ⟨111⟩ axis closest to $(A_P)_1$ and the second specifies the direction of $(A_{Si})_{II}$.

3. *ENDOR Spectrum*

ENDOR studies were initiated primarily in order to identify the impurity giving rise to the 100% abundant $I=\frac{1}{2}$ hyperfine splitting.[11] From Eq. (4), the nuclear resonance frequencies ($\Delta M=0$, $\Delta m_j=\pm 1$) are

$$\nu_n{}^j(M)=\frac{1}{h}\{\sum_\alpha [MA_{j\alpha}-(\mu_j/I_j)H]^2 n_{j\alpha}{}^2\}^{1/2}. \quad (6)$$

The study was performed only on the higher frequency transition, the lower frequency transition usually being too weak to detect.

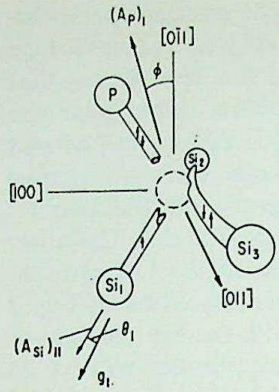

FIG. 6. Simple model of the *E* center as the neutral charge state of a vacancy next to a substitutional phosphorus atom.

The frequencies of the ENDOR transitions versus magnetic field orientation in the {110} plane are shown in Fig. 5 for each of the branches of the spectrum shown in Fig. 3, and are labeled accordingly. Also indicated are the positions of the principal hyperfine axes as determined from these measurements. (The splitting of the *ba–ca*, *bd–cd*, *ab–ac*, *db–dc*, and *bc–cb* pairs arises from ≈1.5 deg misalignment of the ⟨110⟩ axis of the crystal around which the orientation studies were made and would not exist if the crystal were perfectly aligned.)

The $A_{j\alpha}$ can be determined from the doublet splitting in the EPR spectrum, as described in the previous section. With these, we may solve (6) for μ_j using the ENDOR frequencies of Fig. 5. The result is $|\mu_j|=1.13\pm 0.06$. Phosphorus ($\mu_P=+1.1305$[12]) is the only atom in the periodic table with a 100% abundant $I=\frac{1}{2}$ nucleus in this range and the atom involved has therefore been proven to be phosphorus.

Having identified the atom as phosphorus, we may now use the more accurate value,[13] $\mu=+1.1305$, to determine the values of $\mathbf{A}_P$ along the principal axes and these are given in Fig. 4. Also, for greater accuracy, we modify Eq. (6) to include terms second order in $A/g\beta H$. This gives for the ENDOR transition with H along a principal axis (α) of $\mathbf{A}_j$,

$$(h\nu_n{}^j)_\alpha=\Big|A_{j\alpha}M-(\mu_j/I_j)H-(A_{j\beta}A_{j\gamma}/2h\nu) \times[S(S+1)-M^2]-\frac{A_{j\beta}{}^2+A_{j\gamma}{}^2}{4h\nu}M(2m-1)\Big|. \quad (7)$$

Here ν is the EPR frequency, and $A_{j\beta}$ and $A_{j\gamma}$ are the other two principal values of **A**. These second-order

[11] The sensitivity, although adequate for the study of this 100% abundant nucleus, was not sufficient to study the 4.7% abundant Si^{29} hf interactions. As a result this interesting part of the problem, i.e., probing out the wave function on more distant silicon neighbors, has yet to be done.

[12] H. Kopfermann, *Nuclear Moments* (Academic Press, Inc., New York, 1958), p. 451.

[13] In assuming this value for μ, we are ignoring possible contributions to the magnetic field at the nucleus arising from the orbital angular momentum induced into the wave function by the external magnetic field—the equivalent of the "chemical shift" in NMR studies. Using arguments similar to those given by G. W. Ludwig and H. H. Woodbury [Phys. Rev. 117, 1286 (1960)], we conclude, from the small g shifts encountered here, that the effect is negligible with respect to the experimental errors indicated in Fig. 4.

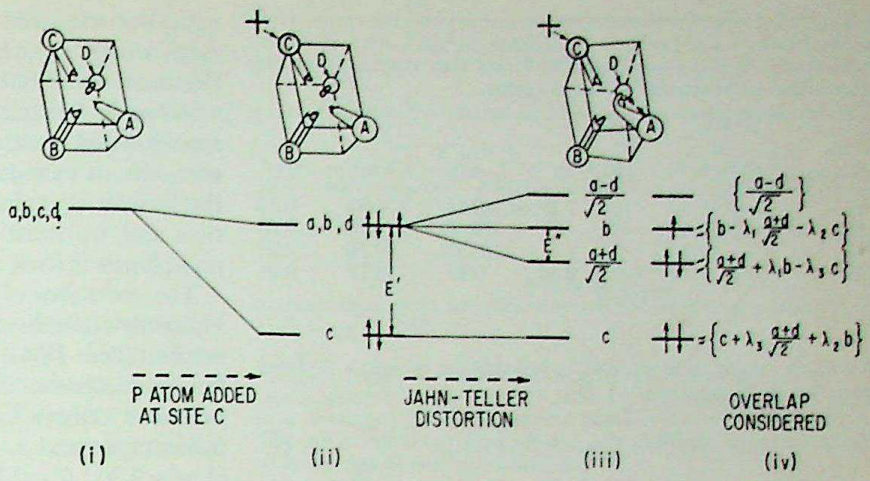

FIG. 7. Simple LCAO molecular orbital model of the electronic structure of the E center. (i) Four degenerate (ignoring overlap) orbitals of the isolated vacancy. (ii) The lowering of the c orbital due to the extra nuclear charge of the phosphorus atom at C. (iii) Lifting of the degeneracy of the a,b,d orbitals by a Jahn-Teller distortion. (iv) Modifications to the wave functions when small overlap between the atomic orbitals is considered. (These wave functions are orthogonal and normalized only through first order in the λ_i.)

corrections are small, and were therefore used only in determining the principal values given in Fig. 4. Equation (6) was otherwise quite satisfactory for fitting the observed spectra. The absolute signs of $A_{j\alpha}$ could not be determined, but fitting the data of Fig. 5 with Eq. (6) requires that the signs of all principal values be the same.

B. Discussion

1. Model

In order to interpret the experimental results, it will be convenient to present an approximate description of the model at the outset. This is shown in Fig. 6 for the defect giving rise to the specific sets of axes shown in Fig. 4. It is the neutral charge state of a lattice vacancy trapped next to a substitutional phosphorus atom impurity. We can visualize the construction of the defect as follows: Initially, there are four broken bonds around the vacancy, one each for the four atoms surrounding it. Because of the extra nuclear charge of the phosphorus atom, two electrons are accommodated in its broken orbital with their spins paired off. Two of the remaining silicon atoms pull together to form an electron pair bond leaving an unpaired electron in the orbital of the remaining silicon atom. EPR arises from this unpaired electron explaining the large hyperfine interaction with one silicon atom. The $\mathbf{A}_{Si}$ and $\mathbf{g}$ axes reflect primarily the $\langle 111\rangle$ axis of the broken bond orbital on this silicon atom.

A somewhat more detailed consideration of the electronic structure of the defect is shown in Fig. 7. In the absence of overlap, the dangling orbitals of an isolated lattice vacancy (a,b,c,d) associated with the four neighboring silicon atoms (A,B,C,D) give four degenerate one-electron orbitals. Replacing atom C by a phosphorus atom is equivalent to adding an extra positive charge at this site. This partially removes the degeneracy and orbital c is lowered in energy. In the neutral charge state, five electrons are accommodated in these orbitals, two paired in the c orbital and the remaining three in the a,b,d set. Because of the degeneracy associated with the partially filled a,b,d orbitals, a spontaneous distortion takes place to remove this degeneracy, as shown. Viewed this way, the "pair bonding" of silicon atoms 2 and 3 in Fig. 6 can be considered simply as a manifestation of the Jahn-Teller[14] effect.

If we now consider the effect of small additional overlap between the remaining orbitals, the wave functions will be modified slightly as shown in panel (iv) of Fig. 7. In this scheme, the unpaired electron is primarily located in orbital b of silicon atom B but has a small percentage ($\lambda_1^2/2$) on silicon atoms A and D and (λ_2^2) on phosphorus atom C. Because we expect the Jahn-Teller splitting (E'') to be smaller than the Coulomb energy associated with the lowering of the c orbital (E'), we expect $\lambda_1^2>\lambda_2^2$.

This is still a considerable oversimplification, of course, because the electronic wave functions will also spill over somewhat onto the more distant neighbors. However, analysis of the hyperfine interactions in the following section shows that $\sim 70\%$ of the wave function can be accounted for on these four atoms alone and this simple localized "molecule" should therefore be a reasonable first approximation.

In the next two sections the hyperfine interactions and the g tensor will be considered quantitatively in terms of this model. In the remaining sections, other consequences of the model will be explored as quantitative tests for the model.

2. Hyperfine Interactions

Following the arguments of the previous section, let us construct the wave function for the unpaired electron as a linear combination of atomic orbitals centered on the atom sites near the defect

$$\bar{\psi}=\sum_i \eta_i\psi_i. \tag{8}$$

[14] H. A. Jahn and E. Teller, Proc. Roy. Soc. (London) **A161**, 220 (1937).

TABLE I. Hyperfine parameters (a_j and b_j) and the corresponding molecular wave function coefficients (α_j^2, β_j^2, and η_j^2) calculated from the observed hyperfine interaction constants for the atom sites in the vicinity of the E center.

Atom site	a_j (10^{-4} cm^{-1})	b_j (10^{-4} cm^{-1})	α_j^2	β_j^2	η_j^2
Si_1	(−)115.7	(−)17.2	0.14	0.86	0.59
Si_2	(−) 12.4	···	(0.30)	(0.70)	0.03
Si_3	(−) 12.4	···	(0.30)	(0.70)	0.03
P	(+) 9.32	(+) 0.63	0.29	0.71	0.01

At each atom site j, we approximate ψ_j as a hybrid $3s3p$ orbital given by

$$\psi_j=\alpha_j(\psi_{3s})_j+\beta_j(\psi_{3p})_j. \tag{9}$$

For the atoms adjacent to the vacancy, we take the p function as directed approximately along the ⟨111⟩ direction from the site to the center of the vacancy. To a good first approximation, the hyperfine interaction at the jth nuclear site is determined solely by ψ_j, i.e., that part of the wave function close to the nucleus. In this approximation, the hyperfine interaction is axially symmetric along the p-orbital axis and can be written

$$A_{\parallel}=a+2b,$$
$$A_{\perp}=a-b. \tag{10}$$

Here the isotropic term a arises from the Fermi contact interaction

$$a_j=(16\pi/3)(\mu_j/I_j)\beta\alpha_j^2\eta_j^2|\psi_{3s}(0)|_j^2, \tag{11}$$

where μ_j is the magnetic moment and I_j the spin of the jth nucleus. The anisotropic term b results from the dipole-dipole interaction averaged over the electronic wave function and is given by

$$b_j=(4/5)(\mu_j/I_j)\beta\beta_j^2\eta_j^2\langle r_{3p}^{-3}\rangle_j. \tag{12}$$

In Appendix A, we have estimated $|\psi_{3s}(0)|^2$ and $\langle r_{3p}^{-3}\rangle$ for neutral silicon and phosphorus, using the recent Hartree-Fock calculations of Freeman and Watson.[15] These values are given in Table III in the Appendix.

Table I gives the results of analysis for α_j^2, β_j^2, η_j^2 for each of the atom sites of Fig. 6, using Eqs. (8)–(12), the hyperfine constants given in Fig. 4 and the estimates of Table III. Equations (11) and (12) predict that a_j and b_j should have the same sign as μ_j. With this assumption, there is no ambiguity in determining the a_j and b_j from (10) even though the absolute values of $A_{\parallel}$ and $A_{\perp}$ were not determined. The signs of the a_j's and b_j's in Table I are in parenthesis to indicate that they were not determined experimentally. In treating the phosphorus hyperfine interaction we have ignored the small departure from axial symmetry $[(A_P)_2\neq(A_P)_3]$ and have ignored the additional contribution to b_j that arises from dipole-dipole interaction with the unpaired electron centered mainly on the neighboring Si_1 site. A crude calculation suggests that this interaction contributes $\sim 0.1-0.2$ (10^{-4} cm^{-1}) to the anisotropic term and it should be included in a more sophisticated treatment. It appears small enough, however, that it cannot account by itself for the tilting of the hf axis away from the ⟨111⟩ "normal bond" direction and we must conclude that the orbital on the phosphorus is itself significantly tilted in this direction.

The estimates of a_j for the Si_2 and Si_3 sites comes indirectly from an experiment to be described in a later section (Sec. IVA), and is included here at this time for completeness. Only a_j can be estimated in this experiment and we have had to assume α_j^2 and β_j^2, i.e., percentage s and p, in order to compute η_j^2. The choice of $\alpha^2\approx 0.30$, $\beta^2\approx 0.70$ was made to agree with that observed in the A center,[16] where the unpaired electron is incorporated in a similar two atom bond between next neighbors across a vacancy.

We are thus able to account for ~60% of the wave function as localized in a dangling orbital on a single silicon atom (Si_1 of Fig. 6, atom B of Fig. 7) neighboring the vacancy. The orbital is approximated by ~86% $3p$ character and is directed toward the vacancy. The enhanced p-like character over a 25%s−75%p, (sp^3), tetrahedral orbital[17] could be caused by the relaxing of the Si_1 atom away from the vacancy. Since the orbital on this atom is not involved in bonding to the other atoms across from the vacancy (see Fig. 7), we would expect the Si_1 atom to be pulled away from the vacancy by the strong bonds to its three remaining nearest neighbors (not shown in Figs. 6 and 7). Si_1 and its three nearest neighbors would then tend to approach a planar configuration for which the bonding orbitals would be sp^2 and the dangling orbital pure p.[18]

An additional ~7% of the wave function is accounted for on the three other atoms surrounding the vacancy, ~3% each on the two silicon atoms (Si_2 and Si_3) and a still smaller amount (~1%), as anticipated in the previous section, on the phosphorus. The remaining ~30% of the wave function is presumably spread over more distant silicon neighbors. [The hyperfine interaction with some of these sites is still large enough to give partially resolved structure on the shoulders of the lines in the spectra (see Fig. 2). The Si_2 and Si_3 interactions contribute to these shoulders, but the total intensity of the structure indicates that there must also

[15] R. E. Watson and A. J. Freeman, Phys. Rev. 123, 521 (1961).

[16] Our previous analysis of the A center (Refs. 1,4) with somewhat different estimates of $|\psi_{3s}(0)|^2$ and $\langle r_{3p}^{-3}\rangle$, indicated that, for it, the wave function was 37% s and 60% p on the main two silicon atoms next to the vacancy and with 70% of the total wave function accounted for by them. A reanalysis, using the new estimates of these quantities given in Table III, gives ~30% s and ~70% p, but with essentially the same fraction of the wave function accounted for. Similar changes, in the fraction s and p character only, are required for the other centers analyzed in Ref. 4.

be three or four additional sites for which the hyperfine interaction is of comparable magnitude. These then could account for an additional 10–15% of the wave function leaving only 15–20% to be further spread out. The weaker hyperfine interaction on these more distant sites is unresolved and contributes only to the breadth (~2.5 G between half-maximum points) of the central part of the line.]

3. *g Tensor*

We have determined that the wave function consists primarily of a dangling bond on a single silicon atom. Let us therefore consider the g tensor to be expected for such a single broken-bond orbital. We start with the Hamiltonian for a bound electron in a magnetic field.[19]

$$\mathcal{H}=2\beta\mathbf{H}\cdot\mathbf{S}+\frac{e\hbar}{2mc}\mathbf{S}\cdot\left[\mathbf{E}\times\left(\mathbf{p}+\frac{e}{c}\mathbf{A}\right)\right]+\frac{e}{2mc}(\mathbf{p}\cdot\mathbf{A}+\mathbf{A}\cdot\mathbf{p})+\frac{e^2}{2mc^2}A^2. \quad (13)$$

The second term gives rise to the spin-orbit interaction where $\mathbf{E}$ is the electric field seen by the electron, $\mathbf{p}$, its momentum and $\mathbf{A}$, the vector potential. The third term gives the interaction between the motion of the electron and the external magnetic field, and the last term is the usual diamagnetic interaction.

We choose a gauge for $\mathbf{A}$ with the atom involved as center, i.e.,

$$\mathbf{A}=\tfrac{1}{2}\mathbf{H}_0\times\mathbf{r}. \quad (14)$$

With this choice, the third term becomes $\beta\mathbf{H}_0\cdot\mathbf{L}$. Equation (13) then leads to the following expression for the g shift, accurate to first order in the spin-orbit interaction,

$$\Delta g_{ij}=-2\sum_n\frac{\langle 0|(\mathbf{V}_{so})_i|n\rangle\langle n|L_j|0\rangle}{E_n-E_0}. \quad (15)$$

where

$$\mathbf{V}_{so}=(\beta/mc)\mathbf{E}\times\mathbf{p}.$$

The sum is over all excited states.

The form of the g tensor to be expected is apparent from Eq. (15). It will be axially symmetric around the direction of the broken bond orbital axis and the g shift along the axis will be zero.[20] There can be a non-zero g shift perpendicular to this axis, however.

We note that the observed g tensor (Fig. 4) is approximately axially symmetric around the 1 axis (which is approximately the bond axis, see Fig. 6), as expected. Also, the g shift along this axis, although not zero, is

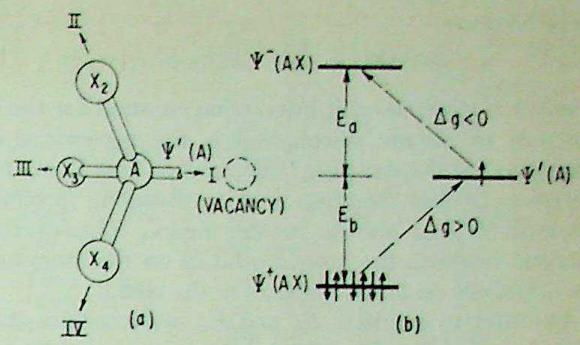

FIG. 8. Localized "molecule" considered in the g-shift calculation (see Appendix B). (a) Atom A with its broken bond $\Psi(A)$ next to a vacancy. (b) Corresponding one-electron molecular states. The matrix elements involved in the g shift are indicated along with the sign of their contribution.

significantly smaller than that along the 2 and 3 axes. If we consider the small negative shift along the bond axis as arising from the 40% of the wave function *not* accounted for in this oversimplified treatment, we are left with $\Delta g_{\parallel}=0$ and $\Delta g_{\perp}\approx+0.01$ to be contributed by the dangling bond. Since $\approx 60\%$ of the wave function is in this bond, this requires $\Delta g_{\parallel}=0$, $\Delta g_{\perp}\approx+0.017$ for a fully occupied dangling bond.

Experimentally, we can take the view that these values are reasonable in that other defect structures in silicon which we have studied and interpreted in terms of dangling bonds also indicate $\Delta g_{\parallel}=0$ and with positive values for $\Delta g_{\perp}$ of this magnitude.[1,4] Theoretically, however, the calculation of these quantities represents a very complex problem. Treated properly, the excited states of Eq. (15) are the continuum of all valence and conduction band states of the solid.

In previous publications,[1,4] we have carried out a simplified treatment of this problem in which we considered only the localized "molecule" made up of the atom in question and its three nearest neighbors as shown in Fig. 8. In this treatment, we used simple one-electron LCAO bonding $[\bar{\psi}^+(AX)]$ and antibonding $[\bar{\psi}^-(AX)]$ molecular orbitals between the atom and its neighbors as approximations to the excited localized valence and conduction band states of (15). The matrix elements to the bonding orbitals, being "hole"-like, were shown to give rise to a positive g shift, while those to the antibonding ones, being "electron"-like, gave rise to a negative shift. The net shift was shown to be the difference between these two *competing* effects. However, it has been pointed out to us that in the derivation, the spin-orbit matrix elements were not handled correctly,[21] leading to an error in the final result. We take this opportunity to correct this error. The result (rederived in Appendix B) should

[19] C. P. Slichter, *Principles of Magnetic Resonance* (Harper and Row, Publishers, Inc., New York, 1963), Chap. 7.

[20] The orbital may be made up of a linear combination of several atomic orbitals (s,p,d, etc.), but by symmetry, all will have $m_l=0$ along the bond axis. As a result, there are no matrix elements for the component of angular momentum along this axis giving $\Delta g_{\parallel}=0$.

[21] We are grateful to R. H. Silsbee for pointing out this error to us. Our error involved replacing $\mathbf{V}_{so}$ by $\lambda\mathbf{L}$, with λ the spin-orbit constant for the free atom. For the molecular excited states considered here, the more general form of (15) should have been used.

Digitized by Arya Samaj Foundation Chennai and eGangotri

have been

$$\Delta g_1 \approx \lambda\{[1/E_b)-(1/E_a)\}\beta_A^2, \qquad (16)$$

where λ is the spin-orbit interaction constant for the $3p$ electron of atomic silicon, β_A^2 is the percentage $3p$ character for the dangling bond, and E_b and E_a are the energies to the bonding and antibonding orbitals, respectively, as shown in the figure. The overlap integral between the atomic orbitals on the atom and its neighbors no longer appears in the result.

In order to estimate E_b and E_a, we recognize that making up a localized state in the band picture requires summation over all k. E_a and E_b must therefore represent suitable averages over the available states in the bands. Present estimates of the band structure of silicon[22] would suggest that these average excited state energies would be $\sim$1–2 V into the respective bands from the band edges. We do not know the energy-level position associated with the dangling bond of the E center but we *do* know that an *additional* electron can be accommodated at $(E_c-0.4)$eV. This means that the single electron level is lower in energy and, as a guess, we take it as $\approx E_v$, the valence band edge. This gives $E_b \approx 1.5$ eV, $E_a \approx 2.5$ eV. With $\lambda = 0.02$ eV,[23] $\beta_A^2 = 0.86$ (Table I), this gives

$$\Delta g_1 \approx +0.005.$$

This is the correct sign but is a factor of $\sim$3 too low. There was some arbitrariness in the estimates of E_b and E_a, to be sure, but it is not felt that a realistic adjustment of the values could make up this large a factor. (This is particularly evident in the Si-A center,[1] for instance, where the energy level is known to be close to the *conduction band* edge and the g shifts are still positive and of comparable magnitude.)

We thus conclude that the large g shifts must result, in significant part, as a result of stronger matrix elements of (15) to the bonding orbitals (valence band) than to the antibonding ones (conduction band). Within the framework of our localized molecule approximation, there are two effects that we did not previously treat that tend in this direction. One results from the fact that the molecular obritals used in (I) were not orthogonal to the $1s$, $2s$, $2p$ atom cores. We have modified the treatment to take this properly into account (see Appendix B) and we find that (16) is replaced by

$$\Delta g_1 \approx \lambda\{(1+\gamma)/E_b-(1-\gamma)/E_a\}\beta_A^2. \qquad (17)$$

In Appendix B, we estimate $\gamma \sim +0.17$, giving, with $E_b \approx 1.5$ eV, $E_a \approx 2.5$ eV,

$$\Delta g_1 \approx +0.008.$$

This is an increase in the right direction but it is still not enough.

Another effect is a *nuclear shielding* effect. The effect of the positive charge of the neighboring atom core should be to enhance the charge density near the core of the atom to which it is bound for the bonding orbitals but to deplete it for the antibonding ones. This effect is well established in the H_2 molecule, for instance, where the contraction of the $1s$ atomic orbitals in the bonding state is equivalent to an increase of nuclear charge by 20%.[24] Such a contraction in our case would enhance the spin-orbit matrix element of (15) and further increase the "contact" to the valence band.

It would be difficult to include this effect properly in our simple LCAO treatment. However, a measure of its importance is seen in the fact that the observed spin-orbit splitting in the valence band of silicon (0.044 eV)[25] is actually $\sim$50% *greater* than that for the free atom, (0.03 eV).[23] On the other hand, if we were to calculate the spin-orbit splitting using the LCAO molecular bonding orbitals in (I), we would get a *reduction*. For instance, if we ignore the $2p$ core terms, the effective spin-orbit constant would be reduced directly by the normalization factor $(1+S)\cong 1.7$ [see (I)]. By a calculation similar to that for the g shift, we find that inclusion of the $2p$ core terms recovers some of this loss by the factor $1+2\gamma=1.34$, but we would still predict a reduction of $\sim$1.25. This would indicate that the "contraction" of the valence band wave functions is therefore of considerable importance.

It is interesting to note that in our simple treatment, it would require an effective $\gamma \sim 0.8$, to account for the observed 50% increase in valence band spin-orbit interaction. Such a value in (17) would give $\Delta g_1 \approx +0.017$! This agreement is clearly not entirely coincidental in that both the g shift and the enhanced valence band spin-orbit interaction reflect the same phenomenon—the contraction of the wave function around the cores in bonding states.[26]

We conclude that the indicated values $\Delta g_{\parallel}=0$, $\Delta g_1 \approx +0.017$ are *reasonable* ones for a single broken bond orbital in silicon. In the case of the E center, with $\sim$60% of the wave function in such an orbital, this accounts for the gross features of the g tensor, i.e., $\Delta g_1 \approx 0$, $\Delta g_2 \approx \Delta g_2 + 0.01$. The remainder of the wave

[22] J. C. Phillips, Phys. Rev. 125, 1931 (1962).

[23] The spin-orbit interaction constant λ is two-thirds the free atom spin-orbit splitting as given in C. E. Moore, *Atomic Energy Levels*, Natl. Bur. Std. (U. S.) Circular No. 467 (U. S. Government Printing Office, Washington, D. C., 1949).

[24] See C. A. Coulson, Trans. Faraday Soc. 33, 1479 (1937) for a discussion of these effects.

[25] S. Zwerdling, K. J. Button, B. Lax, and L. M. Roth, Phys. Rev. Letters 4, 173 (1960).

[26] The correct characterization of molecular wave functions in the vicinity of the atomic cores is a subject of considerable current controversy [W. Marshall and R. Stuart, Phys. Rev. 123, 2048 (1961); R. G. Shulman and S. Sugano, *ibid.* 130, 506 (1963); J. C. Phillips and L. Liu, Phys. Rev. Letters, 8, 94 (1962)]. In the case of substantial ionic character, the situation is not so clear. In the case here of strong covalent bonds, however, it appears that substantial contraction and expansion of the bonding and antibonding orbitals, respectively, must occur around the atoms. The article by Phillips and Liu, and Ref. 54 treat this point in some detail.

function (~40%) presumably can account for the remaining g shifts.

IV. MOTIONAL EFFECTS

In the previous sections, we have presented a model for the E center, and we have shown that it is compatible with the observed hyperfine interaction and the g tensor. There is always the question, however, as to whether this model is unique. Are there other possible microscopic configurations that might also be compatible with these quantities? We desire to test the validity of the model in as many ways as possible.

The model of Fig. 6 predicts a number of motional effects which we will test in the following sections. For instance, for the particular phosphorus-vacancy direction shown in the figure, there are two other entirely equivalent configurations, corresponding to bonding Si_1 and Si_3 together and leaving the unpaired electron on Si_2, or Si_1 and Si_2 together, with the unpaired electron on Si_3. These together with the configuration depicted in Fig. 6, represent the three equivalent Jahn-Teller distortions of Fig. 7. The barrier for reorientation from one distortion direction to another should not be large (being comparable to the Jahn-Teller energy) and we expect thermally activated reorientation to manifest itself at relatively low temperatures. This motion can be studied in the resonance in two ways: (1) If the correlation time for the reorientation process is short enough ($\tau \lesssim 10^{-7}$ sec), the individual lines in the EPR spectrum become lifetime broadened and give a direct means of studying the nature and kinetics of the motion. Such a study is described in Sec. IVA; (2) in IVB, the motion is revealed by studying the preferential alignment of the defects induced by the application of uniaxial stress to the crystal. In addition to revealing the nature and kinetics of the reorientation process, the magnitude and sense of the stress induced alignment also confirm other important features of the model.

The vacancy-phosphorus direction is another "degree of freedom" that can be probed by stress. In Sec. IVC, preferential alignment of this axis of the defect is achieved by stress at elevated temperatures. The study of the magnitude and sign of the alignment plus the kinetics of its recovery gives a further test of the model.

A. Low-Temperature Linewidth Studies

In the temperature region ~60–150°K, the E center spectrum is observed to change drastically as shown in Fig. 9.[27] Initially, some of the lines appear to broaden

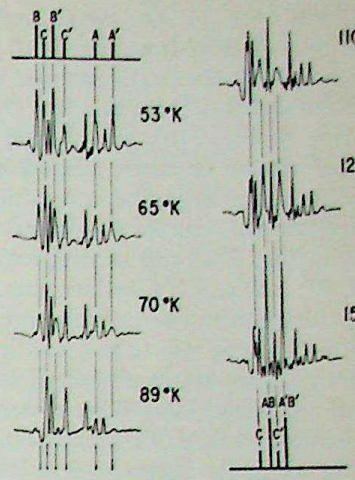

FIG. 9. E-center spectrum versus temperature showing the effect of thermally activated reorientation from one Jahn-Teller distortion direction to another (Ref. 27), $\mathbf{H} \| \langle 111 \rangle$.

and disappear as the temperature is raised and at the higher temperature end a simplified spectrum emerges.

This behavior suggests thermally activated reorientation of the defects. In general, if a defect with an anisotropic g tensor is jumping from one orientation in the lattice to another, its g value will change abruptly with each orientation. In the resonance experiment, this means that, if we are tuned to a particular multiplet in the spectrum (which corresponds to the g value of a particular orientation for the defect), a given defect is alternately brought into resonance, then out, as it executes this random reorientation. This will give rise to a lifetime broadening of the multiplets. As the temperature is raised and the jumping rate increases, the multiplets will tend to broaden out and disappear. At higher temperatures and higher jump rates, motional narrowing will eventually begin and new sets of lines will emerge at the average position of the original multiplets.

Now let us consider the E center in detail and, in particular, determine what we expect if the reorientation motion is from one Jahn-Teller distortion to another. Figure 3(b) shows the variation of the g value versus crystalline orientation for the differently oriented defects. By reference to Figs. 4 and 6, we recognize that the labels on the various curves of Fig. 3(b) have a simple interpretation in terms of the model for the defect. Labeling the four different $\langle 111 \rangle$ axes a through d as in Fig. 4, the first letter of the label specifies the vacancy-phosphorus direction and the second letter specifies the direction from the vacancy to the silicon atom with the unpaired electron. Stated more simply, *for the nearest neighbor sites of the vacancy depicted in Fig. 7, the first letter of the designation gives the phosphorus site and the second letter gives the silicon site for the unpaired electron.* (The defect orientation of Fig. 6 is "*cb*.")

Now consider the thermally activated reorientation from one Jahn-Teller distortion direction to another. In terms of the defect labeling scheme, each time a defect executes a reorientation, its second letter changes,

[27] Also noticed in Fig. 9. are weaker lines, not associated with the E center, which do not change throughout this temperature region. Some of these arise from another center which appears to have roughly the same g variations as the E center and which also displays a phosphorous hyperfine splitting, but of approximately half the magnitude. The interference with the E-center spectrum, and its weaker intensity, has prevented a detailed analysis. We have no model for this defect but presumably it could be an E center paired off with another defect such as oxygen or another vacancy, etc.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

but its first does not. The corresponding g-value change can be read directly from Fig. 3(b).

We now treat the particular case when the magnetic field is parallel to a ⟨111⟩ axis (the conditions of Fig. 9). Referring to Fig. 3(b), the number of distinguishable g values reduces to three, labeled A, B, and C. With the phosphorus hyperfine interaction, this gives rise to three *pairs* of lines for the central group spectrum as shown in Fig. 3(a) and as designated in Fig. 9 as A, A', B, B', and C, C'. Consider now that the magnetic field is tuned to resonance for multiplet C (or C'). For the defects giving rise to this multiplet, the particular reorientation we are considering has no effect because each of the three Jahn-Teller distortions gives rise to the identical g value. (This multiplet arises from the defects for which the magnetic field is pointing along the phosphorus-vacancy direction. By symmetry, it is apparent that each of the three distortions is equivalent with respect to this axis.) Therefore the motion predicts no effect on the CC' multiplets. (There will be a slight narrowing due to the partial motional averaging of Si^{29} hf broadening by neighbors, but we ignore this in this discussion.) In Fig. 9, it is noted that these multiplets (C' is easiest to observe) do indeed stay sharp throughout this temperature range in agreement with the predictions.

The defects with the other three phosphorus-vacancy directions give rise to resonance at $A(A')$ or $B(B')$ and, for them, reorientation causes a jumping between the two resonance values. Gutowsky and Saika[28] have treated a problem which is formally similar to this and we can apply their results directly to this problem. Their results are shown schematically in Fig. 10, in which we consider hopping between two resonance fields A and B separated by $\delta\omega=(g\beta/\hbar)\Delta H$, and with relative probabilities p_A and p_B of being at each of these two fields. (For our case $p_A=\frac{1}{3}$, $p_B=\frac{2}{3}$.) At low temperatures, we have two lines (I) of relative amplitudes p_A and p_B and with widths determined by static interactions (in our case, Si^{29} hf interactions with distant neighbors). As the characteristic reorientation time τ becomes shorter (II), the motion contributes a Lorentzian broadening

$$g(\omega)=\frac{(T_2/\pi)}{1+(\omega_0-\omega)^2T_2^2} \tag{18}$$

to each of the multiplets, where T_2 for each multiplet is given in the figure. At higher temperatures where $\tau\delta\omega\ll 1$, (III), motional narrowing is manifested by the emergence of a line at the weighted average between A and B, which is again Lorentzian broadened with the $(T_2)_{AB}$ given in the figure. As τ becomes shorter the central line narrows further ultimately going over into a temperature-independent width now determined by static interactions that have not been averaged out.

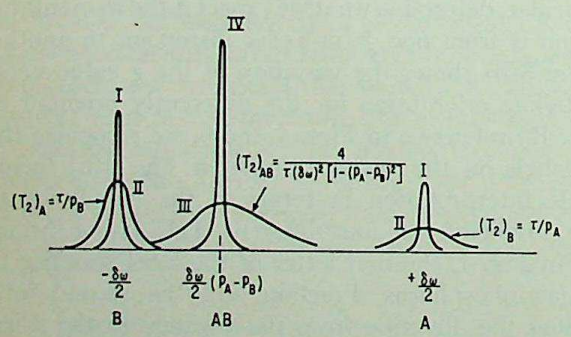

FIG. 10. Effect of thermally activated "hopping" between two resonance positions A and B, with relative probabilities p_A and p_B of being at each site, according to Gutowsky and Saika (Ref. 28). As the temperature increases and the lifetime τ for the "hopping" process decreases, the spectrum changes from (I) low-temperature multiplets at A and B, to (II) broadening of multiplets, to (III) disappearance of multiplets and emergence of a line at the average position AB, to (IV) narrowing of the averaged line.

[28] H. S. Gutowsky and A. Saika, J. Chem. Phys. 21, 1688 (1953). The formulas in Fig. 10 are derived from Eq. (18) of this reference.

Inspection of Fig. 9 shows that the AA' and BB' multiplets broaden as predicted (A' and B show clearly the broadening and final disappearance in the first panel with A' twice the width of B as expected throughout), along with the ultimate emergence and narrowing of the $AB-A'B'$ pair at the weighted average position in the second panel. Similar studies with $\mathbf{H}\|\langle 100\rangle$ and $\mathbf{H}\|\langle 110\rangle$, also confirm the expectations of the model. The motionally averaged spectrum at elevated temperature is axially symmetric reflecting the phosphorus-vacancy direction around which the averaging has taken place. The g values within experimental accuracy agree with those predicted from the weighted averages of the values in Fig. 3(b).

Using the formulas for T_2 in Fig. 10, we can estimate τ from a study of the linewidths versus temperature in both the early broadening and final narrowing regions. The results are given in Fig. 11. {In measurement, the linewidths $\Delta\omega=(g\beta/\hbar)\Delta H$ were taken as the width between half-maximum points observed in the derivative of dispersion recordings as in Fig. 9. For a line of Lorentzian shape, $T_2=1/\Delta\omega$. The points plotted at each temperature represent the *average* of two different methods for subtracting out the contribution due to the static width, $(\Delta\omega)_0$. One method assumed $T_2=[\Delta\omega-(\Delta\omega)_0]^{-1}$, the result expected for the convolution of two Lorentzian shapes. The other took $T_2=[\Delta\omega^2-(\Delta\omega)_0^2]^{-1/2}$, somewhat characteristic of two Gaussians. Since we anticipate the correct behavior to be somewhere in between these two simple approaches, we have simply averaged the two estimates. The accuracy of the data (limited by overlapping of lines, presence of unrelated spectra, temperature uncertainties, etc.) does not warrant a more detailed treatment. We recognize also that a detailed treatment is not trivial. For instance, the static contributions are not strictly constant, being themselves presumably partially motionally narrowed throughout the same region.}

In spite of the uncertainties, we could make a

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

reasonably good estimate of τ because the broadening and narrowing regions are separated by about two decades. However, we will defer this until the next section, where additional experimental data allow a more accurate estimate. We note only that the activation energy is $\sim$0.06 eV.

Study of motional effects on the Si^{29} satellites is also informative. This is shown in Fig. 12 for $H\|\langle 100\rangle$. At 20°K, (observed under fast passage conditions in dispersion), we see the Si^{29} satellites with a total splitting of 126 G. In the motionally averaged state (displayed in the figure as derivative of absorption, explaining the apparent difference in the character of the resonance), the Si^{29} satellites are found to be $\approx$ three times as intense relative to the central group but with a splitting reduced to 51 G. This is just what we expect because in the motionally averaged state, the defect becomes a *three* silicon center. That is, in the model of Fig. 6, the unpaired electron is hopping between the Si_1, Si_2, and Si_3 sites so fast as to be indistinguishable from a defect in which the electron is in a LCAO molecular orbital spread over all three. The hyperfine satellites now arise when any one of the three equivalent silicon sites is Si^{29}, which is three times as probable as one, and therefore three times as intense. The hyperfine splitting is determined now by

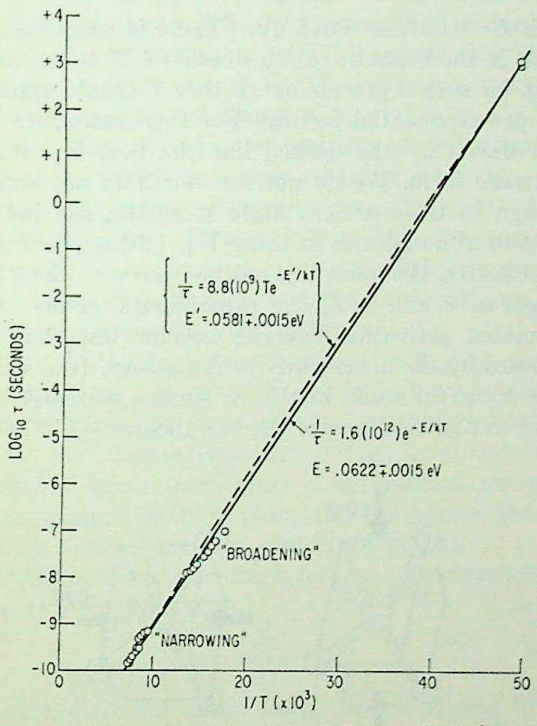

FIG. 11. Lifetime τ of the Jahn-Teller reorientation versus temperature. The two curves represent fits to two different theories (see text).

$$A'(\langle 100\rangle) = \tfrac{1}{3}A_1(\langle 100\rangle) + \tfrac{1}{3}A_2(\langle 100\rangle) + \tfrac{1}{3}A_3(\langle 100\rangle), \quad (19)$$

where $A_1(\langle 100\rangle)$ is the hf term for the defect configuration of Fig. 6 when Si_1 is Si^{29}, and A_2 and A_3 are the correspondingly smaller terms when Si_2 and Si_3 are Si^{29}. The meaning of Eq. (19) is that if one of the three silicon sites is a Si^{29} there is an interaction of A_1 for the third of the time the electron is located mostly on that atom but there is also A_2 and A_3 for each of the other one-thirds when the electron is primarily located on the other two silicon atoms.

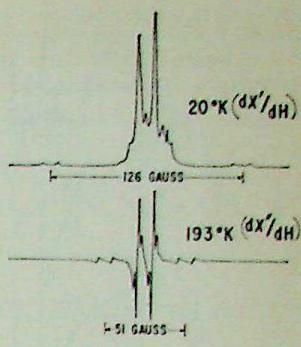

FIG. 12. Comparison of the motionally averaged E-center spectrum at 193°K with that at 20.4°K at $H\|\langle 100\rangle$.

With $|A'(\langle 100\rangle)| = 51$ G, $|A_1(\langle 100\rangle)| = 126$ G, we can solve Eq. (19) for A_2 and A_3, which must be equal by symmetry. This gives

$$A_{2,3}(\langle 100\rangle) = \pm 13.2 \text{ G} = \pm 12.4(10^{-4})\text{cm}^{-1},$$

where the sign must be the same as $A_1(\langle 100\rangle)$. Assuming the interaction to be axially symmetric along a $\langle 111\rangle$ direction, this gives the isotropic constants a_2 and a_3 which are entered in Table I.

Summary: Forgetting the model for a moment, we have determined the following about the center as a result of the linewidth studies: The center undergoes thermally activated reorientation around a particular $\langle 111\rangle$ axis associated with the defect. The activation energy is low ($\sim$0.06 eV), and from the hyperfine studies we have determined that the motion is an *electronic* one. That is, this is *not* the reorientation of a molecular unit but is rather an electronic *bond switching* in which the unpaired electron hops between *three* equivalent atoms which are for all purposes fixed in the lattice.

In terms of the model, this is precisely the behavior expected for thermally activated reorientation of the defect from one Jahn-Teller distortion direction to the other. The 0.06 eV we feel is a reasonably value for the activation energy of the process.[29] This must be considered an important confirmation of the model.

B. Low-Temperature Stress Studies

All of the possible orientations of the E center are equally probable in the cubic silicon lattice and, at

[29] In a simple model, the three silicon atoms go through the symmetrical undistorted position in reorienting. In this case, the 0.06 eV would be equal to the Jahn-Teller stabilization energy. Remembering that this energy is the difference between the total electronic stabilization energy and the increased energy stored in the lattice, which in turn is half the electronic energy, we get for the electronic stabilization energy 0.12 eV. In Fig. 8, this energy is associated with two electrons in the $(a+d)$ orbital so that the energy per electron $E'' \approx 0.06$ eV.

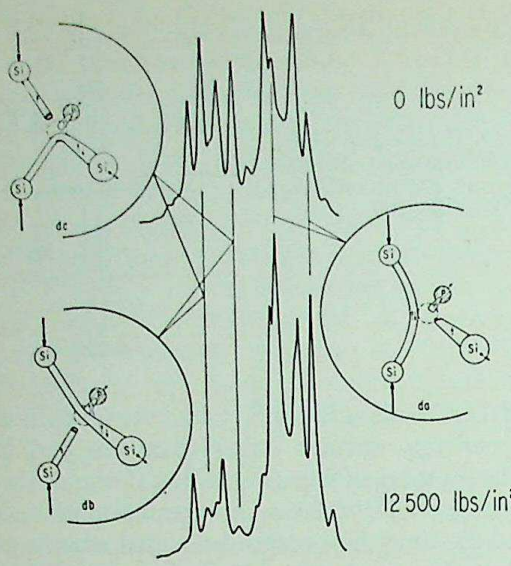

FIG. 13. Change in the E-center spectrum (H‖[011]), under [0$\bar{1}$1] compressional stress. The insets show a typical defect orientation for each multiplet.

thermodynamical equilibrium, we have equal numbers of defects in each of these orientations. If we now strain the crystal, and distort it from cubic symmetry, the various orientations are no longer equivalent and, if the defects are free to reorient, they will do so, tending to seek out the lowest energy orientation. This stress induced alignment is the static analog of the internal friction experiment.

EPR gives a unique way of observing the alignment in that the amplitudes of the multiplets in the spectrum give a direct measure of the relative number of defects in each of the allowed orientations, allowing a microscopic study of the process.[30] We here apply this to study the same "bond-switching" motion that was described in the previous section.

In Fig. 13, the effects on the spectrum of applying a uniaxial compressional stress along a ⟨110⟩ axis of the crystal at 20.4°K is observed. (The spectrum is observed with the magnetic field along another ⟨110⟩ axis, perpendicular to the stress direction.) The insets identify a representative set of defects—and their corresponding letter designation—to be associated with each multiplet. It is seen that there is a large effect, the *dc* and *db* orientations being strongly suppressed and the *da* being proportionally enhanced. This is again consistent with the "bond-switching" motion, the phosphorus-vacancy direction remaining unchanged. (The intensity simply "sloshes" between the indicated multiplets with no change in total area.) The *sense* of the alignment is an *additional* confirmation of the model in that the defect prefers to align in such a way that the applied compression serves to push the two bonding silicon atoms closer together as expected. In terms of Fig. 7, the applied stress adds to the Jahn-Teller distortion and lowers the electronic energy of the defect. We will return to the magnitude of the alignment but first let us consider the kinetics.

Upon removing the stress at 20.4°K, the recovery to the original unstressed spectrum is observed to follow a single exponential law with a time constant $\tau=1.3\pm0.2(10^3)$ sec. This τ is the same characteristic reorientation time that appears in the formulas of Fig. 10 for the linewidth studies and is therefore also plotted in Fig. 11. This value together with the linewidth study estimates span 13 decades in τ, allowing a very accurate determination of τ. The points fall well on a straight line giving

$$\tau^{-1}=1.6(10^{12})e^{-E/kT}, \tag{20}$$

with $E=0.0622\pm0.0015$ eV. [There is some disagreement in the literature as to whether (20) is the correct form for such a process or whether T should appear in the pre-exponential factor.[31] For this reason, we have also shown by the dashed line the best fit with the alternate form. We do not feel our data are accurate enough in their present state to distinguish between the two although the fit using Eq. (20) appears somewhat better. We point this out because with these large ranges of τ and $1/T$, our experimental errors in the estimated activation energies become less than that imposed by the uncertainty in the theory. It is possible that a careful study in this or similar systems[32] could serve as a critical test of the two theories.]

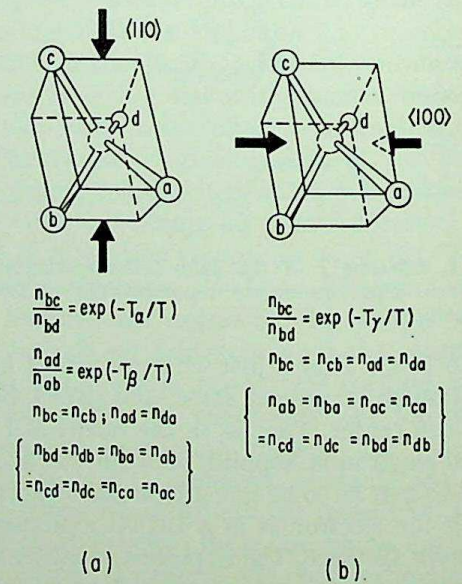

FIG. 14. Boltzmann factors governing the populations of the different defect orientations for the (a) ⟨110⟩ and (b) ⟨100⟩ stress experiments. The subscripts *ij* refer to the defect orientation according to the convention established in the text.

[30] A detailed study of another EPR center (the Si-*A* center) using this technique has been previously described by us in (I). See also W. Kanzig, Phys. Chem. Solids 23, 479 (1962).

[31] See R. H. Doremus, J. Chem. Phys. 34, 2186 (1961) for a discussion of this point and for further references to the literature.

[32] The silicon divacancy [G. D. Watkins and J. W. Corbett (to be published)] also has two spectra which are suitable for such a study.

A quantitative study of the *degree* of alignment has also been performed versus stress and temperature. For this, the effects of stress along both ⟨100⟩ and ⟨110⟩ axes were investigated. By symmetry, the ⟨100⟩ stress creates two nonequivalent sets of orientations while the ⟨110⟩ stress creates three (see Fig. 14). Assuming a Boltzmann distribution between the sets, this defines a single energy difference kT_γ for the ⟨100⟩ stress and two, kT_α and kT_β, for the ⟨110⟩ stress as indicated in the figure.

Fit to a Boltzmann distribution given by the formulas in Fig. 14, the alignment in all cases shows T_α, T_β, and T_γ linearly proportional to stress within experimental accuracy. The exponential dependence upon $1/T$ has also been verified. For this study, estimates in the range 20–50°K were made from the relative intensities of the multiplets as described above. An estimate was also made at 160°K from the *shift* in the resonance field of the motionally averaged spectrum (reflecting the relative change of p_A and p_B in Fig. 10). The fact that *shifts* in the *positions* of the resonance multiplets at high temperatures occur, and that they can be accurately predicted by measurements on the relative *amplitudes* of the multiplets in the low-temperature spectrum confirms again that the high-temperature phase is properly characterized as a motional averaging of the low-temperature configurations.

In Table II, the measured values for T_α, T_β, and T_γ determined at a stress of 12 360 lb/in.^{2} are given. To interpret these, let us take a very simple view of the defect. We assume that the change in energy of a particular defect orientation is determined solely by the component of strain along the line joining the two bonding silicon atoms (Si_2 and Si_3 of Fig. 6).

We define a change in the defect energy per unit strain along this direction as

$$M=(dE/d\epsilon)_{\mathrm{Si-Si}}. \tag{21}$$

Defining ϵ_{ad} as the strain along the line joining the *ad* sites, etc., we obtain

$$\begin{aligned} kT_\alpha&=(\epsilon_{ad}-\epsilon_{ac})M\,,\\ kT_\beta&=(\epsilon_{bc}-\epsilon_{cd})M\,,\\ kT_\gamma&=(\epsilon_{ad}-\epsilon_{ac})M\,. \end{aligned} \tag{22}$$

These follow directly from the formulas of Fig. 14 when the change in energy of the *bc* site is set equal to $M\epsilon_{ad}$, etc. In (I) these strains have been calculated in terms of the elastic moduli and applied stress and, using these formulas with Eq. (22), we can solve for M using the experimental values of Table II. Selection of M for the best fit gives

$$M=+16.8 \text{ eV/unit strain.}^{33} \tag{23}$$

[33] In footnote 29, we concluded that the electronic stabilization energy associated with the Jahn-Teller distortion was ~0.12 eV. This, with Eq. (23) serves to define an "effective" strain associated with the Jahn-Teller distortion of ~0.7%. Whether this in turn bears any simple relation to the actual motions of the atoms neighboring the vacancy is not clear, however.

TABLE II. Comparison of the observed and calculated (see text) energy differences (in °K) for the differently oriented defects under stress (see Fig. 14). The applied stress is 12 360 psi.

Stress	T_j	Observed (°K)	Calculated (°K)
⟨110⟩	T_α	+9	+11
	T_β	−90	−94
⟨100⟩	T_γ	+85	+81

The values computed from Eq. (22) using this constant are also given in Table II.

The agreement in Table II is quite good considering the oversimplified model that we have taken in the analysis. The positive value of M means that the energy is lowered when the atoms are pushed together as we would expect for two normally next nearest neighbors with rather weaker overlap. The magnitude of M is close to the value +16.0 eV/unit strain deduced in (I) for a similar Si-Si pair bond in the A center. As in the A center, we argue that the magnitude is not unreasonable being of the same order of magnitude as deformation potentials in silicon.[34] We thus conclude that the stress experiments give substantial additional confirmation to the model.

C. High-Temperature Stress Studies

There is another "degree of freedom" for the defect, the phosphorus-vacancy axis, which has not been probed as yet. In the low-temperature studies this axis remained fixed. In terms of the model, it should be more difficult for this axis to change because *atoms* must rearrange rather than the easier *electronic* rearrangement involved in the low-temperature motion.

This phosphorus-vacancy axis reorientation can be revealed by stress alignment at elevated temperatures. For this a crystal was compressed along a ⟨110⟩ axis to ~26 000 psi at room temperature in an external squeezing apparatus for ~1 h, then removed and quickly inserted into the microwave cavity and cooled to 20.4°K for study. A significant alignment was achieved as can be seen in Fig. 15. By reference to Figs. 3(b) and 14, we see that the preferred direction for the phosphorus-vacancy axis is in the plane perpendicular to the stress direction.

From Fig. 15, we estimate the degree of alignment[35]

$$\frac{n_\perp}{n_{||}}=\frac{n_{ad}+n_{ac}+n_{ab}}{n_{bc}+n_{ba}+n_{bd}}\cong 1.75. \tag{24}$$

Analysis of Eq. (24), similar to that in the previous section where we consider only the $M=16.8$ eV/unit

[34] C. Herring and E. Vogt, Phys. Rev. 101, 944 (1956).

[35] We estimate the alignment in Fig. 15 to be 1.5. We increase this value by ~15% to take account of partial recovery during the ~75 sec at room temperature between removal of stress and eventual cooling of the sample (see Fig. 16).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

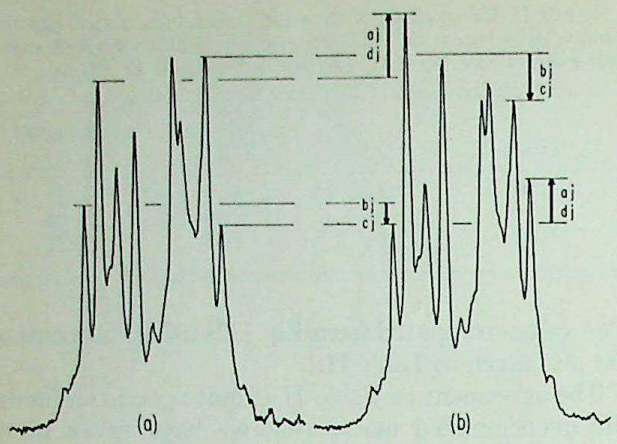

FIG. 15. E-center spectrum (H‖[011]) (a) before and (b) after 26 000 psi [0$\bar{1}$1] compressional stress at room temperature. The defect orientations corresponding to the lines in the spectrum are indicated.

strain associated with the Si–Si bond, predicts $(n_\perp/n_{11})=1.34$. The alignment is therefore in the same sense as that dictated by the preference of the defect to align its Si–Si bond along the compressed direction. If we include another parameter for the change in energy per unit strain at right angles to this, along the phosphorus-vacancy direction,

$$N=(dE/d\epsilon)_{\text{P–Vac}}\cong -9 \text{ eV/unit strain}, \quad (25)$$

the value of 1.75 is obtained. The sign is consistent with an outward relaxation of the phosphorus atom from the vacancy in its normal configuration which is to be expected since there is no bonding to hold it in (see Fig. 7). It is not possible to make a value judgment on the magnitude, but it does not seem out of line with the value for M, for instance.

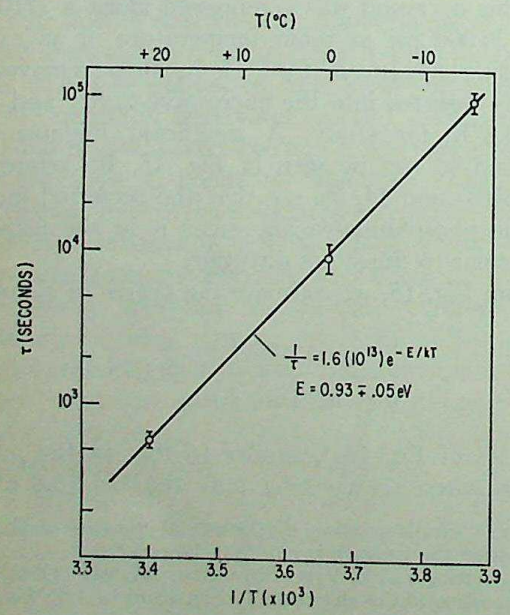

FIG. 16. Characteristic recovery time versus temperature for the phosphorous-vacancy axis reorientation.

The kinetics of the reorientation process was studied by monitoring the recovery from the stress induced alignment versus annealing. During each anneal, the sample remained in the cavity which in turn was held at the annealing temperature for a specified time interval. At the end of each annealing interval, the cavity was plunged back into the cryostat and the remaining alignment monitored from the spectrum at 20.4°K. The results are shown in Fig. 16. We obtain for the characteristic relaxation time of the reorietnation process,

$$\tau^{-1}=1.6(10^{13})\exp(-E/kT),$$

with

$$E=0.93\pm 0.05 \text{ eV}.$$

Let us now inquire as to the microscopic process by which the defect reorients. That is, of what process are we measuring the kinetics? Interchange of the phosphorus and vacancy serves only to "invert" the defect and does not achieve the reorientation we are observing. The most likely remaining process is the one shown in Fig. 17 in which the vacancy must make four consecutive jumps, two away from the phosphorus and then two back. The fact that the defect must partially dissociate in order to reorient has some interesting consequences.

First let us note that the combination of reorientation plus the phosphorus-vacancy interchange allows the defect to diffuse through the lattice as an entity. We anticipate the activation energy for the vacancy-phosphorus interchange to be small, being comparable to the value for the isolated vacancy motion ($\sim\frac{1}{3}$ eV).[36] The limiting process for diffusion should therefore be the reorientation. We thus conclude that in measuring the activation energy for reorientation, *we are also measuring the activation energy for the diffusion of the phosphorus-vacancy pair in the lattice.*

The fact that the vacancy must separate partially from the phosphorus in order for the defect to reorient gives a simple explanation as to why the activation energy is larger than that associated with the isolated vacancy motion. The difference ($\sim$0.6 eV) can be associated with binding energy that must be overcome in order for the vacancy to separate to the next-next-nearest neighbor position (position 3 in Fig. 17). This is not the *total* binding energy, however, because we do not detect any loss in E centers in the process. That is, there is still sufficient binding at this remote position to assure that most of the vacancies return.

There are several bits of experimental information that give us guides in estimating the remaining binding energy at this next-next-nearest site. For instance, we note that the E centers decay upon standing at room temperature at a rate suggestive of a time constant $\lesssim$6 weeks.[37] On the other hand, from Fig. 16, we deter-

[36] G. D. Watkins, J. Phys. Soc. Japan 18, Suppl. II, 22 (1963).

[37] The actual rate may be slower than this. The loss of E centers in the spectrum can also be caused by decay of other centers which in turn alters the Fermi level so that E centers still present are no

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

mine that the defect is reorienting once every ~400 sec at this temperature (~25°C). We may therefore conclude that the vacancy gets away only once in $\lesssim 10^4$ opportunities at the next-next-nearest site. This, in turn, can be related to a Boltzmann factor weighting the separation and recapture processes at this site,

$$\alpha \exp(-\Delta E/kT) \lesssim 10^{-14}, \qquad (26)$$

where α is a geometric factor (~1). Taking $\alpha=1$, we obtain $\Delta E \gtrsim 0.25$ eV. This quantity is not strictly equal to the binding energy at this site but rather gives a difference in barrier heights as shown in Fig. 18. However, it is clearly related (being perhaps somewhat larger) and serves as an indication of its magnitude.

It is interesting to note that a calculation of the binding energy between a single positive and a single negative charge separated by the same distance and immersed in a dielectric constant equal to that of silicon (11.6) gives 0.28 eV. This is certainly suggestive

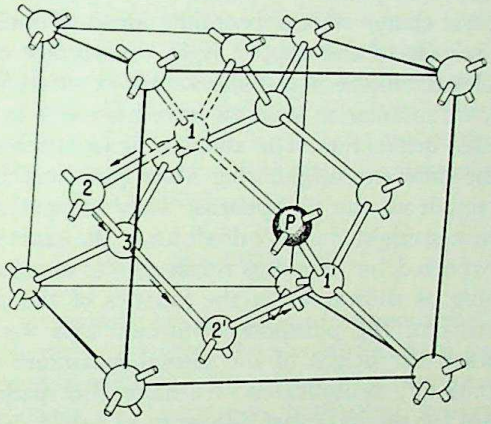

FIG. 17. The mechanism for the phosphorus-vacancy axis reorientation. The vacancy in the normal nearest position (No. 1) must make two jumps away from the phosphorus to site No. 3 and then return to a new (No. 1′) nearest site.

and perhaps not an unreasonable way to view the defect at this separation. The over-all defect is neutral and, in separating into components, the phosphorus will tend to be positively charged, its normal ionized state when isolated.

The indication that $\lesssim 10^4$ reorientations are occurring before disassociation means that the defect is diffusing through the lattice as an entity for considerable distances. Considering the approximate nature of these estimates it is not clear then whether the annealing of the E center actually is a result of its dissociation or whether it is the result of long-range migration as an entity with subsequent trapping by other defects. An experiment that may bear upon this is that reported by Saito *et al.*[38] They have studied by electrical measurements the annealing kinetics of a deep acceptor at $(E_c-0.4)$eV in floating zone silicon produced by irradiation. Considering the conditions of their experiment, it is possible that they are monitoring the E center anneal, as they have suggested. They observe first-order kinetics with a characteristic recovery time τ given by[39]

$$\tau^{-1} \cong 10^{13} \exp(-0.94/kT).$$

The close agreement of this activation energy to that which we estimate for *diffusion* suggests that the annealing they are studying is the diffusion to traps. This is also consistent with the pre-exponential factor of 10^{13} indicating, with our pre-exponential factor of $\sim 10^{13}$ for the single reorientation process, $\sim 10^5$ diffusional jumps before trapping. Analysis similar to that leading to (26), but using $\lesssim 10^5$ jumps without separation and at the higher temperatures of anneal used by Saito *et al.*(~175°C) gives $\Delta E \gtrsim 0.45$ eV. This value is also indicated in Fig. 18.

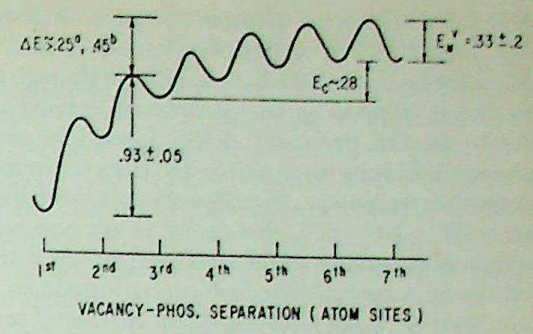

FIG. 18. The potential energy (in eV) of a vacancy in the vicinity of a substitutional phosphorus atom, as determined from the experiments on the E center. The abscissa denotes the various neighbor positions in order of increasing separation, and are not necessarily in a straight line. The quantity ΔE was estimated from annealing studies by (a) EPR and (b) electrical measurements.

On the other hand, there is also evidence for dissociation in that some Si-A centers (oxygen-vacancy pairs) are observed to form as the Si-E centers disappear. This has been observed in electrical measurements[40] and has also been observed by us in resonance. These vacancies could be liberated of course, after trapping. In any event, we recognize from our estimates here that it is touch and go as to whether the vacancy and phosphorus stay together long enough to reach a trap as an entity or whether they dissociate first, and that probably both processes are occurring. To investigate this in detail one would require studies over a wide range of temperatures and defect concentrations.

V. SUMMARY AND CONCLUSIONS

We conclude that the Si-E center resonance arises from the neutral charge state of a lattice vacancy ad-

longer in the proper charge state for resonance. This complication has discouraged us from making detailed annealing studies for this center.

jacent to a substitutional phosphorus atom. It is presumably formed when a lattice vacancy, formed at random in the lattice by irradiation, diffuses through the lattice, and is trapped by the phosphorus impurity. It appears to be the dominant defect formed in phosphorus-doped floating zone silicon by electron irradiation at room temperature. In pulled crystals, containing oxygen $\sim 10^{17}-10^{18}$ cm^{-3}, this center is not observed, the oxygen now serving as the dominant vacancy trap to form the Si-A center.[1] The Si-E center introduces an acceptor level at $\sim(E_c-0.4)$eV. With the Fermi level position above this level, the defect is negatively charged and is not observed in the resonance.

The model of the center deduced from the studies in this paper is one in which two of the three silicon atoms adjacent to the vacancy pull together to form a pair bond with the unpaired electron observed in the resonance left primarily to the third silicon atom. This distortion can be viewed as a manifestation of the Jahn–Teller effect. The primary confirming features in the spin resonance are summarized as follows:

(1) Analysis of the resolved Si^{29} hyperfine interactions indicates that $\sim$60% of the wave function is localized in a dangling bond on a single silicon atom. An additional 20–25% of the wave function can be accounted for by partially resolved hyperfine interactions on a few (5-6) near-neighbor sites, with the remaining 15–20% presumably spread out over more distant sites.

(2) The spectrum also reveals resolved hyperfine interaction with a 100% abundant $I=\frac{1}{2}$ impurity. ENDOR measurements confirm that this impurity is phosphorus. Only $\sim$1% of the wave function is localized on this atom.

(3) The g tensor is nearly axially symmetric reflecting the axis of the dangling bond which makes up most of the wave function. Its anisotropy is similar to other defects which we have studied and have identified as made up of dangling bonds associated with vacancies. Also, a simple "localized molecule" treatment of the defect has been given which indicates that the magnitude and sign of the g shifts are reasonable.

(4) Motional broadening and narrowing effects are observed in the spectrum in the temperature region 60–150°K and are attributed to the thermally activated reorientation from one Jahn-Teller distortion direction to the other. Analysis confirms that the motion is that of an electronic "bond switching" (not atom motion) and that the motion is around the phosphorus-vacancy axis as predicted by the model.

(5) This motion is also studied by stress induced alignment at 20.4°K. Combined with the linewidth studies, the kinetics of the reorientation process can be obtained with very high precision. The observed activation energy $\sim$0.06 eV appears reasonable for this process. The *sense* of the alignment is consistent with the natural preference of the defect to align so that the applied stress aids the Jahn-Teller distortion. The *degree* of alignment can be accounted for by a simple model which only considers the change in energy per unit strain along the axis joining the bonding Si-Si pair. The magnitude deduced for this parameter is reasonable, being of the order of observed deformation potentials.

(6) Stress-induced alignment of the phosphorus-vacancy axis is also studied. The sense and magnitude can also be accounted for in terms of the model. The kinetics of this process, with an activation energy of 0.93 ± 0.05 eV, appear reasonable for the atom rearrangements required by the model.

The E center, in addition to being an important defect in radiation damage studies, may play an important role in unirradiated silicon. High-temperature diffusion of substitutional impurity atoms, as well as self-diffusion, is generally believed to be via lattice vacancies. As a result, such impurity-vacancy interactions are important in understanding the mechanics of impurity diffusion. The E center represents a unique opportunity to probe this interaction in detail. Being the neutral charge state appropriate for the Fermi level in the middle of the gap, it is in the correct charge state relevant to the high-temperature experiments. In Fig. 18, we summarize what we have been able to learn about this interaction. The abscissa denotes schematically the different neighboring atom positions as one moves out from the phosphorus. They are not necessarily in a straight line. We don't know the exact shape to be expected but it seems reasonable to assume it is something as shown. From the kinetics of the stress-orientation of the phosphorus-vacancy axis we have determined the height of the second maximum to be 0.93 ± 0.05 eV, as indicated. We have also made two estimates for the indicated difference in barrier heights ΔE from annealing studies. The smaller estimate comes from EPR measurements and the larger one comes from electrical measurements. From previous studies[36] we estimate that the activation energy for the isolated vacancy motion is[41] $E_M{}^V=0.33\pm0.20$ eV. The indicated estimate of the binding energy $E_C\sim0.28$ eV at the third-neighbor site comes from a simple calculation of the electrostatic interaction between a negative vacancy at this site and a positive phosphorus atom. This value is seen to be generally consistent with the other experimentally determined estimates.

We have therefore been able to deduce quite a bit about the details of the phosphorus-vacancy interaction. It is hoped that future experiments can narrow further

[41] The value for p-type silicon has been determined to be (Ref. 36) 0.33 ± 0.03 eV. However, in annealing studies in n-type silicon (Refs. 3, 36), it is found that both A and E centers emerge in two discrete temperature regions. One of these is presumably to be associated with long-range motion of the vacancy, and, depending upon which we select, we either deduce $\sim0.1-0.2$ eV or $\sim0.4-0.5$ eV for the activation energy of the vacancy motion. This difference from the p-type value presumably reflects the role of charge state in the mobility of the vacancy. Since we do not know the charge state appropriate to Fig. 18, we indicate an error ±0.2 eV to bracket these extremes.

the errors in $E_M{}^V$ and ΔE with the result that this interaction will eventually be rather precisely mapped out. However, even with the present uncertainties we can draw certain conclusions:

From Fig. 18, we see that there is a sizeable binding energy ($\sim$1.0 eV) between the phosphorus atom and a vacancy in their closest bound state.[42] Because of this attractive interaction there is an enhanced probability of finding a vacancy near the phosphorus at elevated temperatures and we therefore expect the diffusion of the phosphorus to be enhanced over that for silicon self-diffusion. However, we recognize that *it is only the binding at the third-atom site that is operative in enhancing the diffusion* because the vacancy must go through this site in order for the phosphorus atom to diffuse.[43] For this binding energy, we take the Coulomb estimate E_C=0.28 eV. We estimate the error in this quantity somewhat arbitrarily as $\pm$0.15 eV, which we feel, in view of the general consistency of the values in Fig. 18, is overly cautious.

Phosphorus diffusion in silicon has been measured and the activation energy has been determined to be[44] 3.66$\pm$0.18 eV. However, there has been no corresponding measurement of self-diffusion in silicon. Using the value 0.28$\pm$0.15 eV for the lowering of the phosphorus activation energy, we therefore estimate the activation energy for silicon self-diffusion

$$E_{\text{self-diff.}}=3.94\pm0.33 \text{ eV}. \quad (27)$$

Since this quantity has not been measured directly, we feel that this probably represents the best present estimate that can be made for this important quantity.

Combining this with the activation energy for vacancy motion of 0.33$\pm$0.20 eV, we obtain for the formation energy of the lattice vacancy[45]

$$W=3.6\pm0.5 \text{ eV}. \quad (28)$$

APPENDIX A: ESTIMATE OF $|\psi_{3s}(0)|^2$ AND $\langle r_{3p}{}^{-3}\rangle$ FOR THE NEUTRAL $3p$ ATOMS

In previous publications,[1,4] we have used $|\psi_{3s}(0)|^2_{Si}\approx24(10^{24})$ cm^{-3} and $\langle r_{3p}{}^{-3}\rangle_{Si}\approx17(10^{24})$ cm^{-3} in the analysis of resonance centers. These estimates were originally made using various Hartree functions, available only for higher ionization states of silicon, as guides. Since then, Hartree-Fock calculations for neutral silicon, as well as all of the other neutral $3p$ atoms, have been reported by Watson and Freeman[15] and a revised estimate of these quantities is in order.

In Table III, the first two columns show $|\psi_{3s}(0)|^2$ and $\langle r_{3p}{}^{-3}\rangle$ determined from the Watson and Freeman wave functions[46] for the atoms aluminum through chlorine. Consider first $|\psi_{3s}(0)|^2$. As was pointed out by Kohn and Luttinger,[47] direct comparison with experiment in the case of the alkalies shows that Hartree-Fock wave functions generally underestimate $|\psi_s(0)|^2$, and the true values will probably be somewhat larger than these values. In the case of silicon, Kohn and Luttinger estimated an appropriate scaling factor by comparing the Hartree-Fock estimate of $|\psi_{3s}(0)|^2$ for the alkali-like Si^{3+} ion[48] with that predicted by the Goudsmit formula[49] for such ions and assuming the same scaling factor to apply for Si^0. Their result was that the Hartree-Fock value should be increased by $\sim$19%. Applying the same correction to the Watson and Freeman value for Si^0, we obtain the final estimate of 31.5(10^{24}) cm^{-3} shown in the table.

Now consider $\langle r_{3p}{}^{-3}\rangle$. Barnes and Smith[50] have estimated this quantity from an analysis of optical fine structure splittings and their values are given in column three of Table III for each of the $3p$ atoms. In the case of aluminum[51] and chlorine,[52] atomic beam hyperfine measurements give accurate determinations of $\langle r_{3p}{}^{-3}\rangle$, also shown in the table, to which we can compare the estimates of Barnes and Smith. We see that the agreement is very good, the atomic beam values lying $\sim$3% higher. We thus increase the Barnes and Smith estimates by 3% for the remaining atoms to give the final estimate of $\langle r_{3p}{}^{-3}\rangle$ shown in the last column.

We note that the $\langle r_{3p}{}^{-3}\rangle$ determined from the Watson and Freeman wave functions are uniformly too low. It is interesting to note that for Si^0, the value must be increased by 19% to agree with our final estimate. Although this agreement with the scaling factor for

[42] We remind the reader that these arguments (and the values in Fig. 18) apply only to the neutral charge state of the defect and therefore when the Fermi level is near the middle of the gap. This should apply to the high temperatures used in diffusion studies for anything but the most heavily doped materials.

[43] This important fact (see Sec. IVC and Fig. 17) has been generally overlooked by previous authors.

[44] C. S. Fuller and J. A. Ditzenberger, J. Appl. Phys. 27, 544 (1956).

[45] We have, of course, assumed throughout this discussion that both phosphorus and self-diffusion proceed by the vacancy mechanism. If other mechanisms are also involved, the formation energy will be even larger.

[46] We are indebted to B. Segall for supplying us with tabulated values of the $3p$ Watson and Freeman wave functions from which $\langle r_{3p}{}^{-3}\rangle$ were calculated.

$|\psi_{3s}(0)|^2$ must be considered somewhat fortuitous, it does suggest that both $\langle r_{3p}^{-3}\rangle$ and $|\psi_{3s}(0)|^2$ are underestimated by a comparable amount in these Hartree-Fock wave functions. This then suggests a consistent way to determine the proper $|\psi_{3s}(0)|^2$ scaling factor for the other atoms: For the atoms other than Si, the scaling factor was determined as being equal to the ratio of our final estimate of $\langle r_{3p}^{-3}\rangle$ to that determined from the Freeman-Watson wave functions. The scaling factor thus determined is shown in Table III along with the corresponding final estimate of $|\psi_{3s}(0)|^2$ for all the $3p$ neutral atoms.[53]

We will not attempt to set limits of accuracy on the values of Table III. There are still sufficient uncertainties in the applicability of these free atom values to those of a bonded atom surrounding a defect in a solid to make such speculations somewhat academic for our use, anyway. However, Table III does give a set of reasonable values, consistently arrived at, for the complete $3p$ series of neutral atoms.

In this paper we have used only the values for silicon and phosphorus. In subsequent papers in this series, we will have occasion to use the estimates for others of the atoms in the table.

APPENDIX B: APPROXIMATE LCAO TREATMENT OF THE g SHIFT

We approximate the one-electron LCAO molecular orbitals of Fig. 8 as:

$$\bar{\psi}'(A)=\sigma_3{}^{I}(A)=\alpha_I\psi_{3s}(A)+\beta_I\psi_{3pI}(A),$$

$$\bar{\psi}^{\pm}(AX_2)=N^{\pm}[\sigma_3{}^{II}(A)\pm\sigma_3{}^{-II}(X_2) \mp\sum_i \epsilon_i\{\psi_i(A)\pm\psi_i(X_2)\}], \quad \text{(B1)}$$

with similar expressions for the other orbitals. Here $\sigma_3{}^{\rm I}$, $\sigma_3{}^{\rm II}$, $\sigma_3{}^{\rm III}$, and $\sigma_3{}^{\rm IV}$ represent four orthogonal cylindrical orbitals made up of $3s$-$3p$ atomic wave functions, where the superscript represents the axis of the directed orbital as shown in Fig. 8. (By $\sigma_3{}^{-\rm II}$, we denote an orbital pointed in the opposite direction from $\sigma_3{}^{\rm II}$.) We have included small admixtures of the core wave functions ψ_i, ($1s$, $2s$, and $2p$), in order to orthogonalize the total wave function to the core. The small admixture coefficients are given by

$$\epsilon_i=\langle\sigma_3{}^{-\rm II}(X_2)|\psi_i(A)\rangle, \quad \text{etc.}$$

The normalization coefficients are

$$N^{\pm}=[2(1\pm S-\sum_i \epsilon_i{}^2)]^{-1/2},$$

with

$$S=\langle\sigma_3{}^{\rm II}(A)|\sigma_3{}^{-\rm II}(X_2)\rangle.$$

A typical orbital angular momentum matrix element of (15) is

$$\langle\bar{\psi}^{\pm}(AX_2)|L_j|\bar{\psi}'(A)\rangle = \sum_k \langle\bar{\psi}^{\pm}(AX_2)|\sigma_3{}^{k}(A)\rangle\langle\sigma_3{}^{k}(A)|L_j|\sigma_3{}^{I}(A)\rangle.$$

Substituting the expression for $\bar{\psi}^{\pm}(AX_2)$ given by Eq. (B1), and using the fact that only $\sigma_3{}^{\rm II}(A)$ has significant overlap with any of the terms for $\bar{\psi}^{\pm}(AX_2)$, we obtain

$$\langle\bar{\psi}^{\pm}(AX)_2|L_j|\bar{\psi}'(A)\cong\tfrac{1}{2}(N^{\pm})^{-1}\langle\sigma^{\rm II}(A)|L_j|\sigma^{\rm I}(A)\rangle. \quad \text{(B2)}$$

Now consider the corresponding matrix element in (15) involving $\mathbf{V}_{so}$

$$\langle\bar{\psi}'(A)|(\mathbf{V}_{so})_i|\bar{\psi}^{\pm}(AX_2)\rangle = (\beta/mc)\langle\sigma_3{}^{\rm I}(A)|(\mathbf{E}\times\mathbf{p})_i|\bar{\psi}^{\pm}(AX_2)\rangle. \quad \text{(B3)}$$

The electric field $\mathbf{E}$ is large only near the nuclei of atoms A and X_2 and therefore, in these matrix elements, tends to weight strongly only the parts of the wave functions near the atomic cores. To a good approximation we may therefore retain in Eq. (B1) only the atomic terms centered on atom A giving

$$\cong(\beta/mc)N^{\pm}\langle\sigma_3{}^{\rm I}(A)|(\mathbf{E}\times\mathbf{p})_i|\sigma_3{}^{\rm II}(A)-\epsilon_{2p}\psi_{2p\rm II}(A)\rangle.$$

[53] The scaling factor is not constant throughout the series but is largest at the beginning. A further check that this variation is not unreasonable is given by noting that an even larger scaling factor of 1.42 is required in the case of neutral sodium (which starts this row in the periodic table), in order to raise the value determined from the Hartree-Fock calculations [D. R. Hartree and W. Hartree, Proc. Roy Soc. (London) A193, 299 (1948)] (3.56×10^{24} cm^{-3}) to that observed experimentally [P. Kusch and H. Taub, Phys. Rev. 75, 1477 (1949)] (5.05×10^{24} cm^{-3}).

(The terms centered on atom X_2, though not zero near atom A, are slowly varying there, and therefore do not contribute significantly to the spin-orbit interaction.) Having reduced the matrix elements to those on atom A only, we may now make the substitution $\mathbf{E}=[\mathbf{r}/r]E(r)$ for the central force field near the nucleus of atom A, leading to the familiar free atom expressions

$$\langle nlm|(\mathrm{V}_{so})_i|n'l'm'\rangle=\delta_{ll'}\lambda_{nl,n'l}\langle lm|L_i|lm'\rangle,$$

with

$$\lambda_{nl,n'l}=(\beta/mc)\langle nl|[E(r)/r]|n'l\rangle.$$

This gives, upon straightforward manipulation,

$$\langle\bar{\psi}'(A)|(\mathrm{V}_{so})_i|\bar{\psi}^{\pm}(AX_2)\rangle \cong N^{\pm}[\lambda_{3p}\mp(\epsilon_{2p}\lambda_{2p,3p})/\beta_I]\langle\sigma^{\mathrm{I}}(A)|\mathbf{L}_i|\sigma^{\mathrm{II}}(A)\rangle. \quad \text{(B3')}$$

Substituting (B2) and (B3') into (15), and summing over-all excited orbitals in (B1),

$$\Delta g_{\mathrm{II}}=0,$$

$$\Delta g_{\perp}\cong\lambda_{3p}\beta_I{}^2\left[\frac{1+\gamma}{E_b}\quad\frac{1-\gamma}{E_a}\right], \quad \text{(B4)}$$

with

$$\gamma=-\frac{\lambda_{2p,3p}\epsilon_{2p}}{\lambda_{3p}\beta_I}. \quad \text{(B5)}$$

Here, γ is a positive number because $\lambda_{2p,3p}$ and ϵ_{2p} will always be of opposite sign, a consequence of the fact that ψ_{3p} has one more radial node than ψ_{2p}. [In our previous treatment (I), the core overlap terms were not included in the wave functions. For these wave functions, $\gamma=0$, and (B4) leads to Eq. (16) in the text of the present paper.]

We may estimate γ, as follows: We approximate $\lambda_{2p,3p}$ as $-(\lambda_{2p}\lambda_{3p})^{1/2}$ using the values $\lambda_{2p}=0.40$ eV estimated by Liu[54] from x-ray emission data[55] and $\lambda_{3p}=0.02$ eV.[23] We calculate ϵ_{2p} from Eq. (19) using Slater atomic orbitals[56] and standard overlap integral formulas[57] in conjunction with certain required integrals tabulated by Rosen.[58] For the normal Si-Si lattice distance and with the $\sigma^i(A)$ taken as the tetrahedral sp^3 hybrids (25% $3s$, 75% $3p$), we obtain $\epsilon_{2p}=0.033$. With $\beta_I=(3)^{1/2}/2$ for the tetrahedral hybrid, this gives $\gamma\cong 0.17$.

Experimental Investigations of Single Injection in Compensated Silicon at Low Temperatures*

Bob L. Gregory† and Angel G. Jordan
Electrical Engineering Department, Carnegie Institute of Technology, Pittsburgh, Pennsylvania
(Received 23 December 1963; revised manuscript received 24 February 1964)

Experimental investigations of the phenomenon of single carrier, space-charge limited injection in silicon at liquid-helium temperatures have been performed in an attempt to validate the model for space-charge limited currents (SCLC) in an insulator with traps. Comparisons between predicted and experimental characteristics were performed on p_+pp_+ devices fabricated by diffusion techniques. Pulse and dc measurements were made to obtain steady-state current-voltage characteristics for the above devices. Modifications were observed in the SCLC characteristics due to field-dependent carrier mobilities, the exact nature of which could be determined from the experimental steady-state characteristics. The density of deep trapping centers in the above material at liquid-helium temperature, corresponding to the compensation, was obtained by measurements of the traps-filled voltage. An independent value for the compensation in the same material was obtained by Hall measurements in the temperature range $20°K<T<77°K$. Transient measurements of the single-carrier current were performed, from which values for the capture probability and capture cross section for the deep trapping center could be obtained. A comparison was made between the capture cross section obtained in this manner and the theoretical prediction of the "giant trap" model.

INTRODUCTION

THE theory of space-charge limited currents (SCLC) in insulators with traps as proposed by Lampert[1] has been employed frequently in recent years to explain the current-voltage characteristics of insulator structures. In some instances, however, uncertainty arose in the interpretation of the insulator characteristics because of apparent disagreement between material parameters obtained from the single injection interpretation and independent material measurements. For example, in CdS, single-carrier SCLC was investigated by Bube[2] in an attempt to correlate the trap density with the traps filled voltage (V_{TFL}) as defined by Lampert. However, his determinations of trap density obtained from measurements of the apparent traps filled voltage differed by as much as three orders of magnitude from independently obtained trap-density values.

This experimental uncertainty in the model for SCLC in insulators with traps prompted the work in this paper. It was observed, originally by Lampert, that the purest insulator in which to test the model would be a high-purity semiconductor at low temperatures (sufficiently low to cause the equilibrium carrier density to be completely negligible). Since the dopant densities in the semiconductor would be known (or could be determined by Hall effect measurements), one should be able to quantitatively compare the predictions of the theoretical model with the experimental characteristics. Other important results expected from investigation of single injection at low temperatures are:

(1) the capture probability, hence capture cross section, of the deep trapping levels present due to compensation could be measured directly by pulse techniques;

(2) the field dependence of the drift mobility could be determined from the SCLC characteristic in the Child's law region;

(3) the injecting nature of contacts at low temperatures could be explored; and

(4) the nature of scattering mechanisms at low temperatures could be better understood by interpreting the field-dependent mobility data.

p_+pp_+ SILICON DEVICES AT LOW TEMPERATURES

As mentioned above, the ideal material in which to examine the model for single-carrier SCLC should be a high-purity semiconductor at low temperatures. In actuality, however, one is limited to germanium or silicon since no other sufficiently pure semiconductors are available. Furthermore, high-purity germanium is unsuitable for these investigations since at low temperatures impact ionization occurs at quite low field strengths,[3,4] destroying its insulating nature. Thus, presently only silicon is suitable for investigating SCLC at low temperature; furthermore, since highest purity silicon is invariably p type due to the presence of boron, p-type material was chosen for the experiment in this work.

As the temperature of a sample is reduced to below the extrinsic range ($T<50°K$ in lightly doped material) the free holes, produced by thermal ionization of noncompensated acceptor centers, recombine with ionized acceptors producing neutral centers. At 4.2°K (liquid-helium temperature) virtually all free holes will have disappeared and N_A-N_D neutral acceptor centers will have appeared. The electrical effect of the compensated

centers at low temperature is to produce trapping levels for injected carriers. The positively charged donor centers would be trapping levels for injected electrons. Similarly, the negatively charged acceptor centers would be traps for injected holes. In this simplified model the impurities consist of N_A shallow acceptors and N_D shallow donors (shallow at room temperature) where $N_A > N_D$. The trapping kinetics for this model depends in large part on the "capture cross section" of the ionized centers. The theoretical considerations which allow this cross section to be determined will be discussed in a later section dealing with the cascade capture process.[5]

To fabricate a single-carrier SCLC device, one must determine which actual contacts exhibit the properties assumed in the model. To reiterate these properties, one contact must be "ohmic" and the other "blocking." At the ohmic contact a large reservoir of holes which can be readily injected into the bulk under forward bias must exist. Such contact is not easily achieved for temperatures in the liquid-helium range. For example, it is known that most metal contacts to silicon create Schottky-type barriers at the metal-semiconductor interface which, though small at room temperature in some cases, are extremely large compared to kT at 4.2°K. Such a barrier would, of course, prevent hole injection at this temperature. A nondegenerate diffused or alloyed p contact would also be unsuitable for use as an injecting contact at these low temperatures since the contact region would merely be an extension of the insulating bulk. However, a degenerate p_+ contact appears to be suitable for the injecting contact at low temperatures since in the degenerate p_+ region there exists a large number of mobile holes which could easily be injected into the insulating region because only a slight barrier exists.

The exact nature of the blocking contact at low temperatures is not so important. Any contact which prevents neutralizing electrons from entering when holes are being injected at the ohmic contact is satisfactory. For this investigation of SCLC the most suitable contact would again be a degenerate p_+ contact since no rectification is desired. No electrons can be injected at this contact at low temperatures regardless of the bias polarity.

The structures in which SCLC was explored at low temperatures were, therefore, p_+pp_+ devices with degenerate p_+ regions. The schematic potential solution for the entire structure in equilibrium is shown in Fig. 1. The metallurgical junctions occur at $X=0$, d in this diagram.

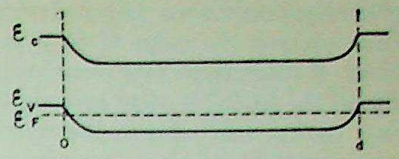

FIG. 1. p_+pp_+ structure in equilibrium.

FIELD-DEPENDENT MOBILITIES AT LOW TEMPERATURES

At temperatures in the liquid-helium range carrier mobilities become field-dependent for values of electric field orders of magnitude smaller than at room temperature. To obtain an explanation for this phenomenon, one must consider the temperature dependence of the mobility. Since at 4.2°K the low-field mobility in lightly doped silicon is more than two orders of magnitude greater than its room-temperature value,[6] the carrier drift velocity at this temperature for a given field strength is likely to greatly exceed the room temperature drift velocity at the same field strength. Therefore the breakdown of the constant mobility assumption, which occurs when the energy given to mobile carriers by the field between collisions is comparable to the equilibrium carrier energy, should occur at greatly reduced electric fields at low temperatures due both to the increased mobility and to the decreased equilibrium carrier energy at these temperatures.

The two principal mechanisms which determine the form of the mobility field dependence are acoustical and optical scattering. Only at very low fields must ionized impurity scattering be considered.[7]

The equation governing the dependence of the mobility μ and electric field E when only acoustical scattering is of importance is

$$\mu = (8/3)^{1/4}(\mu_{LOC})^{1/2}E^{-1/2}, \qquad (1)$$

where μ_{LO} is the acoustical scattering limited zero-field mobility and c is the velocity of sound in the semiconductor.

The field strength at which optical scattering should become important in determining the mobility can be approximated by employing the above equation. If one equates the carrier drift velocity as calculated from this equation to the saturated drift velocity as obtained by equating the carrier kinetic energy to the Raman energy $\mathcal{E}_R$ the following results,

$$(8/3)^{1/4}(\mu_{LOC})^{1/2}E^{1/2} \cong 1/2(2\mathcal{E}_R/m^*)^{1/2}, \qquad (2)$$

where m^* is the density-of-states effective mass.

When the appropriate constants are inserted, it is obtained that in p-type silicon for $E > 50$ V/cm optical scattering should determine the mobility at 4.2°K. This result is surprising when one considers that electric fields near 10^5 V/cm were required at room temperature[8] to cause the carrier drift velocity to approach saturation.

As shall be seen in the following section, the minimum electric field value for which SCLC is observed in the

present compensated silicon devices at low temperatures exceeds the value of 50 V/cm by more than an order of magnitude. One would expect, therefore, that for all the SCLC devices investigated at low-temperature optical scattering is the process determining the carrier mobility.

The simple model for optical scattering, which assumes all carriers are scattered optically upon reaching the threshold energy for optical-phonon emission, allows no carrier energies higher than the threshold energy and predicts drift velocity saturation. When higher carrier energies are allowed, as would be in any realistic model, the drift velocity would not actually saturate. If, for example, the mobility varied as $E^{-\alpha}$, where $\alpha<1$, as some workers have reported, the drift velocity would be proportional to $E^{1-\alpha}$. If one assumes that due to optical scattering the hole mobility μ_P is given by the expression

$$\mu_P=K_0E^{-\alpha}, \tag{3}$$

the constants K_0 and α can be evaluated empirically by comparing the observed Child's law region characteristics to the theoretical Child's law characteristic. When the mobility variation of Eq. (3) is assumed, one can calculate the Child's law characteristic. The resulting equation relating the current density j to the terminal voltage V is

$$j=[(3-\alpha)/(2-\alpha)]^{2-\alpha}(\epsilon K_0)/(2-\alpha)V^{(2-\alpha)}/d^{(3-\alpha)}, \tag{4}$$

where ϵ is the permittivity of the material and d is the device thickness. This equation can be seen to be correct by allowing α to equal zero. In this case the equation reduces to the familiar square-law characteristic for constant mobility.

TRAPPING AT LOW TEMPERATURES

At low temperatures in p_+pp_+ single injection devices, the hole trapping process should involve "giant" traps[5] since Coulombic attraction exists between injected holes and the negatively charged compensated boron atoms. An injected hole would therefore be trapped first in a large orbit excited state of a negative boron center via the emission of a single acoustical or optical phonon. After being trapped in this excited state, the hole would decay to the ground state of the center via a cascade of single-phonon processes.

Whenever carriers are injected into insulators where deep trapping centers exist, the rate at which the carriers are trapped is naturally related to the capture cross section of the centers. In the case of holes injected into p type silicon, the rate at which the carriers are trapped is given by the equation

$$dp/dt=-\bar{B}pN_A^-, \tag{5}$$

where N_A^- is the density of ionized acceptors, p is the density of injected holes, and $\bar{B}$ is the mean-capture probability. $\bar{B}$ is obtained by averaging $B(\mathcal{E})$ over the energy distribution of the injected carriers. The energy-dependent capture probability can be written as

$$B(\mathcal{E})=\sigma(\mathcal{E})(2\mathcal{E}/m^*)^{1/2}, \tag{6}$$

where $\sigma(\mathcal{E})$ is the energy-dependent cross section.

The mean capture probability is therefore seen to be

$$\bar{B}=\langle\sigma(\mathcal{E})(2\mathcal{E}/m^*)^{1/2}\rangle. \tag{7}$$

The experimental values of $\bar{B}$, from which estimates for the capture cross section can be made, can be obtained by comparing the experimental current transients with the analytically derived characteristic. For the condition of slow trapping (the drift transit time $t_d\ll\tau_t$, the trapping time) the following analysis may be employed to obtain the analytical characteristic.

TRANSIENT SCLC IN THE PRESENCE OF SLOW TRAPPING

Carrier flow in a plane parallel insulator with deep traps can be described with four equations: the transport equation, the continuity equation, Poisson's equation, and a rate equation describing the trapping process. If diffusion currents are again neglected, these four equations are as written below:

$$j(X,t)=q\mu_pp(X,t)E(X,t); \tag{8}$$

$$\frac{\partial j(X,t)}{\partial X}=-q\left[\frac{\partial p(X,t)}{\partial t}+\frac{\partial p_t(X,t)}{\partial t}\right]; \tag{9}$$

$$\frac{\partial E(X,t)}{\partial X}=\frac{q}{\epsilon}[p(X,t)+p_t(X,t)+N_D-N_A-n-n_t]; \tag{10}$$

and

$$\frac{\partial p_t(X,t)}{\partial t}=\bar{B}p(X,t)[N_T-p_t(X,t)], \tag{11}$$

where q is the electronic charge, p_t the density of trapped holes, n the density of mobile electrons, n_t the density of trapped electrons, and N_T the density of trapping centers.

In writing Eq. (11), the generation of carriers from the deep traps has been assumed to be negligible. Additional assumptions which appear to be appropriate to the low-temperature situation are:

(1) due to the quasistationary[9] behavior of the carrier flow in the slow trapping situation, both (a) the current divergence $\partial j(X,t)/\partial X$ and (b) displacement currents may be neglected;

(2) at 4.2°K, both n and n_t are negligibly small in p-type material;

(3) since the injected holes are captured on acceptor centers, N_T is equal to N_A in Eq. (11); and

(4) since $t_d\ll\tau_t$, the trap free SCLC solution is assumed to apply at $t=0$.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The simplified equations can be rewritten as

$$j(t)=q\mu_p p(X,t)E(X,t), \tag{12}$$

$$\frac{\partial p(X,t)}{\partial t}=-\frac{\partial p_t(X,t)}{\partial t}, \tag{13}$$

$$\frac{\partial E(X)}{\partial X}=\frac{q}{\epsilon}[p(X,t)+p_t(X,t)+N_D-N_A], \tag{14}$$

$$\frac{\partial p_t(X,t)}{\partial t}=\bar{B}p(X,t)[N_A-p_t(X,t)]. \tag{15}$$

To solve this system of equations for $j(t)$, one proceeds as follows:

(1) relate $p_t(X,t)$ and $p(X,t)$ via Eqs. (13) and (15);

(2) relate $j(t)$ to $p_t(X,t)$ using these results and Eq. (12); and

(3) substitute SCLC initial conditions into the problem obtaining the solution for $j(t)$.

The resulting expression for $j(t)$ is

$$j(t)=J_0\left[\frac{1-[2(2-\alpha)^2(d/X)^{(\alpha-1)/(2-\alpha)}V_{\mathrm{TFL}}/(3-\alpha)V]}{1-[2(2-\alpha)^2(d/X)^{(\alpha-1)/(2-\alpha)}V_{\mathrm{TFL}}/(3-\alpha)V]\exp\bar{B}tN_D\{1-(3-\alpha)(X/d)^{(\alpha-1)/(2-\alpha)}V/2(2-\alpha)^2V_{\mathrm{TFL}}\}}\right]. \tag{16}$$

Equation (16) does not agree completely with the assumptions made in its derivation since it predicts a nondivergenceless current. The divergence is not great, however, since the exponent of the X terms, $(\alpha-1)/(2-\alpha)$, is much less than one for values of α appropriate to the devices of the following section. In fact, for $\alpha=1$, corresponding to drift-velocity saturation, the X dependence disappears altogether yielding a completely divergenceless current. Since the assumptions upon which the present analysis is based are strictly valid only for the case of drift-velocity saturation, the theoretical current transients shall be calculated under this assumption. The difference in form between the characteristics obtained in this manner and the results of an exact solution should not be great since, for values of α reasonably close to one, the X dependence of the current in Eq. (16) is greatly depressed. Hence, by matching the theoretical current transients obtained assuming drift-velocity saturation to the experimental characteristics, one should be able to obtain approximate values for $\bar{B}$ even though the drift velocity has not reached saturation. The theoretical transient characteristic to be employed in these comparisons is obtained by substituting $\alpha=1$ into Eq. (16). This yields

$$j(t)=J_0\left[\frac{1-V_{\mathrm{TFL}}/V}{1-(V_{\mathrm{TFL}}/V)\exp\{\bar{B}tN_C(1-V_{\mathrm{TFL}}/V)\}}\right]. \tag{17}$$

Several limit checks may be performed on this solution to compare it to reality. For example, an obvious limit check is an examination of the behavior of the equation as $t\rightarrow\infty$ for the two cases of $V<V_{\mathrm{TFL}}$ and $V>V_{\mathrm{TFL}}$. For $V<V_{\mathrm{TFL}}$, Eq. (17) predicts that $j(t)\rightarrow 0$ as $t\rightarrow\infty$. This corresponds to the result expected from physical considerations. For the second situation where $V>V_{\mathrm{TFL}}$, the equation predicts that $j(t)\rightarrow J_0(1-V_{\mathrm{TFL}}/V)$, which also corresponds to the expected behavior. An additional check on the equation may be obtained by allowing the density of compensation N_D to become very large. In this case, V_{TFL}/V would be much greater than 1 and $j(t)\rightarrow J_0\exp(-\bar{B}tN_d)$. This simple exponential is the transient characteristic one would expect from physical reasoning for this case, since the density of ionized trapping levels is so large as to remain essentially constant even though carriers are being trapped.[9]

DEVICE CONSTRUCTION AND EVALUATION

The degenerate p_+ contacts were formed by comparatively low-temperature boron diffusions. For the temperatures employed (900–950°K) the surface concentration of boron exceeded 10^{20} cm^{-3} as was observed from sheet resistivity and junction depth measurements on identically diffused n-type wafers.[10] These measurements indicated junction depths of approximately 1 μ in addition to the above value of surface concentration.

Two techniques were employed to fabricate single injection devices from the diffused wafers. Circular devices with areas of approximately 10^{-2} cm^2 were obtained by masking and etching. Rectangular devices of comparable area were made by scribing and breaking the diffused samples. Leads were attached to the above devices by thermocompression bonding aluminum wire.

To obtain measurements at 4.2°K on these devices, a shielded, light-tight cryostat was employed. To obtain the necessary low temperature, the cryostat was inserted into the liquid-helium chamber of a double-walled transport Dewar.

To measure the steady-state current-voltage characteristics over the relatively large range of currents observed in SCLC devices, several techniques were employed. Below 1 mA, dc measurements could be taken without appreciable heating. Consequently currents between 10^{-9} and 10^{-3} A were observed using dc schemes. Point by point measurements were made in some cases using a well-shielded circuit employing a

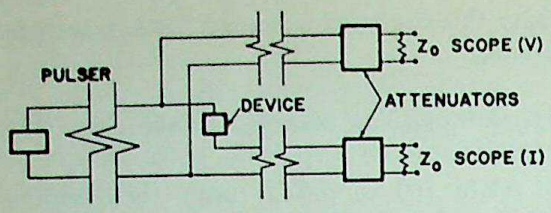

FIG. 2. Pulse measurement circuit.

precision decade resistance box to sense the current. In many instances, however, the dc data were obtained using an oscilloscope as an X-Y plotter. This procedure speeded up the data taking process considerably while still allowing accuracy within the range required. In some cases the device characteristics were observed on a curve tracer when high accuracy was not needed.

For currents greater than 10^{-3} A where heating would prevent dc measurements, the steady-state current-voltage characteristics were obtained using repetitive submicrosecond pulses. The pulse measurement setup, as shown in Fig. 2, differed slightly from the dc setup since to prevent reflections the transmission lines were matched with their characteristic impedance Z_0 at all terminations. The pulse duration in these measurements varied between 100 and 300 nsec. The repetition rate was approximately 150–350 pulses per second. A fast rise-time oscilloscope (Tektronix 555) was used to observe the pulses in all cases.

The single-shot pulse measurements, used to approximate the trap-free SCLC, were taken with the same circuit as shown in Fig. 2. A single-shot measurement was made by pulsing the device once after it had been thermally cycled from 300 to 4.2°K. The oscilloscope traces corresponding to the single-shot voltage and current pulses were recorded on high speed film, providing records from which the data could later be taken and analyzed.

EXPERIMENTAL CURRENT-VOLTAGE CHARACTERISTICS

The experimental steady-state current-voltage characteristics as obtained at 4.2°K for p_+pp_+ silicon devices exhibited the structure one would expect for SCLC in an insulator with deep trapping levels. In Fig. 3 the steady-state characteristic has been plotted for device II. This characteristic, which is typical of all the devices tested, clearly shows the presence of a traps-filled voltage, at which point the current increases steeply with voltage. When the traps-filled voltage is measured for this device and for the others constructed from the same material, the values tabulated in Table I are obtained. If the trap density were uniform, as was previously assumed above, a d^2 dependence would be observed in V_{TFL}. By plotting $\log V_{TFL}$ versus $\log d$, where d is the minimum thickness, a straight line of slope two would connect the measurements for the various devices for this dependence. In Fig. 4 this plot is shown including the possible errors in device thickness

TABLE I. Traps-filled voltage values and the corresponding minimum thicknesses for several devices.

Device	Minimum thickness (cm)	V_{TFL} (V)
O	7.7×10^{-3}	31
II	6.8×10^{-3}	25
III	8.2×10^{-3}	36
IV	9.0×10^{-3}	44
VII	1.1×10^{-2}	57
VIII	7.2×10^{-3}	25
IX	8.2×10^{-3}	32.5

measurements ($\pm5\,\mu$). The experimental points lie very close to the predicted slope-two line. The traps-filled voltage value obtained for each device allows a determination of the trap density in the device. When this is done for all the devices in Table I, a mean trap density of 6.1×10^{12} cm^{-3} is obtained. The maximum deviation from this value in the devices measured was approximately 10%.

From the steady-state curve in Fig. 3 the form of the current-voltage characteristic in the Child's law region can be determined. However, the limited data in this region make the determination, with any degree of accuracy, rather difficult. To decrease the possible error associated with fitting the Child's law region, single-shot pulse measurements can be made, to approximate the trap-free characteristic. These measurements, as taken for the device in Fig. 3 are plotted as the boxed data points on the same curve. The agreement between the steady-state and single-shot curves in this figure indicates the usefulness of the single-shot measurements in obtaining an extension of the Child's law region.

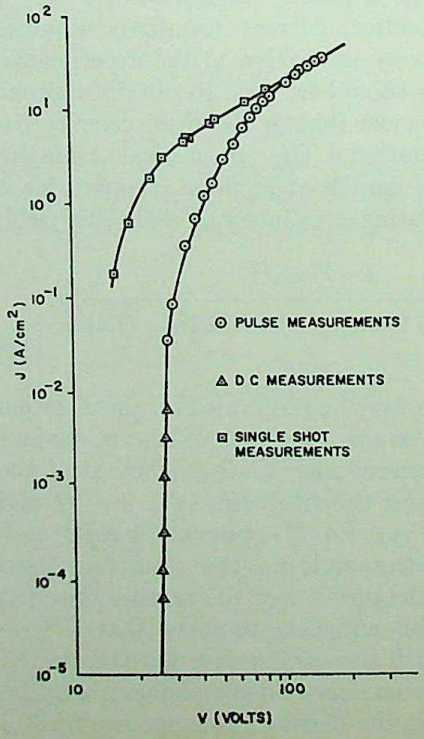

FIG. 3. Steady-state and single-shot pulse measurements for device II.

By measuring the slope m of the characteristic in the extended Child's law region one can obtain from Eq. (4) $m=(2-\alpha)$. For the devices analyzed a mean value of 0.64 was obtained for α.

From the value of K_0 and the slope of the characteristic in the Child's law region, the field-dependent carrier mobility at low temperatures can be determined. In the range of applied fields 3×10^3 V/cm$<E<3\times10^4$ V/cm the relationship between mobility and electric field was found to be

$$\mu_P(E)\approx(2.6\pm1.4)\times10^5E^{-(0.64\pm0.04)}\ \text{cm}^2/\text{Vsec}. \quad (18)$$

The steeply rising region of the steady-state characteristic following V_{TFL} can be obtained analytically for the two cases of constant mobility or constant drift velocity. However, for the more general situation where the mobility is field-dependent but the drift velocity not saturated, no analytical solution can be obtained. To obtain the characteristic for this case a numerical solution would be necessary. The effort required to obtain this solution would not be justifiable since little additional information would result. However, the basic fact about the steeply rising region is that any model, which assumes the onset of SCLC after a traps-filled voltage, predicts an extremely steep characteristic regardless of the applicable $\mu(E)$ function. This prediction is most definitely verified by the previous experimental characteristics.

CAPTURE PROBABILITY AND CAPTURE CROSS-SECTION MEASUREMENTS

The mean capture probability,[5] $\bar{B}$, can be obtained from the same single-shot pulse measurements that were utilized to obtain the extended Child's law region of Fig. 3. Two pulse recordings, typical of those employed to obtain $\bar{B}$, are shown in Fig. 5 as photographed from the oscilloscope display.

There are two ways in which one can obtain $\bar{B}$ from the single-shot current response. One can (a) match the theoretical transient characteristic [Eq. (17)] to the experimental pulse, or (b) estimate the initial time constant of the decaying current pulse and compare it to the theoretical initial time constant.

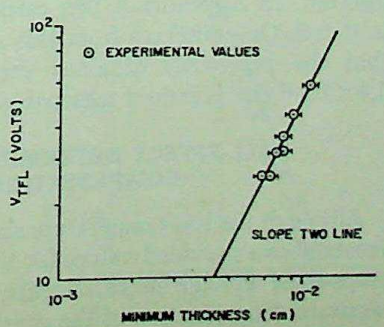

FIG. 4. Thickness dependence of V_{TFL}.

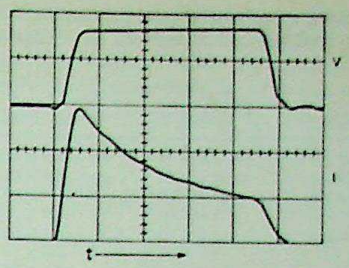

FIG. 5. Typical voltage and current transients obtained by single-shot pulse measurements. Scales: $t=40\times10^{-9}$ sec/major division: $V=25$ V/major division; $I=20$ mA/major division.

Equation (17) is rewritten for clarity as

$$j(t)=J_0\frac{1-V_{TFL}/V}{1-(V_{TFL}/V)\exp\bar{B}N_d(1-V/V_{TFL})t}.$$

It is seen to contain the parameters J_0 and $\bar{B}$ in addition to the previously determined constants N_d and V_{TFL}.

Some uncertainty exists as to where $t=0$ should be situated on the experimental pulse in order to cause it to correspond to the analytical characteristic of Eq. (17). Due to the accumulated rise time of the generator, oscilloscope, and measuring circuit there exists an uncertainty of approximately 20 nsec. Two alternative methods of matching the theoretical and experimental characteristics present themselves. One can assume

(a) that the beginning of the current pulse, $i(t)$, through the device corresponds to approximately 20×10^{-9} sec before the peak of the $i(t)$ pulse, or

(b) that negligible trapping occurs prior to the peak of the $i(t)$ pulse in which case this point would correspond to $t=0$ in the theoretical characteristic.

Case (a) involved matching the theoretical and experimental characteristics at two points to allow determination of both J_0 and $\bar{B}$ for each pulse. This technique was therefore called a "two-point fit." Case (b) involved matching the characteristics at only one point since J_0 was known. This case was called a "one-point fit." In Fig. 6 the experimental pulse responses of two typical devices are plotted as circled points. Both one- and two-point fits were performed for these units and the results are also shown. It was observed that for these and other pulses the one-point fit tended to more closely approximate the experimental results. This would indicate that no appreciable trap filling occurred for most pulses before the peak of the experimental characteristic.

The second general technique for calculating the mean capture probability from the experimental data was to relate the initial time constant τ_{TO} for decay of the current pulse to $\bar{B}$. Since at $t=0$ the density of trapping centers is approximately equal to N_D, one obtains that

$$B=1/\tau_{TO}N_D, \quad (19)$$

where τ_{TO} may be obtained by estimating the initial

VII	2-Point fit	6.0×10^{-6}	1.1×10^{-12}	4.9×10^{3}
IX	Initial slope	$(1.75\text{–}3.5)\times10^{-6}$	$(3.6\text{–}7.3)\times10^{-13}$	3.3×10^{3}
IX	Initial slope	1.5×10^{-6}	3.3×10^{-13}	2.7×10^{3}
IX	2-Point fit	3.8×10^{-6}	7.2×10^{-13}	4.4×10^{3}
IX	1-Point fit	2.2×10^{-6}	4.2×10^{-13}	4.4×10^{3}
IX	1-Point fit	1.4×10^{-6}	2.1×10^{-13}	8.3×10^{3}
IX	1-Point fit	1.4×10^{-6}	2.3×10^{-13}	6.6×10^{3}

slope of $i(t)$ on a semilogarithmic plot. For this reason this technique was called the "initial slope" method.

In Table II the values of $\bar{B}$ obtained by these three methods for several devices have been tabulated. The average electric field (V/d) is shown for each measurement. Because of the large scatter of the experimental results, no field dependence could be detected in the B measurements. By averaging the values for each of the techniques one obtains: (a) $\bar{B}=2.4\times10^{-6}$ from initial slope measurements, (b) $\bar{B}=2.0\times10^{-6}$ from one-point fitting of the theoretical characteristic, and (c) $\bar{B}=7.2\times10^{-6}$ from two-point fitting of the theoretical characteristic.

Since the value of $\bar{B}$ given in (c) does not agree well with (a) or (b) the value of $\bar{B}=2.2\times10^{-6}$ cm³/sec is chosen as the most probable.

In order to calculate a meaningful capture cross section for the trapping levels from the $\bar{B}$ value given above, one must know not only the energy distribution of the carriers but also the energy dependence of the capture cross section since $\bar{B}$ is given by Eq. (7). However, in the high-field case certain assumptions about the energy distribution of the carriers can be made which simplify the relationship between $\bar{B}$ and σ. For this case, because of the heating effect of the electric field on the carriers, optical mode scattering is the dominant energy-loss mechanism. If one assumes that the component of the carrier energy contributed by the field between optical collisions is much greater than the carrier energy remaining after a collision, the average carrier energy will be given by

$$\mathcal{E}_d=(1/2)m^*v_d^2, \tag{20}$$

where v_d is the drift velocity. If one also assumes that few carriers have energy is excess of $\mathcal{E}_R$, Eq. (7) simplifies to

$$\bar{B}=\sigma(\mathcal{E}_d)(2\mathcal{E}_d/m^*)^{1/2}. \tag{21}$$

Replacing the quantity

$$(2\mathcal{E}_d/m^*)^{1/2}$$

by its equivalent

$$K_0E^{1-\alpha},$$

one obtains from (21) the simple expression

$$\sigma(\mathcal{E}_d)=\bar{B}/K_0E^{1-\alpha}. \tag{22}$$

The values of $\sigma(\mathcal{E}_d)$ calculated by applying Eq. (22) to the values of $\bar{B}$ in Table II have been included in this table. The mean value of σ as taken from the initial slope and one point fit calculations is

$$\bar{\sigma}\approx4.4\times10^{13}\text{ cm}^2.$$

This value applies for a mean electric field of 4.6×10^3 V/cm.

The above experimental capture cross section can be compared to the prediction of the giant trap model by calculating the theoretical value of the energy-dependent capture cross section via relationships derived by Lax.[5] For the case of trapping via optical-phonon-emission Lax's theory predicts values for the capture cross section in the range

$$1.4\times10^{-13}\text{ cm}^2<\sigma<5.6\times10^{-13}\text{ cm}^2,$$

when constants appropriate to silicon at 4.2°K are inserted. In Appendix A this calculation is performed in detail. One observes from this range of values of σ that the previously obtained experimental value of 4.4×10^{-13} cm² is indeed reasonable.

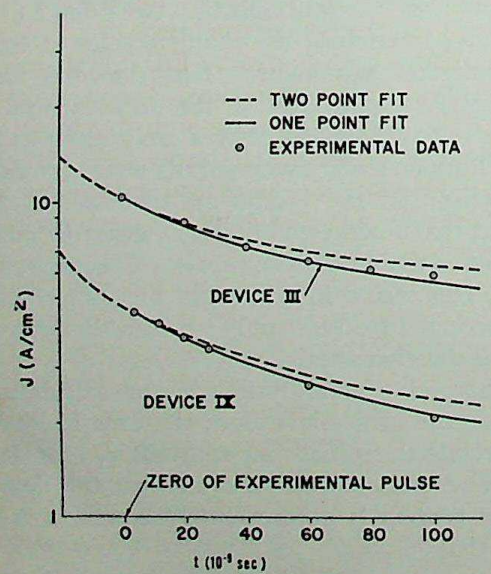

FIG. 6. Theoretical and experimental transient characteristics for devices III and IX.

HALL-EFFECT DETERMINATION OF COMPENSATION

Although the low-temperature single injection experiments above provided values for the compensation via traps-filled voltage measurements, it was felt that a separate determination of the compensation by a more

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

conventional technique was necessary for corroboration. For this purpose Hall-effect measurements were performed over the temperature range $25°K < T < 77°K$, whereby one could obtain both the majority dopant depth and degree of compensation.

The temperature-dependent hole concentration in p-type silicon at low temperatures is known to be given by the expression

$$p = \left(\frac{2\pi m^* T}{h^2}\right)^{3/2} \frac{(N_A - N_D)}{2N_D} \exp(-\mathcal{E}_A/kT), \quad (23)$$

where $\mathcal{E}_A$ is the acceptor activation energy.

To obtain the compensation N_D from the Hall data one observes that it is necessary to plot the quantity $\ln(pT^{-3/2})$ versus $1/T$. Over the region of applicability of Eq. (23) this plot yields a straight line of slope $-\mathcal{E}_A/k$ from which one obtains the acceptor activation energy. Furthermore, if the linear region of the plot is extrapolated to the $1/T=0$ axis, the intercept allows a determination of the quantity $(N_A-N_D)/N_D$. Since (N_A-N_D) can be obtained from Hall measurements in the exhaustion region, a measurement of the intercept readily yields the compensation N_D.

For three Hall samples this plot is shown in Fig. 7. Device I–II was constructed of material diffused simultaneously with that of the single injection devices previously considered. Device III–II and III–III were fabricated from the results of a separate diffusion performed under near identical circumstances on the same starting material. The results for these three samples are tabulated in Table III. One observes that the results for devices III–II and III–III are quite similar. However, the degree of compensation in these two devices differs by a factor of 2 from that measured for device I–II. This result supports the hypothesis that most of the compensation present in the devices was created during the diffusion step. The compensation observed in device I–II (6.6×10^{12} cm^{-3}) was quite close to the average value of 6.1×10^{12} cm^{-3} obtained from the previous V_{TFL} measurements. This degree of agreement between the two values is quite good, especially since finding N_D in the Hall experiment involves extrapolating the $pT^{-3/2}$ curve over a region as extensive as the straight line region itself.

TABLE III. Impurity concentrations and acceptor depth as determined by Hall-effect measurements.

Device	Type	E_D (eV)	(N_A-N_D) (cm^{-3})	N_D (cm^{-3})	N_A (cm^{-3})
I–II	p	47×10^{-3}	1.7×10^{12}	6.6×10^{12}	8.3×10^{12}
III–II	p	47×10^{-3}	5.4×10^{12}	3.9×10^{12}	9.3×10^{12}
III–III	p	47×10^{-3}	5.6×10^{12}	3.8×10^{12}	9.4×10^{12}

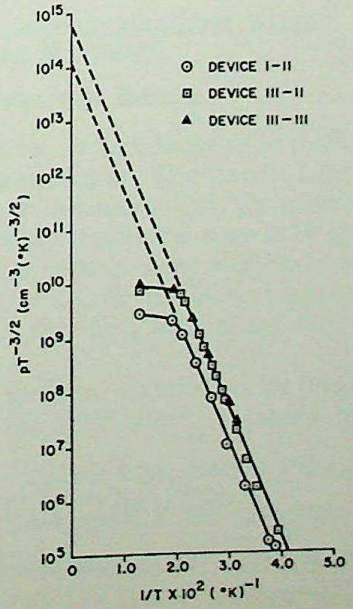

FIG. 7. $pT^{-3/2}$ versus $1/T\times10^2$ for Hall devices I–II, III–II and III–III.

The activation energy $\mathcal{E}_A$ of the acceptor center, corresponding to the trapping depth at 4.2°K, was approximately 0.047 eV for all devices. This value is known to correspond to boron in silicon.[11]

DISCUSSION AND CONCLUSIONS

In considering the model for p_+pp_+ devices at liquid-helium temperature a threshold voltage for injection is found to exist. This threshold is due to the barrier created at the p_+p junction by holes trapped near the junction in the equilibrium situation. The exact form of the Child's law region at low temperatures is dependent on the mobility-electric field relationship appropriate to the range of fields employed. For a mobility dependence as given by expression (3) the general Child's law relationship has the form of Eq. (4).

In order to relate the observed single-shot current pulses to the trapping capture probability, an approximate solution has been obtained for the current as a function of time under the conditions of slow trapping. This solution is as indicated by Eq. (17) if the current flow is assumed divergenceless. This assumption is strictly valid only for the case of drift-velocity saturation; therefore for $\alpha<1$ in expression (3) a slight disparity between the analytical expression for the current density and the actual characteristics is expected to exist.

The experimental results indicate that the SCLC model, modified to include the appropriate field-dependent mobility, applies for p-type silicon at 4.2°K. The steady-state current-voltage characteristics observed at this temperature correspond in form and magnitude to the predictions of the SCLS model for an insulator with a deep trap density of 6.1×10^{12} cm^{-3}. By single-shot pulse techniques the experimental Child's law regions could be extended to lower applied voltages.

[11] N. B. Hannay, *Semiconductors* (Reinhold Publishing Corporation, New York, 1960), p. 472.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Based on these extended power law regions the appropriate form of Child's law was found to be $j \sim V^{1.36}$. The mobility implied by the characteristic in this region was

$$\mu_P \simeq (2.6 \pm 1.4) 10^5 E^{-(0.64 \pm 0.04)} \text{ cm}^2/\text{Vsec}.$$

A trap density of 6.1×10^{12} cm^{-3} was obtained by trap-filled voltage measurements and it should correspond to the compensation in the material. This compensation was measured separately by a Hall-effect experiment over the temperature range $25°\text{K} < T < 77°\text{K}$ and found to be approximately 6.6×10^{12} cm^{-3}, which agrees reasonably well with the value above. Also from the Hall experiment a value for the acceptor level of 0.047 eV was obtained, which agrees reasonably well with the expected value for boron in silicon.

Experimental values for the capture probability and capture cross section were obtained by fitting the analytical characteristic for the current density to the observed pulses. The average experimental value for the mean capture probability was $\bar{B} = 2.2 \times 10^{-6}$ cm^3 sec^{-1}. If all the carriers are assumed to have the same velocity, this value could be converted to a corresponding one for capture cross section. The latter, as obtained by averaging the values obtained from the many experimental measurements of $\bar{B}$, was $\bar{\sigma} = 4.4 \times 10^{-13}$ cm^2. The theoretical value of σ, as predicted by the giant trap model, was calculated for the case of trapping via optical-phonon emission. A value of σ in the range $1.4 \times 10^{-13} < \sigma < 5.6 \times 10^{-13}$ cm^2 resulted. The agreement between experimental and theoretical values is again quite reasonable.

APPENDIX A

For the case of trapping via optical-phonon emission, Eq. (A1) relates σ and $\mathcal{E}$, the carrier energy. This equation is

$$\sigma(\mathcal{E}) = \frac{\pi^2}{8} \frac{w}{l_c} \frac{q^2}{\epsilon} \left(\frac{q^2}{\epsilon \hbar\omega} \right)^2 \times \frac{\lambda}{1-\exp(-\lambda)} \frac{P(\hbar\omega - \mathcal{E})}{(1-\mathcal{E}/\hbar\omega)^{5/2}} (1+a\bar{y})^{1/2}, \quad \text{(A1)}$$

where the various quantities are defined as: $\hbar\omega = \mathcal{E}_r$ the Raman energy (0.063 eV for silicon), $\lambda = \hbar\omega/kT$, $P(\hbar\omega - \mathcal{E})$ = the "sticking probability," $a = ((\hbar\omega - \mathcal{E})/\hbar\omega)$, $\bar{y} \approx 0.85$, l_c = the mean free path for acoustical scattering, and w = a constant which relates the strength of coupling of the carriers to the optical modes to the strength of coupling to acoustical modes.[12] After substituting the appropriate values of the above terms for silicon at 4.2°K into Eq. (A1) one obtains that

$$\sigma = 8.5 \times 10^{-16} w/l_c, \quad \text{(A2)}$$

when $E = 4.6 \times 10^3$ V/cm.

Choosing the pure acoustical scattering mobility at 4.2°K to be approximately 10^6 cm^2/Vsec for p-type silicon, as the results of Putley and Mitchell[6] would indicate, l_c would be approximately 6×10^{-4} cm. Therefore at 4.2°K

$$\sigma \approx 1.4 \times 10^{-13} (w) \text{ cm}^2. \quad \text{(A3)}$$

The value of w can be estimated based on the existing data for mobility versus temperature in the range $100°\text{K} < T < 300°\text{K}$.[6] It would appear that $1 < w < 4$ is applicable for p-type silicon.

For this range of w one finds that

$$1.4 \times 10^{-13} \text{ cm}^2 < \sigma < 5.6 \times 10^{-13} \text{ cm}^2.$$

PHYSICAL REVIEW VOLUME 134, NUMBER 5A 1 JUNE 1964

Ultrasonic Wave Propagation in Doped *n*-Germanium and *p*-Silicon

WARREN P. MASON AND T. B. BATEMAN
Bell Telephone Laboratories, Murray Hill, New Jersey

(Received 9 January 1964)

The effect of doping germanium with *n*-type material and silicon with *p*-type material is to increase the attenuation and decrease the elastic moduli. The decrease in the c_{44} elastic modulus for *n*-type germanium agrees fairly well with theoretical predictions. However, the modulus decrease in *p*-type silicon is much larger and varies with temperature much faster than predicted by any present theory. It is suggested that there is a temperature-induced change in hole population along the energy surfaces. The intervalley relaxation time, which determines the added attenuation, becomes independent of the doping for high dopings with the antimony time being about 100 times that for arsenic. This result indicates that the relative values are determined by the square of the triplet singlet separation which occurs near the impurity atoms. For *p*-type silicon the relaxation time at low temperatures increases very markedly indicating an activation-energy effect. The energies agree well with the energies measured by infrared techniques for the largest excited state orbits around the impurity atoms. The relaxation times measured at high temperatures indicate that the hole is transported $\frac{1}{3}$ cycle from one ⟨111⟩ position to the next.

I. INTRODUCTION

IT was first pointed out by Keyes[1] that the introduction of arsenic, phosphorus, or antimony into germanium—*n*-type doping—produces a decrease in the shear elastic modulus c_{44}. The result was shown to be due to the effect of the electronic part on the strain energy function and to involve only those electrons which change from one valley to another. The experimental results of Keyes and Bruner showed that the measured decrease was about 75% of the calculated decrease and varied with temperature as predicted by theory.

Pomerantz, Keyes, and Seiden[2] showed that the finite time required for electrons to go from one valley to another was a relaxation effect and should result in an attenuation of sound waves at a high frequency. Measurements at 9 kMc/sec did show[2] an absorption so high that it could not be quantitatively determined for any wave involving the c_{44} elastic modulus, while normal phonon-phonon attenuation resulted for any mode not involving this elastic constant.

II. EFFECT OF DOPING GERMANIUM WITH *n*-TYPE MATERIAL

A. Experimental Results

By going to 500 Mc/sec, or less, measurable results were obtained[3] for arsenic doping. The present paper extends these results to antimony and phosphorus doping. These data are of considerable interest in delineating the mechanisms causing changes of electrons from one valley to another and the relaxation times for these processes. Hence, they have been rather extensively investigated.

Figure 1 shows the increased attenuation for longitudinal waves along the ⟨110⟩ direction caused by doping germanium with 10^{18} and 3×10^{19} arsenic atoms per cc. The measurements were made at a frequency of 475 Mc/sec. The difference between the attenuation of the doped and pure crystal is practically independent of the temperature. The elastic modulus is determined by the sum

$$c=(c_{11}+c_{12}+2c_{44})/2. \quad (1)$$

Since it has been shown[1,3] that the only elastic constant that is affected by *n*-type doping of germanium is c_{44}, the attenuation can be ascribed to the results of a resolved shearing stress associated with the longitudinal wave. In fact the attenuation is caused by the finite relaxation time associated with the motion of electrons between the four valleys of the energy surface of *n*-type germanium. It satisfies the relaxation equation

$$A_{(\mathrm{Np./cm})}=(\Delta c_{44}/2\rho V^3)(\omega^2\tau), \quad (2)$$

valid when $\omega\tau\ll1$ and $(\omega/V)\lambda<1$, where λ is the mean free electron path. In this equation Δc_{44} is the change in modulus caused by the doping, ω is $2\pi f$, ρ the density, and V the velocity for the longitudinal wave. Changes in the c_{44} modulus for a doping of 3×10^{19} boron atoms per cc were measured by Bruner and Keyes[1] with the results shown by Fig. 2. This change was determined by the difference in velocities for pure and doped samples measured at 10 Mc/sec. The dashed curve shows the calculated value—from Eq. (13)—for the sample doped with 10^{18} arsenic atoms per cc. Measurements for antimony-doped germanium, shown by Fig. 4, give a very similar change.

The attenuation measurements of Fig. 1 and the velocity measurements of Fig. 2 can be used to determine the relaxation times, which are

$$\tau=4\times10^{-13}\ \mathrm{sec};\quad \tau=2.3\times10^{-13}\ \mathrm{sec}, \quad (3)$$

respectively, for dopings of 10^{18} and 3×10^{19} arsenic atoms per cc. These times are shown plotted on Fig. 3. On account of the small change in attenuation, this method cannot be used to investigate dopings less than 10^{18}

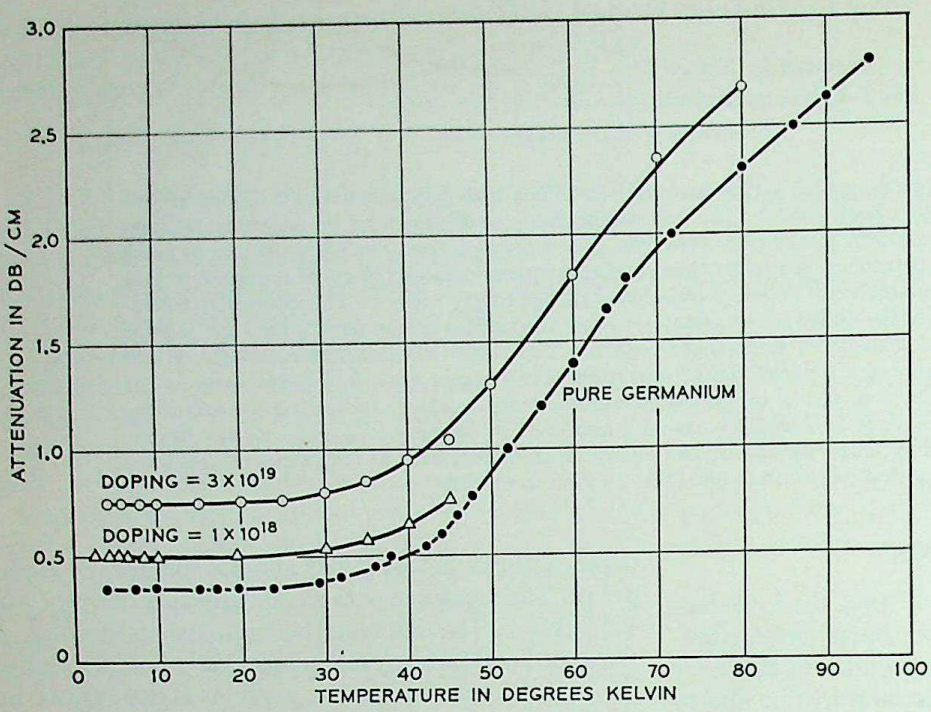

FIG. 1. Attentuation measurements of pure and arsenic-doped germanium. Longitudinal waves along ⟨110⟩, frequency 475 Mc/sec.

arsenic atoms per cc. However, another method applicable for lower dopings is the acousto-electric voltage method of Weinreich *et al.*[4] Figure 3 shows the relaxation times for a number of doping levels from 10^{14} to 10^{16} arsenic atoms per cc. At low temperatures the relaxation time is determined by impurity scattering and the solid line of Fig. 3 shows the values obtained as a function of doping using the 40°K values.[4] As the temperature increases, scattering occurs also by collisions with phonons and the dashed lines of Fig. 3 show the modification caused by this type of scattering for the temperatures shown.

The relaxation time for germanium doped lightly with arsenic impurities has been discussed by Weinreich *et al.*[4] as being due to a combination of scattering by neutral and ionized atoms. At low temperatures neutral scattering predominates and this gives a time inversely proportional to the impurity density. If we extrapolate this down to an impurity density of 10^{18}, the indicated relaxation time of 2×10^{-13} is less than the measured value of about 4×10^{-13} sec. For a density of 3×10^{19} the relaxation time approaches the value of 2.3×10^{-13} sec, which appears to be an intrinsic time for going from one valley to another.

An even stronger indication of this effect is furnished by antimony-doped germanium. Figure 4 shows the modulus and attenuation difference between a pure germanium sample and a sample doped with 1.5×10^{18}

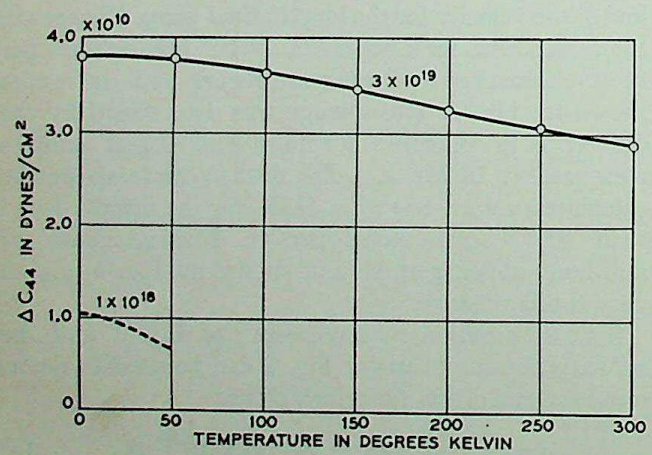

FIG. 2. Change in the elastic modulus c_{44} for arsenic-doped germanium. Measurements made at 10 Mc/sec. Dashed curve shows estimated value for a doping of 1×10^{18} arsenic atoms per cc (after Bruner and Keyes).

antimony atoms per cc. The attenuation is so high for this sample that a measuring frequency of 99 Mc/sec was used. As before the measurements were made along a ⟨110⟩ direction for longitudinal waves. The relaxation time calculated from these measurements is shown plotted by the dashed line of Fig. 4. At low temperatures impurity scattering is dominant and a value of 3.8×10^{-11} sec results. As the temperature is increased, phonon scattering occurs and the value approaches the same value found for arsenic doping at 300°K. The values for impurity doping by antimony are shown by Fig. 3. Another measurement was made for a doping of 10^{17} giving the value of the relaxation time, as shown. Measurements for lower doping have been made by Tell and Weinreich.[5] The results quoted indicate a relaxation time five times as large as that for antimony doping over a range from 10^{14} to 2.5×10^{15} atoms per cc. The resulting relaxation time for the entire range is shown by Fig. 3.

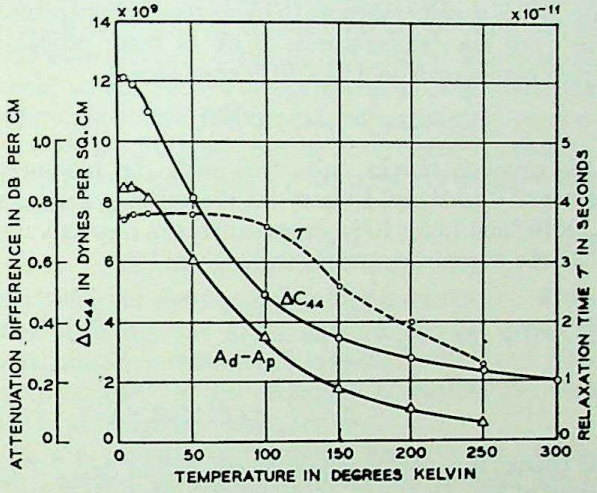

FIG. 4. Attenuation and modulus changes for germanium doped with 1.5×10^{18} antimony atoms per cc. Measurements made at 99 Mc/sec. Dashed line shows corresponding relaxation time.

Here the constancy of the intervalley relaxation time is confirmed over a wide doping range.

B. Theoretical Interpretation

Many experimental results for n-type germanium and silicon have been interpreted in terms of the many-valley model of the energy surfaces. Figure 5 shows the energy surfaces for silicon and it is seen that for the conduction band, one of the surfaces has a very low energy value in k space along the ⟨100⟩ axis. Electrons tend to congregate about these momentum values. Since there are six ⟨100⟩ directions, there are six energy minima or valleys. The six surfaces are shown by Fig. 6. The ovals indicate surfaces of constant energy. Similar considerations apply to the conduction band for germanium except that the minimum energy directions lie

[5] B. Tell and G. Weinreich, Bull. Am. Phys. Soc. 7, 546 (1962).

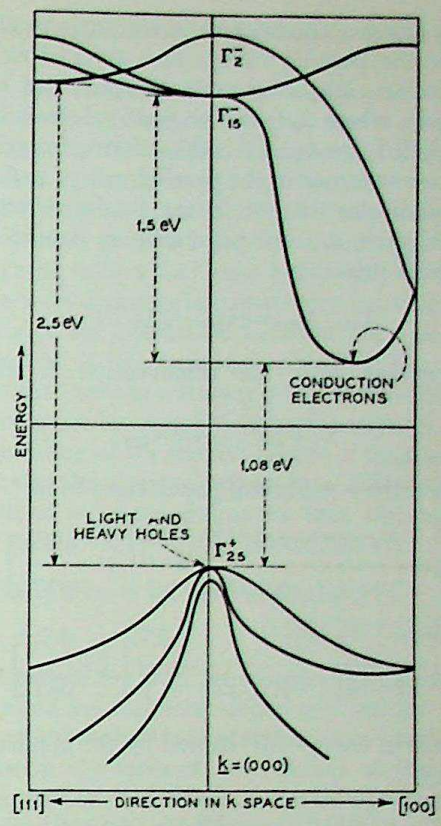

FIG. 5. Energy surfaces in valence and conduction band for silicon.

along ⟨111⟩ axis and occur at the edges of the Brillouin zone.

In the unstressed condition all the valleys have equal energies and electron populations. The effect of a

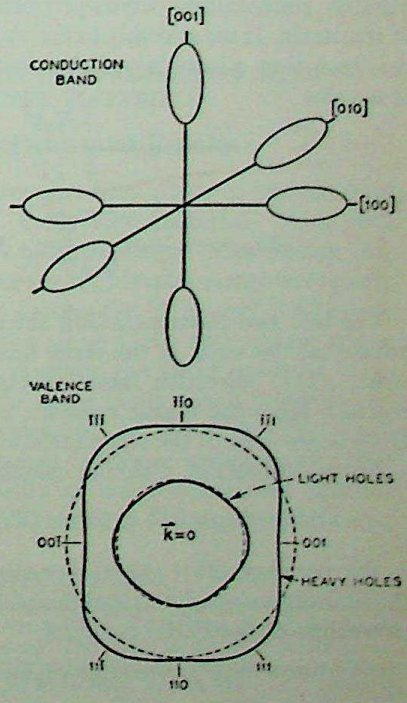

FIG. 6. Top figure: multivalley energy surfaces for n-silicon. Bottom figure: cross section of energy surfaces a constant distance below the origin.

stress T_1 along a crystal axis in silicon is to raise the energy of the parallel valleys and lower those of the perpendicular valleys by amounts $\frac{2}{3}\Phi S_1$ and $-\frac{1}{3}\Phi S_1$, respectively, where S_1 is the longitudinal strain induced by the applied stress and Φ is the deformation potential. This causes electrons in the parallel valleys to flow into the perpendicular valleys. In the nondegenerate range the equilibrium ratio of population is determined by Boltzmann's principle

$$N_{100}/N_{010}=\exp(-\Phi S_1/kT). \tag{4}$$

This, together with the conservation of electrons given by

$$N_0=2N_{(100)}+4N_{010}, \tag{5}$$

determined the equilibrium populations to be

$$\begin{aligned} 2N_{100}&=\frac{N_0\exp(-\Phi S_1/kT)}{2+\exp(-\Phi S_1/kT)}\doteq\frac{N_0}{3}\left[1-\frac{2}{3}\frac{\Phi S_1}{kT}\right];\\ 4N_{010}&=\frac{2N_0}{2+\exp(-\Phi S_1/kT)}\doteq\frac{2N_0}{3}\left[1+\frac{\Phi S_1}{3kT}\right]. \end{aligned} \tag{6}$$

The change in energy ΔW caused by the applied stress is given by

$$\begin{aligned} \Delta W&=\frac{N_0}{3}\left[1-\frac{2}{3}\frac{\Phi S_1}{kT}\right]\frac{2}{3}\Phi S_1-\frac{2N_0}{3}\left[1+\frac{\Phi S_1}{3kT}\right]\frac{\Phi S_1}{3}\\ &=-\frac{2N_0}{9}\frac{\Phi^2 S_1^2}{kT}. \end{aligned} \tag{7}$$

There is no change to first powers of the strain but a negative contribution occurs proportional to the square of the strain. If we add this to the elastic energy $\frac{1}{2}c_{11}S_1^2$, it is seen that a lowering of the elastic modulus occurs of a value

$$\begin{aligned} \Delta c_{11}&=-\frac{4}{9}\frac{N_0\Phi^2}{kT};\\ \text{also}\quad \Delta c_{12}&=-\frac{\Delta c_{11}}{2}=-\frac{2}{9}\frac{N_0\Phi^2}{kT};\quad \Delta c_{44}=0. \end{aligned} \tag{8}$$

The last two relations follow since a shearing strain affects all the wells in the same fashion while a stress along ⟨111⟩ direction also affects all the valleys equally. Since the elastic constant for this direction is $(c_{11}+2c_{12}+4c_{44})/3$, the second relation of (8) must hold.

For n germanium, a similar calculation[1] shows that

$$\Delta c_{11}=\Delta c_{12}=0;\quad \Delta c_{44}=-(N_0/9)(\Phi^2/kT) \tag{9}$$

in the nondegenerate range. For the degenerate range the limiting value of Δc_{44} is obtained by replacing kT by two-thirds of the Fermi energy or

$$\tfrac{2}{3}W_F=(\hbar^2/3m^*)(3\pi^2N)^{2/3}, \tag{10}$$

where $\hbar$ is Plank's constant h divided by 2π, N is the number of free electrons, which is equal to the number of impurity atoms in the degenerate range, and m^* the density of states mass

$$m^*=(m_l m_t^2)^{1/3}(n)^{2/3}, \tag{11}$$

where m_l is the longitudinal mass of a single valley, m_t the transverse mass, and n the number of valleys. Inserting the value in (9), the limiting value of Δc_{44} at low temperatures is given by

$$\Delta c_{44_0}=-\frac{4}{3}\left(\frac{4\pi}{3}\right)^{2/3}\frac{N^{1/3}\Phi^2(m_l m_t^2)^{1/3}}{h^2}. \tag{12}$$

Since $m_l=1.57m_0$; $m_t=0.082m_0$, where m_0 is the electron mass 9.1×10^{-28} g, this equation takes the form

$$\Delta c_{44_0}=-1.58\times10^{25}\Phi^2N^{1/3}. \tag{13}$$

From piezoresistance measurements and from other effects Φ is usually taken as 16 eV at room temperature. For very low temperatures 19 eV is more probable which corresponds to 3.04×10^{-11} ergs. Hence,

$$\Delta c_{44_0}=1.44\times10^4N^{1/3}. \tag{14}$$

This equation checks quite well with the measured values of Figs. 2 and 4 where the theoretical values are 4.7×10^{10} and 1.65×10^{10} dyn per square cm, respectively.

At the degeneracy temperature, given by

$$\begin{aligned} kT_D=W_F\quad\text{or}\quad T_D&=\frac{\hbar^2}{2m^*}\frac{(3\pi^2N)^{2/3}}{k}\\ &=7.61\times10^{-11}N^{2/3}, \end{aligned} \tag{15}$$

the change in modulus should be one-half of Δc_{44_0}.[1] The curves of Fig. 4 indicate a value of $T_D=80°$K compared to the calculated value of 99°K. Over a temperature range the ratio of Δc_{44} to Δc_{44_0} follows the relation[1] shown by Fig. 7. Using $T_D=80°$K for Fig. 4, the agreement with the measured value is excellent.

The attenuation A is determined by the product of Δc_{44} and the relaxation time τ which is the time required to go from one valley to another. Measured values are

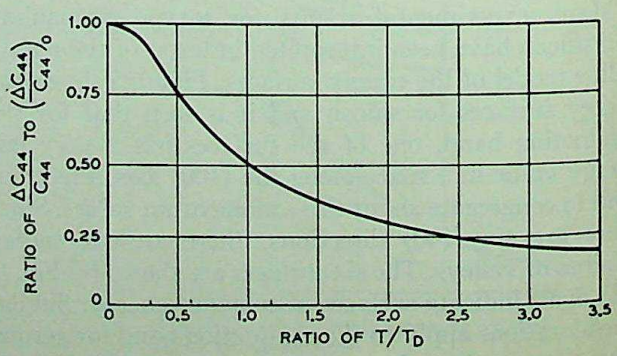

FIG. 7. Calculated ratio of $\Delta c_{44}/\Delta c_{44_0}$ as a function of the ratio of the temperature to the degeneracy temperature (after R. W. Keyes).

shown by Fig. 3. A number of different mechanisms determine this time. For dopings from 10^{14} to 10^{16} and temperatures above 150°K, the scattering mechanism is the collision of electrons with phonons. The total relaxation time, as determined by the conductivity equation, is given by

$$\tau = m^*\sigma/Ne^2 = \mu m^*/e = 0.37\times 1.1\times 10^{-31}/1.6\times 10^{-19} \doteq 2.5\times 10^{-13}\ \text{sec}, \quad (16)$$

where σ is the conductivity in mho/meter, N the number of electrons per cubic meter, e the electronic charge of 1.6×10^{-19} C, μ the mobility in M^2/V sec, and m^* the effective drift mass in kilograms. Using the values for lightly doped samples, the indicated value is about 2.5×10^{-13} sec at 300°K. Hence, about one in every 40 collisions results in a change in valleys.

As the temperature becomes lower, or the doping higher, the intervalley relaxation time is controlled by scattering from impurities. For low dopings this process has been discussed by Weinreich *et al.*[4] as being due to a combination of scattering by neutral and ionized arsenic atoms. At low temperatures neutral scattering predominates and this gives a time inversely proportional to the impurity density. Scattering is probably due to elastic scattering by the impurity atoms which follows[6] a law

$$1/\tau = \pi N R^2 V, \quad (17)$$

where N is the density of impurity atoms per cc, R the effective radius, and V the electron velocity. At 40°K the indicated cross section R^2 is about 5×10^{-13} cm^2. This is attributed[4,7] to an exchange interaction between valleys although no values are given.

As the temperature increases some of the arsenic atoms become ionized and a component is found which varies inversely as the electron density. This component, which has a strong temperature variation, is attributed[4,7] to a capture of electrons in bound donor states followed by re-emission in another valley. As will be shown in the next section, this process has an activation energy and hence the time between capture and re-emission decreases as the temperature increases.

For densities above 10^{18}, the data of Figs. 1 and 4 show that there is no activation energy for the process and the data of Fig. 3 show that the relaxation time tends to reach a constant value independent of the doping level. All of the impurity atoms will be ionized since Fermi degeneracy[8] occurs in germanium at an impurity concentration between 10^{17} and 10^{18} impurity atoms per cc. The impurities for degeneracy[9] are in the order of 10^{17} for antimony and 5×10^{17} for arsenic doping. Hence, bound donor states do not exist for these dopings.

In the neighborhood of an impurity atom the four degenerate energy minima are split into a singlet and triplet states by the valley-orbit splitting. The separations caused by antimony, phosphorus, and arsenic are 0.57×10^{-3}, 2.9×10^{-3}, and 4.15×10^{-3} eV, respectively. One mechanism proposed for the interchange of electrons between valleys is a "giant trapping"[10] of electrons which involves a change in momentum between valleys by means of an interaction between the triplet and singlet states. If the electron is placed in the $1s$ state and simultaneously in a known valley, it will not be in a stationary state, but in a linear combination. At a later time, depending on the relative phases of the singlet and triplet state, the electron will be in a different valley. Weinreich *et al.*[4] have estimated that the relaxation time for such a valley change should be

$$\tau \geq (16/3)(\hbar/\delta E) = 8.4\times 10^{-13}\ \text{sec(arsenic)} = 6.14\times 10^{-12}\ \text{(Sb)}. \quad (18)$$

These values are too large for arsenic-doped germanium and too small for antimony-doped germanium.

Another derivation[11] indicates that the relaxation time should be in the ratio of the squares of the singlet-triplet separation and this is in better agreement with the experimental values. However, since this is essentially an elastic scattering process, the independence of the scattering time versus impurity density is still anomalous. The same is true for the total scattering time of Eq. (17). This time varies from 6 to 2×10^{-14} sec for the doping ranges from 10^{18} to 3×10^{19} impurity atoms per cc. The ratios of the intervalley to total scattering times are about 10 for arsenic and about 1000 for antimony.

III. EFFECT OF DOPING SILICON WITH p-TYPE MATERIALS

A. Experimental Results

Measurements have also been made of the effect of doping silicon with the p-type materials boron and gallium. The first measurements[3] were made for 2.5×10^{18} boron atoms per cc. Measurements were made for longitudinal waves along the ⟨110⟩ and ⟨100⟩ directions and shear waves along ⟨110⟩ with polarizations along ⟨001⟩—which involves the shear modulus c_{44}—and with polarization along ⟨1$\bar{1}$0⟩ which involves the $(c_{11}-c_{12})/2$ elastic modulus. As shown by Fig. 8(a), curve A, the attenuation for shear waves along ⟨100⟩ increases very markedly at low temperatures and becomes so high below 6°K and for a 475 Mc/sec frequency,

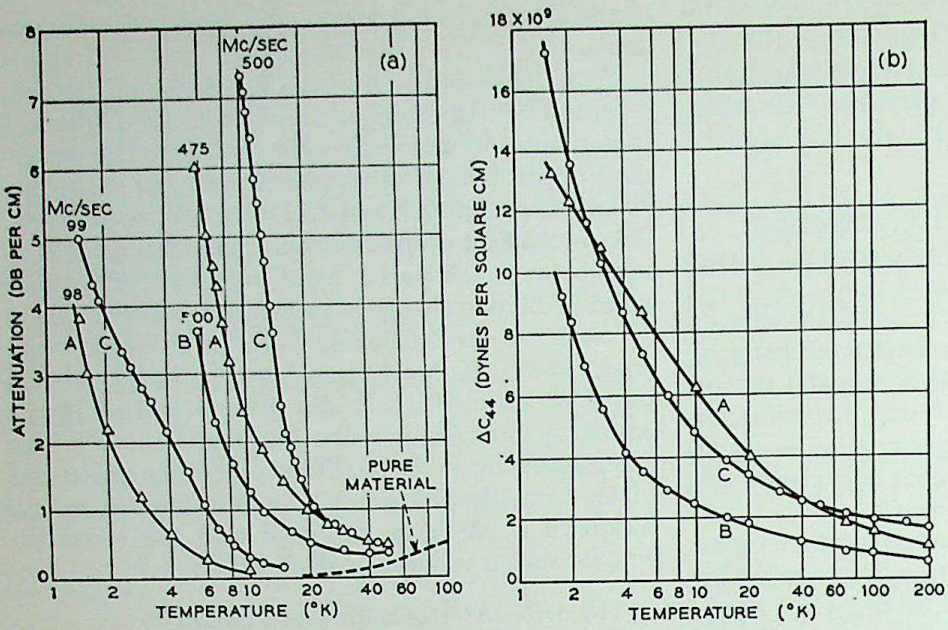

FIG. 8. (a) Measured attenuation as a function of temperature for A (2.5×10^{18} boron atoms per cc), B (5×10^{17} boron atoms per cc), C (1.5×10^{18} gallium atoms per cc). (b) Measured changes in the c_{44} elastic constants for the same conditions.

that it could not be measured. The frequency was shifted to 98 Mc/sec and the curve was measured from 1.5 to 15°K. In the overlap region, it is seen that the attenuation is square law as indicated by the relaxation Eq. (2).

Velocity measurements for pure and doped silicon were made by the pulse overlap method,[12] which is capable of good precision. Figure 9 shows the measured velocities for pure and doped samples. From these measurements, the change in modulus Δc_{44} can be determined and it is shown plotted by Fig. 8(b), curve A. The relaxation time from the measured attenuation and modulus differences can be calculated by using Eq. (2). The result is shown plotted on Fig. 10, curve A. For temperatures above 8°K the relaxation time satisfies the equation

$$\tau_1 = 1.3\times10^{-12}e^{13/T}, \qquad (19)$$

indicating an activation energy δE of 0.00113 eV. At lower temperatures the curve bends off and approaches

another straight line having an equation

$$\tau_1' = 1.13\times10^{-11}e^{2.95/T};\quad \delta E = 2.56\times10^{-4}\text{ eV}. \quad (20)$$

Detailed measurements were also made for longitudinal waves along the ⟨100⟩ direction with the results shown by Fig. 11. Here an increase in both attenuation and modulus change occurred as the temperature decreased, but their ratio, which determines the relaxation time, is approximately constant with a value $\tau_2 = 4.2\times10^{-12}$ sec.

The shear wave measurements along ⟨110⟩ with polarization along ⟨1$\bar{1}$0⟩ and the longitudinal measurements along ⟨110⟩ confirmed the expected relation that

$$\Delta c_{12} = -\Delta c_{11}/2. \quad (21)$$

The attenuations for these modes satisfy, respectively, the equations

$$A = \frac{\frac{3}{4}\Delta c_{11}\omega^2\tau_2}{2\rho V_s^3};\quad A = \frac{[(\Delta c_{11}/4)\tau_2 + \Delta c_{44}\tau_1]\omega^2}{2\rho V_l^3}. \quad (22)$$

The relaxation time τ_1 for shear waves along ⟨100⟩ has an activation energy term. In order to determine the origin of this term, measurements were made for a range of boron doping from 5×10^{17} to 3×10^{19} atoms per cc. Figures 8(a) and (b), curves B, show the results for shear waves along ⟨100⟩ measured at 500 Mc/sec for the doping of 5×10^{17}. The relaxation time is shown plotted on Fig. 10, with an indicated activation energy of 0.00117 eV or nearly the same as for the higher doping. The curves of Figs. 12 and 13 show the attenuation and velocities for the dopings of 10^{19} and 3×10^{19} boron atoms per cc. The lower value still has an increase in attenuation as the temperature is lowered, but the higher doping value has an added attenuation which is independent of the temperature with no activation energy. The doping of 10^{19} satisfies the relaxation equation

$$\tau_1 = 2.1\times10^{-13}e^{4/T}, \quad (23)$$

while the relaxation time for the doping of 3×10^{19} is 10^{-13} seconds independent of the temperature.

In order to complete the interpretation, a measurement was made for a doping of 1.5×10^{18} gallium atoms per cc in a ⟨100⟩ silicon crystal. Measurements were made for shear waves in this direction at a frequency of 500 Mc/sec. The results for the attenuation and

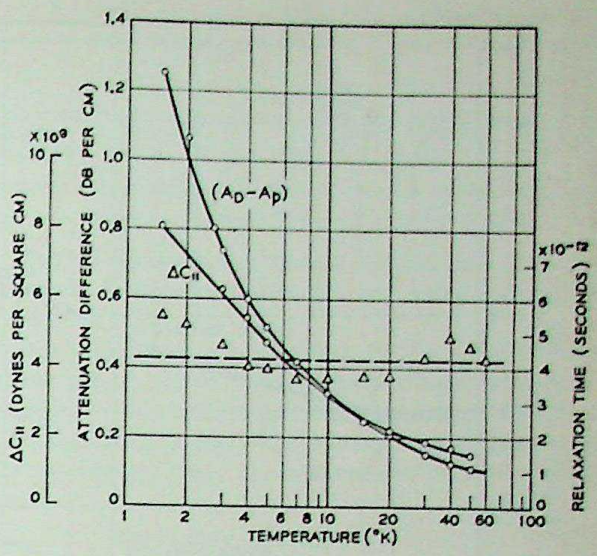

FIG. 11. Attenuation and modulus change Δc_{11} for longitudinal waves along the ⟨100⟩ axis. Dashed line shows an average relaxation time.

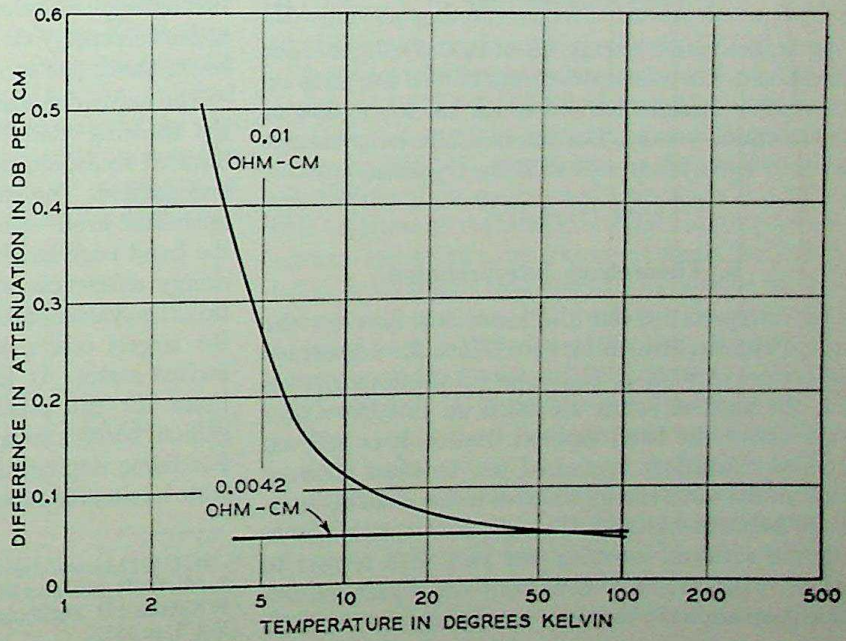

FIG. 12. Attenuation measured at 500 Mc/sec for boron-doped silicon as a function of the temperature. The curve labeled 0.01 Ω-cm is for a doping of 10^{19} boron atoms per cc while the one labelled 0.0042 is for 3×10^{19} boron atoms per cc.

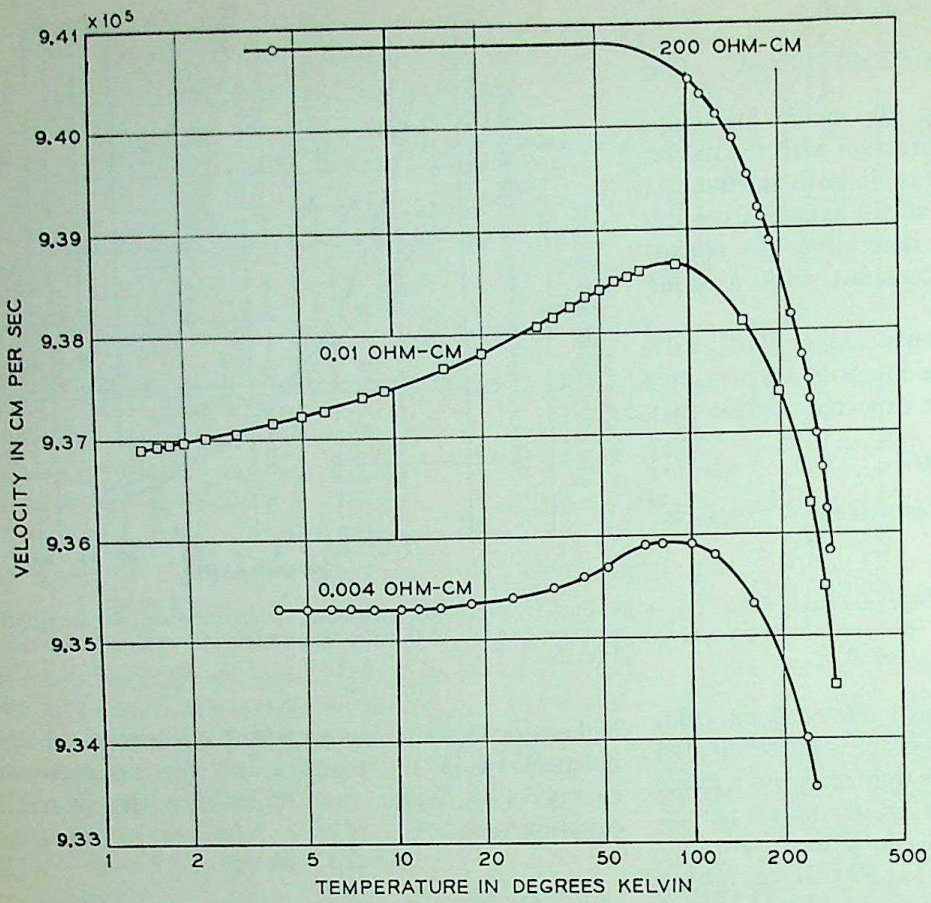

FIG. 13. Measured velocities for pure and doped silicon samples as described in Fig. 12.

modulus changes are shown by Figs. 8(a) and (b) by the curve labeled C. In the lower temperature range, measurements of the attenuation were made down to 1.5°K for a frequency of 99 Mc/sec. A plot of the relaxation time is shown by Fig. 10, curve C. The initial part of the relaxation time satisfies the equation

$$\tau_1 = 5\times 10^{-13} e^{40/T} \text{ sec}, \qquad (24)$$

giving an activation energy δE of 0.0035 eV. At lower temperatures the relation becomes curved but ends up with another straight line τ_1' which has a very low or zero activation energy. For intermediate temperatures the points agree fairly well with the equation

$$1/\tau = 1/\tau_1 + 1/\tau_1'. \qquad (25)$$

B. Theoretical Interpretation

The interpretation for the relaxation time for the p region appears straightforward. Since the degeneracy temperature is 50°K or higher for all the doping levels used, the valence bands are filled up to 0.004 eV or higher above the band minima. Hence, it is believed that the relaxations measured are between different points on the same energy surfaces rather than an interchange between surfaces. The effect of a strain is to warp the surfaces, lowering one part with respect to another. This causes a flow from the higher energy-momentum region to the lower energy regions. The holes change momentum directions near the impurity atoms by being captured in one of the excited states. This can happen with only a small number of collisions with phonons since the energies of the holes and the excited states are not very different. To leave the orbit, however, requires thermal energy to overcome the binding energy of the state, and this energy represent the activation energy measured. As the doping increases the activation energy decreases, and for a doping of 3×10^{19} boron atoms per cc it disappears entirely.

The activation energies for the relaxation time τ_1 of the shearing mode are in good agreement with the infrared measurements for the largest orbits in boron and gallium. The energy levels of the ground state—innermost orbit—and the excited states in relation to the band edge have been discussed by Kohn.[13] These energy differences were measured by infrared absorption. The values of 0.0012 and 0.0035 eV agree well with the largest orbits, lowest energies, for the measured excited states. At lower temperatures, the relaxation times for the primary modes for both boron and gallium become so large that other processes take over. For boron doping, the next process is another excited state having the constants of Eq. (20), while for gallium

[13] H. J. Hrostowski and R. H. Kaiser, Bull. Am. Phys. Soc. [2] 2, 66 (1957); see also W. Kohn in *Solid State Physics*, edited by F. Seitz and D. Turnbull (Academic Press, Inc., New York, 1957), Vol. 5, p. 257.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

doping it appears to be a process without activation energy such as elastic scattering by the impurity atoms.

Another verification that the processes observed are the excited states comes from the high-temperature values of τ_1 and τ_1' for both boron and gallium doping. The frequency with which an orbit is traversed is given by

$$f=\delta E/h \doteq 2.8\times10^{11} \text{ cycles/sec (boron)}$$
$$\doteq 8.4\times10^{11} \text{ cycles/sec (gallium)} \quad (26)$$

for the first—τ_1—process. The time of a cycle is the inverse of these values and the measured constants of 1.3×10^{-12} sec (boron) and 5×10^{-13} sec (gallium) indicate that the transfer of momentum at high temperatures takes place between points that are about one-third of a complete orbit apart. Since the shearing stress raises or lowers the energy surfaces along ⟨111⟩ directions, the closest equivalent positions are 109° apart or about one-third of a complete cycle. The second process τ_1' of Eq. (20) indicates that the hole traverses two-thirds of a much larger orbit before it transfers its momentum.

As the doping increases, the impurity atoms come so close together that bound orbits are no longer possible. In this region the only process left is the elastic scattering by the ionized impurities which follows the law of Eq. (17). If we use the measured relaxation time of 10^{-13} sec for the impurity doping of 3×10^{19} boron atoms per cc, and calculate the velocity from the equation

$$\tfrac{1}{2}m^*V^2=0.6W_F=\tfrac{3}{10}(\hbar^2/m^*)(3\pi^2N)^{2/3}, \quad (27)$$

one finds for the scattering radius R the value of 8.5×10^{-8} cm. Comparing the relaxation time 10^{-13} with the total relaxation time from the conductivity Eq. (16) it appears that about 1 out of 10 collisions results in a change of position on the surface.

The theoretical situation for the change in moduli due to doping for p-type silicon is far from satisfactory. Three theoretical derivations[1,14,15] have been given for the change in shearing modulus. The first solution[1] assumes spherical energy surfaces, as shown by the dashed lines of Fig. 6, and limits consideration to the heavy hole surface. The second solution[14] takes account of the curvature of the two surfaces. In the degenerate range these solutions reduce to the forms

$$\Delta c_{44_0}=-\frac{(8\pi/3)^{2/3}m^*d^2N^{1/3}}{5\hbar^2}$$
$$=\frac{-0.825m^*d^2N^{1/3}}{\hbar^2} \text{ (Keyes)}, \quad (28)$$

$$\Delta c_{44_0}=(-2.38m^*N^{1/3}d^2/\hbar^2) \text{ (Bir and Tursunov)}. \quad (29)$$

[14] G. L. Bir and A. Tursunov, Fiz. Tverd. Tela 4, 2625 (1962) [English transl.: Soviet Phys.—Solid State 4, 1925 (1963)].

[15] P. Csavinszky and N. G. Einspruch, Phys. Rev. 132, 2434 (1963).

TABLE I. Values of Δc_{44} at 1.5°K for various dopings.

	Boron doping				Gallium doping
Doping	3×10^{19}	10^{19}	2.5×10^{18}	5×10^{17}	1.5×10^{18}
$\Delta c_{44}\times10^{-9}$	17.9	12.4	13.5	10.5	17.2

Table I shows measurements for Δc_{44} at 1.5°K for different dopings for boron and one value for gallium doping.

In the degenerate region from 10^{19} to 3×10^{19} boron atoms per cc, the variation is proportional to the one-third power of the doping level in agreement with Eqs. (29) and (30). Taking m^* as $0.44m_0$ as an average value for the two surfaces, the deformation potential values are

$$d=17.2 \text{ eV (Keyes)}; \quad (30)$$
$$d=10.1 \text{ eV (Bir and Tursunov)}.$$

A third calculation has recently been made[15] which yields values close to the value given by Keyes. Csavinszky and Einspruch[15] have considered the spin-orbit coupled band in addition to the two degenerate bands but have assumed spherical symmetry of the bands. For doping up to 10^{19} boron atoms per cc, the two upper bands are sufficient for the calculation and the result obtained is

$$\Delta c_{44_0}=-\frac{1}{5}\left(\frac{8\pi}{3}\right)^{2/3}\frac{d^2}{\hbar^2}[m_{v_1}N_1^{1/3}+m_{v_2}N_2^{1/3}], \quad (33)$$

where $m_{v_1}=0.49m_0$ is the heavy hole mass and $m_{v_2}=0.16m_0$ is the light hole mass. Since

$$N_1/N_2=(m_{v_1}/m_{v_2})^{3/2}=5.35, \quad (34)$$

$N_1=0.85N_0$ and $N_2=0.15N_0$. Hence, for a doping of 10^{19} boron atoms per cc, the value of $d=15.4$ eV.

However, the larger values measured at the lower dopings at 1.5°K—for which asymptotic values have not been reached—and the large variation with temperature shown by Fig. 8(b) cast doubt on the validity of these calculations. It is conjectured that there is a temperature variation of the position of the holes on the energy surfaces and at low temperatures it seems likely that the heavy holes collect near the ⟨111⟩ positions while light holes collect near the ⟨100⟩ positions. As seen from Fig. 6, lower part, which shows the cross sections of the energy surfaces a constant distance below the origin, the heavy-hole ⟨111⟩ positions and the light-hole ⟨100⟩ positions are farthest from the origin and require electrons of higher momentum to reach the surface. Hence, if momentum is equalized in all directions, the surfaces near the origin should be filled up to a level higher than those far away and hence the ⟨111⟩ positions for the heavy-hole surface and the ⟨100⟩ positions for the light-hole surface should have the lower energies. At very

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

low temperatures, holes tend to congregate in these directions.

If this conjecture is correct, the change in modulus for the heavy-hole surface should follow that for germanium, as given by Eq. (12), while that for the light-hole surface should follow Eq. (8) with kT replaced by (10), for the low temperatures, giving

$$\Delta c_{11_0} = -\frac{16}{3}\left(\frac{\pi}{3}\right)^{2/3}\frac{m^* N^{1/3}\Phi^2}{h^2}. \quad (31)$$

If we take an average value of 15 eV for the shear deformation potential d, the indicated change in modulus from Eq. (12)—using $m^*=0.49m_0$ and $N=0.85N_0$, i.e., 2.12×10^{18} heavy holes—is 26.5×10^9 dyn/cm^2, which is not out of line with the values of Fig. 8(b) extrapolated to lower temperatures. For higher doping levels this effect disappears since the momentum differences for the various positions become smaller.

Another piece of evidence that the light holes congregate along ⟨100⟩ positions at low temperatures is furnished by the nearly constant relaxation time of Fig. 11 for longitudinal waves propagated along the ⟨100⟩ direction. The data of Fig. 12 show that p-silicon with boron becomes degenerate for a doping of 3×10^{19} atoms per cc. This is taken to mean that the impurities are near enough together to prevent any excited state orbits around the boron atoms. The smallest orbits will be executed by the heavy holes and hence they will reach degeneracy at a higher doping level than the light hole surface. With a mass ratio of 0.49 to 0.16 or 3.06, the radius will be this factor larger for the light-hole surface. Hence, this surface should become degenerate for a doping of

$$3\times10^{19}/(3.06)^3 \doteq 10^{18} \text{ boron atoms per cc.} \quad (32)$$

Therefore, the constant relaxation time of 4.2×10^{-12} sec for a sample doped with 2.5×10^{18} boron atoms per cc is a confirmation that, at low temperatures, a longitudinal stress along the ⟨100⟩ axis actuates mostly light holes.

If the relaxation time is due to scattering of light holes by impurities, calculations indicate that the scattering radius is about 5×10^{-8} cm, in good agreement with the value obtained for the degenerate heavy-hole surface.

Distribution Functions for the Number of Distinct Sites Visited in a Random Walk on Cubic Lattices: Relation to Defect Annealing*

J. R. Beeler, Jr.
Nuclear Materials and Propulsion Operation, General Electric Company, Cincinnati, Ohio

(Received 17 January 1964)

Distribution functions for the number of distinct sites $S(n)$ visited by a point defect executing a symmetric random walk of n jumps on two- and three-dimensional lattices were computed using the Monte Carlo method. The square planar, simple cubic, bcc, and fcc lattices were treated. In three dimensions, the normal distribution appears to describe $S(n)$ for $n>10^4$ jumps and at 10^4 jumps the derivative $d\bar{S}(n)/dn$ of the average number, $\bar{S}(n)$, of distinct sites is within 0.5% of the value given by Vineyard's exact asymptotic solution. The defect annealing rate was computed using the $S(n)$ distribution in a simple example and this result compared with an analog Monte Carlo solution. The comparison indicated that fluctuations in the initial defect concentration must be considered in computing the initial annealing rate and the mobile defect concentration as a function of time. After 500 jumps the annealing rate, but not the concentration, can be closely approximated without accounting for fluctuations in the initial concentration.

1. INTRODUCTION

IN a monatomic crystal, the migration of a defect, such as a vacancy or an interstitial atom, proceeds as a symmetric random walk[1] on the crystal lattice. The rate at which mobile defects are annihilated or trapped at point sinks is proportional to the rate at which they encounter fresh sites which have not been visited previously. Damask and Dienes[2] will treat the physical side of this process in a forthcoming book. On the basis of a Monte Carlo study, Beeler and Delaney[3] concluded that the average number of distinct sites, $\bar{S}(n)$, visited by a point defect in either a symmetric or an asymmetric random walk of n jumps was of the form,

$$\bar{S}(n)=An^k \quad (1)$$

* Work supported by the U. S. Atomic Energy Commission.

[1] In this discussion a symmetric random walk is one wherein the jump probabilities for each possible jump direction are equal and constant. The vacancy random walk in an alloy is in general asymmetric because of its ordering energy, i.e., the jump probabilities for each possible direction are not equal and also depend upon the position of the vacancy.

for a two-dimensional lattice, and of the form

$$\bar{S}(n)=B+Cn \tag{2}$$

for a three-dimensional lattice, where A, B, C, and k are constants for a given lattice structure. Their computations pertained to vacancy migration in a binary alloy and describe the relation between $\bar{S}(n)$ and the rate of ordering (disordering) for $n\leq 10^4$ jumps. Migration on the square planar simple cubic, bcc, and fcc lattices was investigated. Vineyard[4] subsequently proved that the asymptotic form of $\bar{S}(n)$ for a three-dimensional symmetric random walk is

$$\lim_{n\to\infty}\bar{S}(n)=Cn. \tag{3}$$

The Monte Carlo results of Beeler and Delaney for $d\bar{S}(n)/dn=C$ on the interval $10^3\leq n\leq 10^4$, in the case of zero ordering energy, agree closely with the exact asymptotic results given by Vineyard's analysis, the Monte Carlo results being about 1% larger than the exact asymptotic values. Vineyard also showed that

$$\bar{S}(n)=(8n)^{1/2}/\pi \tag{4}$$

in one dimension.

In this communication we describe the distribution function $F(S;n)$ for $S(n)$, as given by Monte Carlo calculations, for the square planar (sp), simple cubic (sc), bcc and fcc lattices. $F(S;n)$ is the probability that a defect visits S or less distinct lattice sites in n jumps. Direct application of these distributions to defect annealing calculations is illustrated in a simple, yet physically significant numerical example wherein attention is called to the effect of fluctuations in the initial defect concentration upon the initial defect annealing rate. This effect first came to our attention in a comparison of the annealing rate predicted by $F(S;n)$, on the basis of the macroscopic (average) defect concentration, with that obtained directly in a separate analog Monte Carlo annealing calculation wherein fluctuation effects were automatically accounted for. The presence of fluctuations significantly increased the initial annealing rate relative to that obtained on the basis of the macroscopic concentration.

On the interval $1000<n<5000$, $F(S;n)$ appears to start an approach to the normal distribution. A χ^2 analysis indicated that $F(S;n)$ is very probably normal for $n>10^4$ in three-dimensional lattices, but gives no information on the convergence to a normal distribution in two dimensions. Up to $n=10^4$ the density function $f(S;n)=dF(S;n)/dS$ is definitely skewed to the right. This feature enhances the increased initial annealing rate contribution arising from concentration fluctuations. The indicated increase is possibly large enough to be detectable in high-temperature quenching experiments and should exert a dominant influence during the initial stage of defect annihilation and clustering in irradiated specimens.

[4] G. H. Vineyard, J. Math. Phys. 4, 1191 (1963).

2. COMPUTATIONAL METHOD

Distribution functions $F(S;n)$ and density functions $f(S;n)$ for each lattice were estimated by running 1000 independent random walk histories of 10^4 jumps each using an IBM-7090 computer. The mean ($\bar{S}$), mode (S^*), median (S_m) and standard deviation (σ) were computed at 10-jump intervals up to 100 jumps, 100-jump intervals up to 10^3 jumps, and 1000-jump intervals up to 10^4 jumps. In each instance an expected tendency toward the normal distribution was monitored by performing an χ^2 test for 21 deg of freedom[5] and computing the coefficients of skewness (γ_1) and excess (γ_2).[6] $\bar{S}(n)$ and σ were computed using the first 500 histories, the second 500 histories and all 1000 histories. The differences between the results given by each sample set were found to be negligible and on this basis we decided that the 1000-history sample size was sufficiently large to form a basis for annealing calculations. In this regard, it is interesting to note that the difference between the present $\bar{S}$ results, based on a least-squares fit to data from 1000 histories, and the original calculations of Beeler and Delaney, based on a least-squares fit to the data from only 10 histories, is less than 0.5%.

3. DISTRIBUTION FUNCTION RESULTS

Selected plots of $F(S;n)$ for $n=10$, 20, 50, 100, 1000, and 10 000 jumps are given in Figs. 1–4 in terms of the ratio $S(n)/n$. This mode of presentation makes it easier to see how $F(S;n)$ changes as n increases, than if the curves were plotted versus $S(n)$. Let $S_1(n)$ be the largest S value such that $F(S;n)=0$ and $S_2(n)$ the smallest S wave such that $F(S;n)=1$. The range of the distribution is defined as $\Delta S(n)=S_2(n)-S_1(n)$. In all instances $\Delta S(n)/n$, $\bar{S}(n)/n$, $S_m(n)/n$, and $S^*(n)/n$ decrease monotonically as n increases. $S_1(n)/n$ remains more or less constant in the two-dimensional case, the diminution in $\Delta S/n$ arising essentially from a monotonic decrease in $S_2(n)/n$. In the three-dimensional

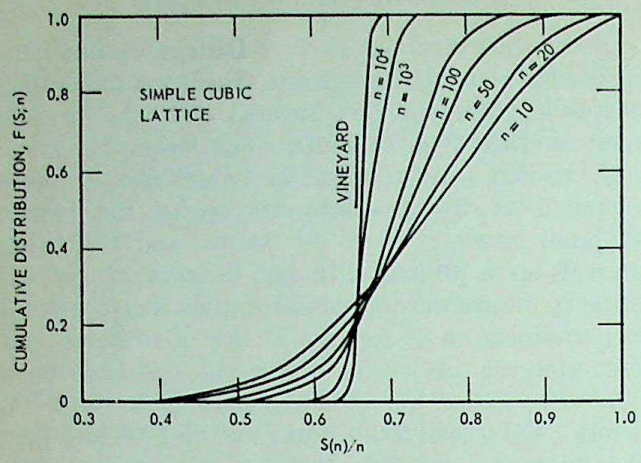

FIG. 2. Distribution function for simple cubic lattice. Vertical tick in Figs. 2–4 indicates Vineyard's asymptotic solution for $S(n)/n$.

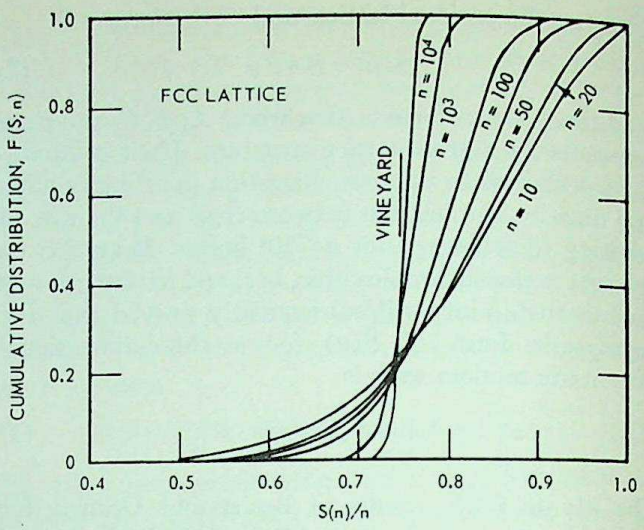

FIG. 4. Distribution function for fcc lattice.

lattices, however, both $S_1(n)/n$ and $S_2(n)/n$ change as n increases, $S_1(n)/n$ tending toward $\bar{S}(n)/n$ from below and $S_2(n)/n$ approaching it from above. The vertical tick defines the lower limit of $\bar{S}(n)/n$ given by Vineyard's calculations for $n\rightarrow\infty$. For all practical purposes, one can consider this asymptotic behavior to be attained at $n=10^4$ jumps. Table I compares the 1000-history Monte Carlo results for $d\bar{S}/dn$ at $n=10^4$ with Vineyard's evaluations for the asymptotic case.

All distributions were skewed negatively for $n\leq 10^4$ as shown by the coefficient of skewness listed in Table II. This skewness is evident from inspection of the curves in Figs. 1–4 for $n\leq 50$. By definition,[6]

$$\gamma_1=\mu_3/\sigma^3, \tag{5}$$

where μ_n is the nth moment of the distribution about the mean. A negative γ_1 means that the tail of the distribution for $S<\bar{S}$ is longer than the forward tail for $S>\bar{S}$. If $\gamma_1>0$ the opposite is true and $\gamma_1=0$ for the normal distribution. A measure of how the shape of the density function $f(S;n)$, in the vicinity of the mode, differs from that for the normal density function is given by the coefficient of excess[6]

$$\gamma_2=\mu_4/\sigma^4 \tag{6}$$

listed in Table III. If $\gamma_2<0$, $f(S;n)$ is more flat in the vicinity of the mode than the normal density function and more peaked if $\gamma_2>0$. In this regard $\gamma_2<0$ for the sp and sc lattices but $\gamma_2>0$ for bcc and fcc lattices. This suggests that γ_1 is independent of the lattice coordination number z but that $\gamma_2<0$ for $z\leq z_0$ where $6\leq z_0<8$.

A χ^2 test was used to judge the over-all fit of a normal distribution to the Monte Carlo data. The averages of the χ^2 values obtained using 21 deg of freedom (23 intervals) are given in Table IV over 500–900 jumps, 1000–5000 jumps, and 5000–10 000 jumps for each lattice. A composite average for the bcc and fcc distributions appears in the last column. According to Evans,[5] for example, given 21 deg of freedom, χ^2 in the range $13\leq\chi^2\leq 30$ indicates that the data at hand is very probably described by the assumed distribution, i.e., the normal distribution in this case. On the other hand, either $\chi^2<10$ or $\chi^2>36$ indicates that it is very unlikely that the data represents a randomly drawn set of values from the assumed distribution. Excepting the sp lattice, χ^2 decreased with increasing n for $n>500$. All χ^2 values were in the plausible fit range $10\leq\chi^2\leq 36$ for $n>1000$. Both the distribution for the sc lattice and that for the bcc lattice exhibited χ^2 values within the

very probable range for $n \geq 6000$ jumps. Because γ_1 and γ_2 for the bcc and fcc distribution behave similarly above $n=1000$ we feel that a composite average of χ^2 for these two lattices may be meaningful. This composite average is listed in the right-hand column. The χ^2 test indicates: (1) $F(S;n)$ is not well approximated by the normal distribution for $n<1000$; (2) the normal distribution is a good approximation to $F(S;n)$ for $10^3<n<10^4$; (3) $F(S;n)$ is very probably normal for $n>10^4$ in the three-dimensional case.

A least-squares analysis gives the following results for $\bar{S}(n)$ and $\sigma(n)$ on the interval $10^2 \leq n \leq 10^4$:

$$\bar{S}(n)=B+Cn, \tag{7}$$

$$\sigma(n)=An^k. \tag{8}$$

Values for the constants A, B, C, and k appear in Table V.

Carlo study on defect annealing in cubic crystallites containing up to 2×10^6 lattice sites. In order to obtain even approximate agreement between the initial annealing rate given by the analog Monte Carlo[7] calculations and that computed using $F(S;n)$, it was necessary to consider the effect of fluctuations in the initial defect concentration within the crystallite. In this section the number of mobile defects remaining after an average of n jumps per defect is computed analytically in two ways. In the first instance the defect encounter probability is computed using $F(S;n)$ and the average concentration over the crystallite; in the second, it is computed using $F(S;n)$ and the average concentrations in each of N_c noninteracting crystallite subvolumes populated according to the random distribution law for M_0 defects in N_c boxes of equal volume. The two expressions are then applied in a numerical example for $M_0=100$ initially mobile defects in a fcc crystallite containing 5×10^5 sites and the results compared with those obtained in the Monte Carlo solution for this system.

A. Average Concentration Approach

Let there exist M_0 mobile defects randomly distributed on Σ lattice sites and M_c defects contained in randomly distributed stable, immobile defect clusters at time $t=0$. Assume that the sole mobile defect removal process is association with other defects at contact. A pair of defects will be taken as stable and immobile in this example. Further, assume that the association probability ϵ at contact is the same when one member of the contact pair is a cluster member as when both defects were mobile just before contact. M_n will denote the number of mobile defects remaining after n jumps per defect. Let $\alpha=1/\Sigma$. The probability

that a mobile defect will encounter a cluster member on the nth jump is

$$\alpha[M_c+M_0-M_{n-1}]p^*(S;n-1)f(S;n-1), \quad (9)$$

where $p^*(S;n-1)$ is the conditional probability for a defect visiting $(S+1)$ distinct sites on the $(n+1)$th jump provided it had visited exactly S distinct sites in n jumps. The probability that a mobile defect will contact another mobile defect is

$$\alpha[M_{n-1}-1]p^*(S;n-1)f(S;n-1). \quad (10)$$

Contact with a cluster leads to the removal of one mobile defect but contact between two mobile defect leads to a depletion of two mobile defects; hence, the difference equation for M_n is

$$M_n=M_{n-1}-\alpha\epsilon[M_c+M_0-M_{n-1}]\times\sum_{S=S_1(n-1)}^{S=S_2(n-1)}[M_{n-1}f(S;n-1)]p^*(S;n-1)-2\alpha\epsilon[M_{n-1}-1]\times\sum_{S=S_1(n-1)}^{S=S_2(n-1)}[M_{n-1}f(S;n-1)p^*(S;n-1)]. \quad (11)$$

By the definition of $f(S;n)$ the summation reduces to $M_{n-1}\langle p^*(n-1)\rangle$. Equation (11) leads to the differential approximation

$$dM/dn\cong-\alpha\epsilon M\langle p^*(n)\rangle[M+(M_c+M_0-2)]. \quad (12)$$

Integration gives

$$\ln[M/(M+M_c+M_0-2)]_0^n=-\alpha\epsilon(M_c+M_0-2)\int_0^n\langle p^*(n)\rangle dn. \quad (13)$$

Collecting terms, one obtains

$$M(n)=M_0[M_c+M_0-2]/\{[2(M_0-1)+M_c]\times\exp[\alpha\epsilon(M_c+M_0-2)P_n]-M_0\}, \quad (14)$$

where $P_n=\int\langle p^*(n)\rangle dn$. Because $\langle p^*(n)\rangle$ is closely approximated by $d\bar{S}(n)/dn$, we will use

$$P_n=\int_0^n[d\bar{S}/dn]dn=\bar{S}(n). \quad (15)$$

$M(n)$ was evaluated for the particular case $\alpha=2\times10^{-6}$, $M_0=100$, $M_c=0$, and $\epsilon=1$. The results are discussed in Sec. 4C.

B. Consideration of Fluctuations

In the estimation of $M(n)$ outlined above one considered (M_c+M_0) defects in a cell of Σ sites and computed the contact probability from the average concentration

$$\bar{C}=(M_c+M_0)/\Sigma \quad (16)$$

TABLE VI. Probability $g(k)$ to find k defects in a subvolume of 5000 sites when the macroscopic defect concentration is $\bar{C}=2\times10^{-4}$ defects per site. $\bar{C}_k$ is the associated cell average concentration.

k	$g(k)$	$\bar{C}_k\times10^4$
0	0.366032	0
1	0.369730	2
2	0.184865	4
3	0.0609992	6
4	0.0149417	8
5	0.00289778	10
6	0.0046345	12

defects per site. The effect of fluctuations in the initial defect concentration upon the annealing rate can be estimated by introducing the density function $g(k)$ for finding exactly k mobile defects $(k=1,2,\cdots,M_0)$ in a given subvolume of a collection of N_c equal subvolumes with atomic-scale linear dimensions. Let $\tilde{M}(n)$ be the number of mobile defects remaining after n jumps, computed on the basis of $\{g(k)\}$ rather than $\bar{C}$, and set $M_c=0$. $\tilde{M}(n)$ then is

$$\tilde{M}(n)=\sum_{k=1}^{M0}M_k(n). \quad (17)$$

The quantity $M_n(k)$ is obtained by substituting $M_{0k}=kg(k)N_c$ for M_0, and $\alpha_k=1/g(k)\Sigma$ for α, in Eq. (14). The result is

$$M_k(n)=M_{0k}(M_{0k}-2)/\{2(M_{0k}-1)\times\exp[\alpha_k\epsilon(M_{0k}-2)P_n]-M_{0k}\}. \quad (18)$$

$\tilde{M}(n)$ was evaluated for the particular case $\alpha=2\times10^{-6}$, $M_0=N_c=100$ and $\epsilon=1$, using[8]

$$g(k)=M_0!(N_c-1)^{M_0-k}/k!(M_0-k)!N_c^{M_0}. \quad (19)$$

Values of $g(k)$ for $k\leq6$ are given in Table VI along with the associated subvolume concentrations. The average value $\langle k\rangle=1$ corresponds to an average concentration of 2×10^{-4} defects per site over the entire crystallite, the concentration used in computing $M(n)$.

C. Comparison with Monte Carlo Solution

In Fig. 5, $M(n)$, $\tilde{M}(n)$ and Monte Carlo solution, $M_{mc}(n)$, are compared for $\alpha=2\times10^{-6}$, $M_0=N_c=100$, and $\epsilon=1$ for $n\leq1000$. We will assume that M_{mc} is a physically more realistic solution than either M or $\tilde{M}$ because one would expect that it better describes the association of initially closely spaced defects. It will be used as the reference in all discussion. The curves become nearly parallel at $n=500$, and although it is not shown in the figure, they remained nearly parallel up to $n=2000$, the point at which the Monte Carlo runs were terminated. It appears, therefore, that dM/dn is

[8] W. Feller, *An Introduction to Probability Theory and Its Applications* (John Wiley & Sons, Inc., New York, 1957), 2nd ed., p. 34.

Digitized by Arya Samaj Foundation Chennai and eGangotri

a good approximation to the true annealing rate for $n>500$ even though M itself is too large. Rapid association of defects, initially closely spaced, accounts for the more rapid falloff in M_{mc} for $n<500$ relative to that exhibited by M and $\tilde{M}$. The Monte Carlo method enables one to easily describe the removal of these initially close defects during the early annealing stage, a process only crudely described by $\tilde{M}$. It would seem that a rigorous analytical description of fluctuation effects in the association of randomly walking defects on a lattice would be somewhat complicated.

If one accepts M_{mc} as being more realistic than either M or $\tilde{M}$, our results indicate that the use of M in interpreting defect removal data would cause one to overestimate the number of jumps per defect required to attain a given removal fraction.[9] Table VII lists the number of jumps $n(M)$ and $n(M_{mc})$ given by M and M_{mc}, respectively, required to remove a given fraction of mobile defects. Extrapolation of the straight line log-log plot of $n(M)/n(M_{mc})$ versus the removal fraction, gave a limiting value of ~ 1.1 for this ratio. In a strict sense, the ratios listed in Table VII should be regarded as lower bounds, especially when they are associated with $n>1000$. Although each defect was initially contained within a cube of 5×10^5 sites, in the Monte Carlo calculations, some defects migrated out of the cube into a defect-free environment during the annealing process. These escaping defects served to increase Σ a maximum of 2.4% at $n=1000$, i.e., a maximum of 1.2×10^4 sites outside the 5×10^5 site cube were visited. This caused dM_{mc}/dn to be slightly smaller than it would have been had all defects remained inside the 5×10^5 site cell. At $n=2000\Sigma$ was increased a maximum of 3.5% by escaping defects.

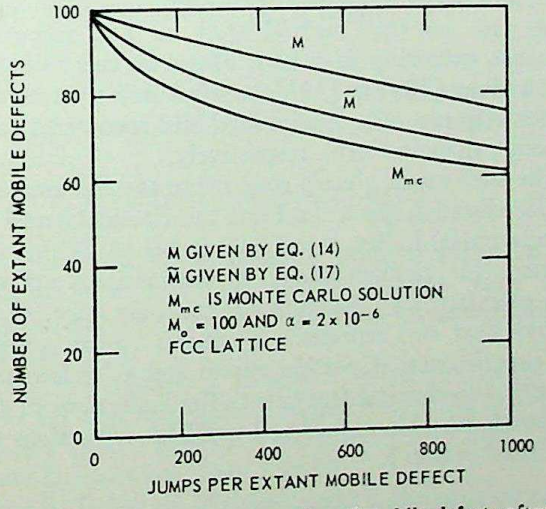

FIG. 5. Comparison of extant number of mobile defects after n jumps as given by M, $\tilde{M}$, and M_{mc} for a fcc lattice.

[9] After completion of this article, experimental evidence supporting this conclusion was found in a paper by F. Dworschak, K. Herschbach, and J. S. Koehler, Phys. Rev. 133, A293 (1964).

TABLE VII. Comparison of the number of jumps $n(M)$ and $n(M_{mc})$ per extant mobile defect, given by M and M_{mc}, respectively, required to remove a given fraction of mobile defects when $M_0=100$ and $\alpha=2\times10^{-6}$.

Fraction removed	$n(\tilde{M})$	$n(M_{mc})$	$n(M)/n(M_{mc})$
0.1	340	60	5.7
0.2	770	200	3.8
0.3	1350	520	7.6
0.4	2300	1070	2.2
0.5	3300	2000	1.6
1.0	...	...	~1.1

Twenty-five Monte Carlo runs of 2000 jumps per extant mobile defect were made to obtain M_{mc}. Five independent runs were made for each of five independent, randomly sampled initial defect distributions in a cube of 5×10^5 sites. A χ^2 analysis of the five initial distributions showed that they were consistent with the density function $g(k)$ of Eq. (19).

5. SUMMARY

The calculations described above indicate:

(1) $F(S;n)$ is not well approximated by the normal distribution for $n<5000$ jumps. However, $F(S;n)$ appears to approach the normal distribution on the interval $5000<n<10\,000$ and to be normal for $n>10^4$ in three-dimensional lattices.

(2) Our results give no conclusive evidence that $F(S;n)$ either does or does not approach the normal distribution in two-dimensional lattices.

(3) The use of Vineyard's asymptotic result for $\bar{S}(n)$, and the assumption that $F(S;n)$ is normal [using Table V for $\sigma(n)$] should give a very good approximation to the distribution of $S(n)$ for $n>10^4$.

(4) A computation of the mobile defect concentration and the *initial* annealing rate must account for the effect of fluctuations in the initial defect concentration.[9] Apparently, however, the annealing rate after the initial annealing stage can be well approximated by considering only the average defect concentration.

Microscopic Dielectric Susceptibility of Germanium

W. COCHRAN
Crystallographic Laboratory, Cambridge, England

AND

J. C. PHILLIPS
Department of Physics, University of Chicago, Chicago, Illinois

(Received 6 January 1964)

The microscopic dielectric susceptibility $\epsilon(q)$ is calculated for germanium using the shell model. It is found that except at $q=0$ the longitudinal and transverse susceptibilities differ and are anisotropic. The results agree qualitatively with Penn's isotropic quantum model based on the random-phase approximation. It is suggested that the quantitative differences may in part represent shortcomings of the RPA in treating the stiffness of covalent bonds.

1. CLASSICAL LATTICE VIBRATION MODELS

MANY classical models have been used to discuss the lattice vibrations of insulators. The interest in such models has been greatly enhanced by the availability of experimentally determined phonon dispersion relations for wavelengths comparable to interatomic separations. Through these models, we may hope to determine certain properties of the valence electron polarizability at short wavelengths.

We may distinguish between two kinds of classical atoms: rigid or polarizable. In each case the valence charge may be regarded as either distributed or localized at a point. For the moment we restrict ourselves to the latter case. The local field corrections in the former case are more involved (Sec. 5).

The rigid point atom yields the simplest models, but is inconsistent with the dielectric properties of ionic crystals. For homopolar Ge, on the other hand, it was natural to suppose that this model would work fairly well. Its failure to fit the dispersion curves determined by inelastic neutron scattering[1] except with forces out to fifth neighbors was shown by Herman.[2]

Polarizable valence electrons can be treated within the adiabatic approximation as charged massless shells. In a free atom the shell and core are connected by an isotropic force constant; in a crystal each shell is also linked to near neighbor cores and shells. This shell model takes account of the fact that an atom can be polarized either through Coulomb or short-range interactions. In germanium displacement of an atom produces a dipole moment on it, but the lowest moment on the atom and its near neighbors is a quadrupole moment. In Lax's theory[3] of the lattice dynamics of germanium, this quadrupole moment is taken to be on the displaced atom; when the shell model is used[4] the interaction involves the component dipoles. This method finds some quantum-mechanical justification in the work of Mashkevich and Tolpygo.[5] It is equivalent to using the atomic displacements and shell displacements (or atomic dipole moments) as generalized coordinates, and writing the energy as a general quadratic form in these coordinates. The shell-shell forces appear formally as the (non-Coulomb) interaction energy of induced dipoles; quantum mechanically they represent the energy required to distort the covalent bonds (Sec. 4).

The microscopic dielectric susceptibility tensor $\epsilon(q)$ is defined by

$$[\epsilon(q)-1]/4\pi=\mathbf{P}(q)/\mathbf{E}(\mathbf{q}). \tag{1.1}$$

Here $\mathbf{E}(\mathbf{q})$ is a macroscopic field of wave number $\mathbf{q}$:

$$\mathbf{E}(\mathbf{q})=\mathbf{E}e^{i\mathbf{q}\cdot\mathbf{r}} \tag{1.2}$$

and $\mathbf{P}$ is the dipole moment per unit cell volume v

$$v\mathbf{P}=\textstyle\sum_i \mathbf{p}_i, \tag{1.3}$$

the sum extending over both atoms in the unit cell. For $\mathbf{q}$ along [100] or [111] axes in cubic crystals, the tensor $\epsilon(\mathbf{q})$ has only longitudinal and transverse components, $\epsilon_l(\mathbf{q})$ and $\epsilon_t(\mathbf{q})$, respectively.

The shell model gives a good fit[4] to the experimental lattice vibration spectrum. From this classical model we calculate $\epsilon_t(q)$ in Sec. 2 and $\epsilon_l(q)$ in Sec. 3. Within the Hartree (or random-phase) approximation, one can also calculate $\epsilon(q)$ quantum mechanically (Sec. 4). It follows that $\epsilon(q)$ represents a natural bridge between the experimental dispersion curves and a fundamental quantum-mechanical treatment. The limitations of this approach due to local field and umklapp corrections are discussed in Sec. 5.

2. TRANSVERSE DIELECTRIC SUSCEPTIBILITY

Within the framework of the shell model, this is a purely classical calculation of the microscopic polarization (1.3) produced by the applied field (1.2). We have[6]

$$Y\mathbf{E}=(\mathbf{S}_t+(Y^2/v)\mathbf{C}_t)\mathbf{W}, \tag{2.1}$$

where Y is a constant equal to the charge on a shell. The applied electric field and dipole moments at the two atoms in the unit cell are vector elements of the column matrices $\mathbf{E}$ and $Y\mathbf{W}$. (The elements of $\mathbf{E}$ are therefore equal.) The short-range and Coulomb forces are represented by the 2×2 matrices $\mathbf{S}_t$ and $\mathbf{C}_t$, respectively. Because we are taking $\mathbf{q}$ along a [111] or [100] symmetry direction, and $\mathbf{E}\perp\mathbf{q}$, the matrix elements of $\mathbf{S}_t$ and $\mathbf{C}_t$ are scalar functions of q. For example, for $q\rightarrow0$ all four elements of $\mathbf{C}$ have the value $-\frac{4}{3}\pi$. Different scalar functions enter for $\mathbf{E}\|\mathbf{q}$, so that $\epsilon_t(\mathbf{q})$ calculated here differs from $\epsilon_l(\mathbf{q})$ calculated in the next section.

According to these definitions we can write the polarization (1.3) as

$$v\mathbf{P}=Y\mathbf{W} \tag{2.2}$$

and from (2.1) and (2.2) it follows that

$$\mathbf{P}=((v\mathbf{S}_t/Y^2)+\mathbf{C}_t)^{-1}\mathbf{E}. \tag{2.3}$$

Since for the Ge lattice the off-diagonal matrix elements of $(v\mathbf{S}_t/Y^2+\mathbf{C}_t)$ are complex conjugates, the polarization waves through the two types of atom are not in phase with the applied field $\mathbf{E}$. Because the matrix is Hermitian, one lags as much as the other leads. We may take the sum of the two to define a real microscopic dielectric susceptibility given by

$$\epsilon_{st}(\mathbf{q})=1+4\pi\sum((v\mathbf{S}_t/Y^2)+\mathbf{C}_t)^{-1}, \tag{2.4}$$

where the sum is over all four elements of the matrix.

We can check the correctness of this procedure by evaluating (2.4) at $q=0$. In this limit the shell-shell forces do not affect the polarizability, which depends only on core-shell forces. We find that in terms of the free atom polarizability per unit cell volume β (2.4) reduces to

$$[\epsilon_{st}(0)-1]/[\epsilon_{st}(0)+2]=\tfrac{4}{3}\pi2\beta, \tag{2.5}$$

which is the Clausius-Mossotti formula.[4,7] Thus (2.4) includes local field corrections properly when the valence electrons are idealized as nonoverlapping spherical shells.

Using the values of $\mathbf{C}_t$ and $\mathbf{S}_t$ given previously in Table III and Appendix 4, respectively,[4] one can now evaluate (2.4) along the [100] and [111] axes. The results are shown in Figs. 1 and 2.

A notable feature of these curves is their periodicity, which is not that of the reduced Brillouin zone. The periodicity is a result of the localization of the two valence shells on the atoms rather than merely in the unit cell. We also note that $\epsilon_{st}(q)$ along the [111] direction has a maximum near $\mathbf{q}=K=2\pi a^{-1}$ (111). This may be an umklapp effect (Sec. 5).

[7] The value of β used here is 0.099, which gives $\epsilon(0)=16.0$. It differs slightly from the value of 0.105 used in Ref. 4.

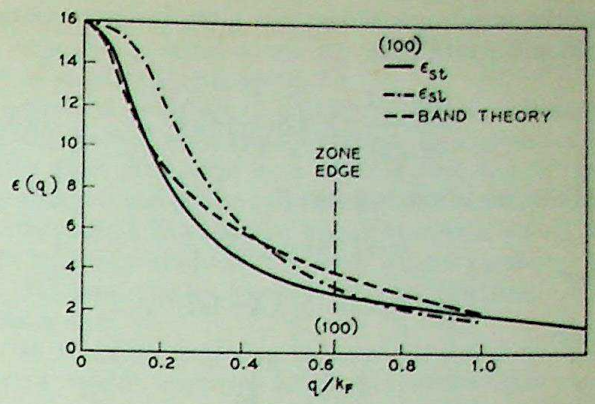

FIG. 1. The longitudinal and transverse shell-model susceptibilities ϵ_{sl} and ϵ_{st}, respectively, as a function of q/k_F along [100] axes, where k_F is the Fermi wave number of a free-electron gas of density equal to the valence electron density in Ge. The curve marked band theory is based on Penn's isotropic band model.

3. LONGITUDINAL SUSCEPTIBILITY

In this case we have

$$Y\mathbf{E}=(\mathbf{S}_l+(Y^2/v)\mathbf{C}_l)\mathbf{W}, \tag{3.1}$$

where as before the elements of the matrix $\mathbf{E}$ are the amplitude of the applied field. The effective field is the sum of the applied, local and macroscopic fields, the two latter being given by $-(Y/v)\mathbf{C}_l\mathbf{W}$. That is, the local and macroscopic fields are not calculated separately by Kellermann's method.[8] At $q\rightarrow0$, for example, the elements of $\mathbf{C}_l$ are all $8\pi/3$. The amplitude of the macroscopic field is -4π times the amplitude of the polarization wave, and this is true for general values of q.[9]

Let P be the amplitude of the polarization wave, E that of the applied field and $E_M=-4\pi P$ that of the macroscopic field. We define $\epsilon_l(q)$ by

$$[\epsilon_l(q)-1]/4\pi=P/(E+E_M),$$

so that

$$[\epsilon_l(q)-1]/4\pi\epsilon_l(q)=P/E. \tag{3.2}$$

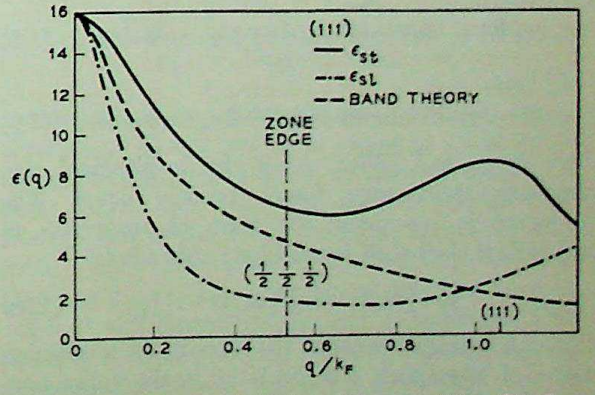

FIG. 2. The same as Fig. 1, but with $\mathbf{q}$ parallel to [111].

By the same argument as was given in the previous section, we then have

$$\frac{\epsilon_l(q)-1}{4\pi\epsilon_l(q)}=\sum\left(\mathbf{S}_l\frac{v}{V^2}+\mathbf{C}_l\right)^{-1}. \tag{3.3}$$

Making use of the fact that if

$$(\epsilon-1)/4\pi=\sum \mathbf{X}^{-1},$$

then

$$(\epsilon-1)/4\pi\epsilon=\sum(\mathbf{X}-4\pi\mathbf{I})^{-1},$$

where

$$\mathbf{I}=\begin{pmatrix}1 & 1\\ 1 & 1\end{pmatrix}.$$

We finally have

$$\epsilon_l(q)=1+4\pi\sum(\mathbf{S}_l(v/V^2)+\mathbf{C}_l-4\pi\mathbf{I})^{-1}. \tag{3.4}$$

The elements of $\mathbf{C}_l$ and of $\mathbf{C}_t$ are related by[8]

$$\mathbf{C}_l+2\mathbf{C}_t=0. \tag{3.5}$$

It is readily verified from (2.4), (3.4), and (3.5), together with the fact that $S_t(0)=S_l(0)$, that $\epsilon_l(0)=\epsilon_t(0)$ (as required by cubic symmetry).

Using the expressions for $\mathbf{S}$ appropriate to longitudinal modes,[4] we have evaluated (3.5) along the [100] and [111] symmetry directions. The results are shown in Figs. 1 and 2, where they are compared with $\epsilon_{st}(q)$. Except at $q=0$ (where shell-shell forces play no role), $\epsilon_{sl}(\mathbf{q})$ is not equal to $\epsilon_{st}(\mathbf{q})$; the difference is small along the [100] direction where $\mathbf{q}$ makes equal angles with all shell-shell force constants, and large along [111] directions where $\mathbf{q}$ is parallel to one of the shell-shell force constants.

The idea that shell-shell forces are chiefly responsible for the difference between $\epsilon_{sl}(\mathbf{q})$ and $\epsilon_{st}(\mathbf{q})$ is borne out by the explicit expressions[4] for $-S/S_0$. These are

[100] trans. $\cos qa/4-i\gamma_s\sin qa/4$, (3.6)

[100] long. $\cos qa/4$, (3.7)

[111] trans.

$$\cos^3\theta+\gamma_s\sin^2\theta\cos\theta+i(\sin^3\theta+\gamma_s\cos^2\theta\sin\theta), \tag{3.8}$$

[111] long.

$$\cos^3\theta-2\gamma_s\sin^2\theta\cos\theta+i(\sin^3\theta-2\gamma_s\cos^2\theta\sin\theta), \tag{3.9}$$

where $\theta=qa/4\sqrt{3}$. With $\gamma_s=0$ the longitudinal and transverse short-range forces become equal. The parameter γ_s measures[4] the ratio of transverse to longitudinal shell-shell forces along cube axes:

$$\gamma_s=[\phi_{xy}(s-s)]/[\phi_{xx}(s-s)], \tag{3.10}$$

where ϕ_{xy} is proportional to the force in the x direction on shell 1 when shell 2 is displaced in the y direction. The value of γ_s used previously[4] was 0.7.

One can express γ_s in terms of the ratio of bond bending to bond stretching forces. One obtains

$$\gamma_s=(k_s-k_B)/(k_s+2k_B). \tag{3.11}$$

Thus, $\gamma_s=0.7$ corresponds to $k_B/k_s=0.13$. This is in quantitative agreement with the ratio of core-core and core-shell bond bending and bond stretching forces required to fit the elastic constants[4] and other theoretical[11] and experimental data[12] in the $q=0$ limit.

4. QUANTUM-MECHANICAL SUSCEPTIBILITY

In treating the real crystal quantum mechanically, we are concerned with fields throughout the unit cell and not merely at the atomic sites. If the external potential is $v(x)$ and the self-consistent total potential is $V(x')$, we have the general relation

$$v(x)=\frac{1}{\Omega}\int\mathfrak{D}(x,x')V(x')dx'. \tag{4.1}$$

Here the integral extends over the volume of the crystal.

The microscopic dielectric susceptibility is $\mathfrak{D}(x,x')$. When (4.1) is Fourier analyzed, taking advantage of periodicity, one obtains[13–15]

$$v(\mathbf{q},\mathbf{K}_p)=\sum_{p'}\mathfrak{D}(\mathbf{q},\mathbf{K}_p,\mathbf{K}_{p'})V(\mathbf{q},\mathbf{K}_{p'}). \tag{4.2}$$

We are interested in the case $\mathbf{K}_p=0$. Then (4.2) may be rewritten

$$v(q,0)=\epsilon(q)V(q)+\sum_{p'}\mathfrak{D}(\mathbf{q},0,K_{p'})V(\mathbf{q},\mathbf{K}_{p'}), \tag{4.3}$$

where the prine on the summation excludes $\mathbf{K}_{p'}=0$.

We have chosen to regard $\epsilon(q)$, the $\mathbf{K}_p=\mathbf{K}_{p'}=0$ component of the operator $\mathfrak{D}$, as the quantum-mechanical analog of $\epsilon_s(q)$. Because of the point nature of the shell model, this choice is not unique. We shall see in Sec. 5 that with this choice the local field corrections to $\epsilon(q)$ associated with a distributed shell charge are small, at least within the first Brillouin zone. We also postpone to Sec. 5 the discussion of the second set of terms on the right of (4.3), which may be called umklapp corrections.

If one knows one-electron wave functions and energies throughout the Brillouin zone, $\epsilon(q)$ may be calculated using the random-phase approximation[16] (RPA). For the static dielectric function we are considering,

$$\epsilon(\mathbf{q})=1+\frac{1}{N}\sum_n\frac{f_{0n}(\mathbf{q})\omega_p^2}{\omega_{n0}^2}. \tag{4.4}$$

The oscillator strengths $f_{0n}(\mathbf{q})$ are, in general, different for longitudinal and transverse polarizations; they are

the same only in the case of an isotropic solid such as a free-electron gas.

An isotropic model of a semiconductor has been studied by Penn.[17] The model contains an energy gap between the valence and conduction bands. Near this gap the Bloch functions are made out of two plane waves, $\mathbf{k}$ and $\mathbf{k}-\mathbf{K}$. The "reciprocal lattice vectors" $\mathbf{K}$ involved are always parallel to $\mathbf{k}$. The umklapp terms are negligible, being of order N^{-1}, where N is the number of atoms in the crystal. The model also makes the longitudinal and transverse dielectric susceptibilities equal. This result may apply more generally than merely to Penn's model. That is, the anisotropy of $\epsilon(\mathbf{q})$ may be a measure of the magnitude of umklapp corrections.

Penn shows that a dielectric susceptibility consistent with his band model is given by the formula

$$\epsilon(q)=1+\left(\frac{\hbar\omega_p}{E_g}\right)^2\frac{1}{[1+(E_F/E_g)(q/k_F)^2]^2}. \quad (4.5)$$

Here E_F and k_F are the Fermi energy and wave number of the valence electrons regarded as a free-electron gas. With $E_F=12$ eV, $E_g=4$ eV, (4.5) reduces to

$$\epsilon(q)=1+\frac{15}{[1+3.0(q/k_F)^2]^2}. \quad (4.6)$$

We have called (4.6) the dielectric function obtained from band theory. It is also plotted in Figs. 1 and 2.

We see that along the [100] axis, where the difference between ϵ_{st} and ϵ_{sl} is small, $\epsilon(q)$ from (4.6) agrees well with ϵ_s. This confirms our identification of $\epsilon(\mathbf{q})$ with the $\mathbf{K}_p=0$ component of $\mathfrak{D}(\mathbf{q},\mathbf{K}_p)$. That the agreement of a classical model with point charges with a quantum-mechanical band model should be so good is at first unexpected. We are less surprised, however, when we remember that the shell model gives a good fit to the neutron data in a rather simple way.

Along the [111] axis, ϵ_{st} differs substantially from ϵ_{sl}, even within the zone. (At the zone edge, $\epsilon_{st}\simeq 3\epsilon_{sl}$). Within the zone, ϵ falls between ϵ_{sl} and ϵ_{st}. We now wish to consider whether the large difference between ϵ_{sl} and ϵ_{st} is real, and if so, what shortcoming of the band model makes the difference zero there.

To answer this question we must discuss the quantum-mechanical equivalent of the parameter γ_s. According to (3.11), $S_0\gamma_s$ increases with k_{ss}, the force constant involved in stretching the covalent bond. The tendency of shell-core forces is to pull the valence charge distributions apart; it is necessary to balance this with a bond stretching force. Quantum mechanically, bond stretching causes a substantial lowering of valence charge density near the covalent plane, defined as the plane midway between the two atoms in the unit cell. This requires an increase in kinetic energy, which is represented by the shell-shell force constant. The charge density at the covalent plane is little altered by bond bending so that $k_b \ll k_s$.

We can now see that the quantum-mechanical generalization of the bond stretching force constant k_s is a force distributed over the covalent face of the atomic cell and acting on a distributed and deformable valence shell. The effect of these refinements should be to reduce the differences between ϵ_{st} and ϵ_{sl} along the [111] axes, perhaps by 50%, but not eliminate them altogether.

It would be interesting to know whether a realistic band model would produce a substantial difference between ϵ_{st} and ϵ_{sl}. From previous experience[18] with $\epsilon(q)$ at $q=0$, it appears that much ingenuity would be required to carry out calculations for $q\neq 0$. It also appears that with many bands, the tendency towards isotropy within the random-phase approximation (4.3) is strong. We suspect that the anisotropy manifested in Fig. 2 indicates that covalent bonding involves short-range correlations which are not treated accurately by the RPA.

5. LOCAL FIELD AND UMKLAPP CORRECTIONS

It was remarked in Sec. 2 that $\epsilon_s(q)$ is periodic along [100] and [111] axes. If we replace a point shell at $\mathbf{R}$ by a specified charge distribution $\sigma(\mathbf{r}-\mathbf{R})$, we find that the force on a shell is

$$\mathbf{E}\int e^{i[\mathbf{q}\cdot(\mathbf{R}+\mathbf{r})]}\sigma(\mathbf{r})d^3\mathbf{r}. \quad (5.1)$$

This is just the previous value, multiplied by the form factor of $\sigma(\mathbf{r})$, which we write as

$$Y(\mathbf{q})=\int\sigma(\mathbf{r})e^{i\mathbf{q}\cdot\mathbf{r}}d^3\mathbf{r}. \quad (5.2)$$

On Fourier analyzing the polarization one finds, e.g., for ϵ_{st},

$$\frac{\epsilon_{st}(q)-1}{4\pi}=\frac{Y^2(q)}{Y^2(0)}\sum\left(\frac{v\mathbf{S}_t}{Y^2}+\mathbf{C}_t\right)^{-1}. \quad (5.3)$$

When an extended charge distribution is used the elements of $\mathbf{C}_t$ will not be the same as those we have met previously, which apply to charges localized at a point (or to nonoverlapping spherical distributions). For example, as the charge is spread out, $C_t(0)$ changes from $-4\pi/3$ to zero, and $C_l(0)$ from $+8\pi/3$ to $+4\pi$. However these changes can be taken up in $\mathbf{S}$, in other words it will always be possible to keep $(v\mathbf{S}/Y^2)+\mathbf{C}$ unchanged. Thus with this quantity unchanged, so that the phonon dispersion curves are unchanged, the right-hand side of (5.3) is multiplied by the damping factor $Y^2(q)/Y^2(0)$ compared to (2.4).

[17] D. Penn, Phys. Rev. 128, 2093 (1962).

[18] D. Brust, J. C. Phillips, and F. Bassani, Phys. Rev. Letters 9, 89 (1962).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

By comparing $\epsilon_s(q)$ with $\epsilon(q)$, we can see that the damping factor must be nearly 1 within the Brillouin zone and start to decrease rapidly for $q \gtrsim k_F$. Outside the zone $\epsilon_s(q)$ represents an analytic continuation of the susceptibility which gives a good fit to that deduced from the phonon dispersion curves inside the zone. The continuation is not unique, as we see from the presence of the damping factor in (5.3). Nevertheless, the damping is probably not so rapid as to destroy the maxima in ϵ_{st} and ϵ_{sl} for $\mathbf{q}$ near $\mathbf{L}=[111]$ reciprocal lattice vector.

Such maxima can be called umklapp effects. Azuma[15] has shown that the umklapp terms in (4.2) lead to an effect of this sort. He finds

$$\epsilon(\mathbf{K}_p)=\mathfrak{D}(\mathbf{K}_p,0)/[1-C_p/\epsilon(0)], \qquad (5.4)$$

where C_p is a number of order unity. The enhancement predicted by (5.4) may be related to the subsidiary maxima found in ϵ_s for $\mathbf{q}$ near $\mathbf{L}$.

6. CONCLUSIONS

In spite of the differences between a classical model of point valence shells and a quantum-mechanical model with valence charge spread over the atomic cell, the microscopic dielectric susceptibility obtained from the shell model is in qualitative agreement with the RPA result, especially within the zone. This provides some microscopic justification of the shell model.

Lax[19] has criticized the shell model on the grounds that its point nature grossly overemphasizes the local field corrections. He cites Stark shifts of nuclear resonances,[20] which place an upper limit on the corrections of order 50%, whereas the point charge model implies corrections by a factor $(\epsilon+2)/3\sim 5$, i.e., ten times larger than the experimental shifts.

Our calculations here demonstrate how the shell model overcomes these difficulties. The microscopic susceptibility calculated from band theory, $\epsilon(q)$, implies small (or, in the case of the isotropic model, no) local field corrections. Nevertheless $\epsilon_s(q)$ agrees well with $\epsilon(q)$ near the zone edge. This is because the short-range forces dominate both the lattice vibration frequencies and $\epsilon_s(q)$ in this region. As $q\to 0$ phase differences between nearest neighbors are reduced, the short-range forces are reduced, and the long-range Coulomb forces become important. In this limit the nature of the charge distribution in the unit cell is irrelevant, so long as it is treated *consistently* to give the right limit,

$$\lim_{q\to 0}\epsilon_{st}(q)=\lim_{q\to 0}\epsilon_s(q)=\epsilon_0=16, \qquad (6.1)$$

for the dielectric properties. This the shell model does; adjustment of β to give $\epsilon_0=16$ automatically renormalizes the theory.

We can now reverse this argument and use the fact that short-range forces dominate near the zone edge to argue that the differences between $\epsilon_{st}(q)$ and $\epsilon_{sl}(q)$ along [111] axes are real. These differences may represent the first observable evidence for departures from the RPA in metals or semiconductors.

Bulk Superconductivity in Dilute Hexagonal Titanium Alloys

F. HEINIGER* AND J. MULLER*
Department of Solid State Physics, Federal Institute of Technology, Zurich, Switzerland
(Received 31 January 1964; revised manuscript received 2 March 1964)

The superconductivity, the low-temperature specific heat, and the paramagnetic susceptibility have been investigated in a series of dilute hexagonal titanium alloys. In the solid solutions with V or Nb, both the transition temperature and the density of states are strongly increased and the entire volume exhibits superconductivity. A similar study of Ti-Fe alloys suggests either an incomplete volume transition or a different entropy variation in the superconducting state.

INTRODUCTION

THE significance of the enhancement of the superconducting critical temperature, which is observed in dilute alloys of titanium with other transition elements, has been subject to considerable controversy.[1–7] Matthias *et al.* interpreted the behavior of these alloys as evidence of the existence of a mechanism of a different type from that provided by the electron-phonon interaction,[1,8] while recent work by Cape[6] on Ti-Mn alloys suggested that the high transition temperatures might simply be due to filamentary cubic precipitations in the hexagonal matrix. The experiments to be described indicate (a) that in dilute solid solutions of Ti with V or Nb, in which cases the hexagonal phase extends to the highest solute concentrations, the enhancement of superconductivity is a real bulk effect; and (b) that the substantial increase of the transition temperature is accompanied by a marked increase of both the electronic specific heat and the magnetic susceptibility. On the other hand, dilute alloys of Ti with Fe show a different calorimetric behavior at the temperature of the diamagnetic transition, and the normal electronic specific heat remains essentially unchanged.

HEXAGONAL ALLOYS OF Ti WITH V AND Nb

The structure of Ti-rich alloys is goverened by the $\alpha-\beta$ phase transition and the Martensite-type diffusionless transformation. The hexagonal alloys containing V or Nb were obtained by quenching after repeated melting in the argon arc. According to x-ray examination, the quenched specimens were single phase up to more than 10 at.% in both cases. The initial slope of the superconducting transition temperature T_c versus solute concentration is practically identical in the V and Nb series, the increase near pure Ti being approximately 1°K per at.%. The observation that very rapid quenching yields somewhat higher transition temperatures has to be interpreted in terms of the state of internal strains or a high concentration of defects, since we have found that Ti-Zr alloys show a similar effect.

Bearing in mind that even a complete diamagnetic transition may not unambiguously indicate a volume effect, we have to rely on the calorimetric transition which is insensitive to possible partial screening. The specific heat of representative samples weighing 3–10 g (small specimens are essential for efficient quenching[9])

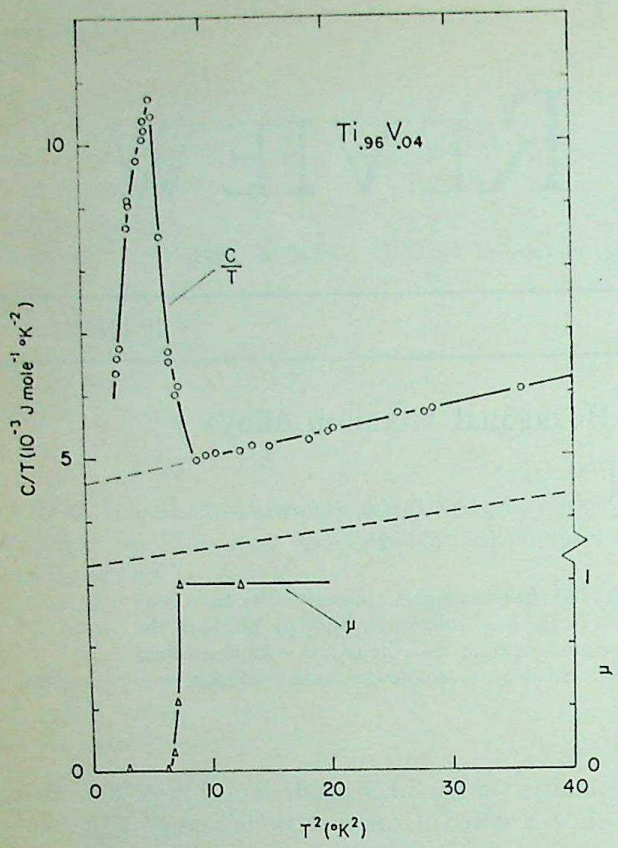

FIG. 1. Specific heat (C/T versus T^2) and magnetic permeability μ of hexagonal $Ti_{0.96}V_{0.04}$. Lower broken line indicates C/T versus T^2 of pure Ti. For T_c versus concentration, see Ref. 2.

have been determined with an absolute accuracy of $\pm 2\%$.[10] Figures 1 and 2 show the results for two alloys (single-phase hcp) containing 4 at.% V or Nb, respectively. Considering the discontinuity at the superconducting transition $[(C_s-C_n)/\gamma T]_{T=T_c}$, we conclude that the bulk of the material is superconducting below the temperature of complete diamagnetic shielding. Therefore, the marked increase of the magnetically observed transition temperature,[2] compared to T_c of pure Ti, is characteristic of the solid solution and is not due to precipitations. Furthermore, as it is seen from Table I, the V and Nb solutes significantly affect the normal electronic specific heat. We also note that the change of γ is much more pronounced than the change of χ. It is reasonable to assume the presence of a large paramagnetic contribution in addition to the spin susceptibility, although in regard to different interaction corrections, γ and χ_{spin} alone need not vary similarly upon alloying. A plot of $\ln(T_c/\theta)$ versus $1/\gamma$ reveals that the data for dilute Ti-V and Ti-Nb essentially agree with those obtained with the isoelectronic Ti-Zr system.[11] Such a relationship is expected qualitatively on the basis of the BCS theory. For the time being, a more detailed interpretation is of little use since the relative importance of the effective Coulomb interaction is not known and no information on the isotope effect in group IV transition elements is available.

TABLE I. Variation of electronic specific heat γ, Debye temperature θ, and magnetic susceptibility χ, of hexagonal alloys of Ti with V and Nb.

	Ti	$Ti_{0.96}V_{0.04}$	$Ti_{0.96}Nb_{0.04}$
γ (10^{-3} J mole^{-1} °K^{-2})	3.3	4.6	4.3
θ_0 (°K)	415	365	340
χ_{at}/χ_{at} (Ti)	(1)	1.09	1.05
χ_{at} (10°K)/χ_{at} (300°K)	0.92	0.92	0.92

In fact, a knowledge of the isotope effect from experiment would permit separation of the interaction into a Coulomb and a phonon part.[12] Unfortunately, attempts of determining the isotopic shift of the transition temperature in[13] Ti and[14] Zr have been unsuccessful due to the difficulties of the sample preparation.

DILUTE Ti-Fe ALLOYS

For comparison, several dilute Ti-Fe alloys with iron content up to 1.5 at.% have been prepared in the same

way as the Ti-V and Ti-Nb specimens. X-ray diffraction showed only hexagonal lines in the quenched state. Optical micrographs closely resembled the one obtained by Cape[6] for as-cast $Ti_{0.99}Mn_{0.01}$. No evidence of a pronounced precipitation of the β phase could be detected. From 0.6 to 1.5 at.% Fe, the midpoint temperature of the change in permeability, observed ballistically in a field of 1 Oe, was found to increase linearly with concentration, in agreement with the earlier data.[1] However, in contrast to the complete diamagnetic transition, the specific heat shows only a slight anomaly (Fig. 3). Similar discrepancies between the amount of flux exclusion and the calorimetric transition have been observed in a number of cases as, e.g., in the σ phase of the Nb-Ir system.[12] A smaller than expected calorimetric anomaly has also been noted by Morin[15] at the apparent T_c of $Ti_{0.99}Fe_{0.01}$. According to the arguments given below, the hypothesis that the observed effect is caused by minor body-centered cubic inclusions seems very improbable, although we cannot rule out completely that traces of the latter may be present. Rather, we are left with two possible interpretations assuming that the transitions do occur in the hexagonal phases (α and α'). Unlike the behavior of Mn in α-Ti,[5-7] the present specific heat data and susceptibility measurements[6] indicate no localized moments on the iron solute.

If we assume a normalized distribution function $f(T_c)$ of the actual volume fraction undergoing a transition at T_c, the observed electronic specific heat will be given by

$$C(T)=\int_T^{T_{c\max}} C_s(T,T_c)f(T_c)dT_c+\int_0^T \gamma(T_c)Tf(T_c)dT_c,$$

where

$$\int_0^{T_{c\max}} f(T_c)dT_c=1.$$

For simplicity, we define

$$x=\int_{T_1}^{T_2} f(T_c)dT_c,$$

with T_2 representing the upper onset of the transition, and $T_1=T_2/2$. Further, we insert the value for $C_s(T,T_c)$ provided by the two-fluid model

$$C_s(T,T_c)=[3\gamma(T_c)/T_c^2]T^3,$$

[15] F. J. Morin (unpublished), quoted in Ref. 6.

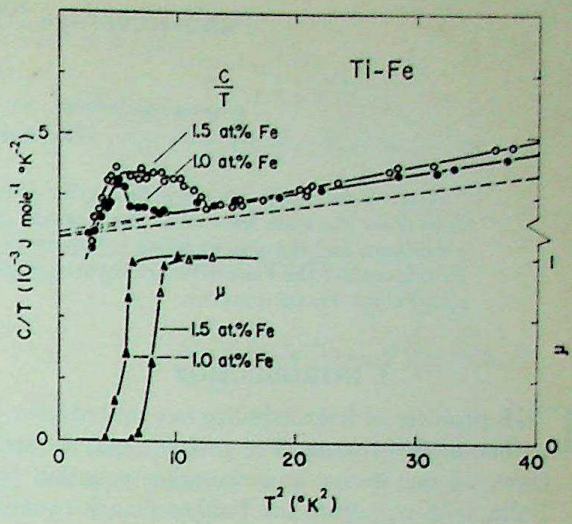

FIG. 3. Specific heat of dilute Ti-Fe alloys. Note complete magnetic transition (μ).

since in the region between T_c and $T_c/2$ this is, for many superconductors, a better approximation than the corresponding BCS function. By the use of a numerical trial and error analysis, we obtain reliably $0.95<x<1$ for the V and Nb alloys, but $0.3<x<0.35$ for Ti+1.5 at.% Fe. If, in fact, only 30% of the volume were superconducting in the latter, a core structure with appreciable microscopic concentration gradients would be required to explain the magnetic transition. On the other hand, this figure almost excludes the possibility of a transition just due to cubic precipitations which are not detected in the x-ray patterns, unless induced superconductivity in the environment of such precipitations were important.

An alternative interpretation of the reduced calorimetric anomaly would have to be based on the assumption that the entropy of the superconducting state is lowered much less than usual, with a corresponding different temperature variation of the energy gap. But if so, it would be difficult to understand why isostructural and isoelectronic dilute Ti-V and Ti-Fe solid solutions, both without localized magnetic states, should exhibit a different kind of superconducting transition.

Time-Reversed Motion in Kinetic Theory*

M. B. Lewis
Technological Institute, Northwestern University, Evanston, Illinois

(Received 22 January 1964)

A set of reversible equations for F_1, the first distribution function and g, the correlation function, are derived for the weak force case. The "forward motion," i.e., development in time from uncorrelated initial conditions, and the corresponding reverse motion are examined. In the "forward motion" the equation for F_1 evolves into the Fokker-Planck equation while in the corresponding reverse motion F_1 is described by an anti-Fokker-Planck equation.

I. INTRODUCTION

THE problem of irreversibility has existed since the time of Boltzmann. The problem may be stated as: How can one derive an irreversible equation (e.g., the Boltzmann equation, the Fokker-Planck equation) on the basis of reversible mechanics? In recent years a number of derivations of irreversible equations have been accomplished based on a variety of assumptions. However, these methods have not completely illuminated the transition from the reversible to the irreversible equations. Most of these methods start from the Bogoliubov-Born-Green-Kirkwood-Yvon (BBKGY) equations,[1] which for an infinite system are

$$\frac{\partial F_s(x_1,\cdots x_s,t)}{\partial t}+\mathfrak{IC}_s F_s(x_1,\cdots x_s,t)$$
$$=-\frac{1}{v}\int dx_{s+1}\sum_{i\leq s}\theta_{i,s+1}F_{s+1}(x_1,\cdots x_{s+1},t) \quad (1)$$
$$s=1,2,\cdots,$$

where $x_i\equiv\{\mathbf{q}_i,\mathbf{p}_i\}$; $\mathbf{q}_i$, $\mathbf{p}_i$ being the position and momentum of the ith particle,

$$\theta_{ij}\equiv\frac{\partial\varphi_{ij}}{\partial\mathbf{q}_i}\cdot\frac{\partial}{\partial\mathbf{p}_i}+\frac{\partial\varphi_{ij}}{\partial\mathbf{q}_j}\cdot\frac{\partial}{\partial\mathbf{p}_j}$$

and $\varphi_{ij}(|\mathbf{q}_i-\mathbf{q}_j|)$ is the intermolecular potential. $\mathfrak{IC}_s$ is given by

$$\mathfrak{IC}_s(x_1,\cdots x_s)\equiv\sum_{i=1}^{s}\frac{\mathbf{p}_i}{m}\cdot\frac{\partial}{\partial\mathbf{q}_i}-\sum_{i<j}^{s}\theta_{ij},$$

and v is the volume per particle. F_s is defined through $D_N(x_1,\cdots x_N,t)$ the probability distribution in Γ space for the entire system by

$$F_s(x_1,\cdots x_s,t)$$
$$=V^s\int\cdots\int D_N(x_1,\cdots x_N,t)dx_{s+1}\cdots dx_N. \quad (2)$$

The sth equation of (1) is obtained by integrating the Liouville equation

$$(\partial D_N/\partial t)+\mathfrak{IC}_N D_N=0 \quad (3)$$

over the coordinates $x_{s+1},\cdots,x_n$.

In particular, the method of Bogoliubov[2] is to assume that all $F_s(s\geqslant 2)$ are functionals of F_1, and the form of the functionals are determined by an assumed boundary condition on the functionals. On this basis, the first BBKGY equation [Eq. (1), $s=1$] becomes the Boltzmann equation (or the Fokker-Planck equation depending on whether the expansion parameter for the distribution function is v^{-1} or the strength of the interaction). The assumptions of Bogoliubov obscure the transition from the set of reversible equations (1) to the irreversible equations. In fact Cohen and Berlin[3] have shown that, on the basis of an equally plausible boundary condition on the functionals, the collision term will be the negative of the Boltzmann collision term (an anti-Boltzmann equation). On the other hand, Green and Piccirelli[4] have shown that, on the basis of a product type condition on $F_s(s\geqslant 2)$ at *the initial time*, the higher distribution functions do, in the course of time, become the functionals of F_1 predicted by Bogoliubov. From this point of view it is no longer important that the Boltzmann equation is time irreversible since the Boltzmann equation evolves from the first BBKGY equation only after some period of time providing the initial $F_s(s\geqslant 2)$ fall within the assumed class of initial conditions. The reverse motion is presumably accomplished, since the BBKGY equations are reversible, by another special class of initial $F_s(s\geqslant 2)$; this motion is probably describable by a single equation for F_1 (such as the anti-Boltzmann equation).[5,6] It is to these points that this paper is devoted.

[5] There remains the question of how one can justify the use of the Boltzmann equation when other types of developments are possible with other types of initial conditions. The answer must be in the following: If we consider a system in which all that is known initially is F_1, then there exists a large class of initial D_N's that give the same F_1 but different $F_s(s\geqslant 2)$. In the spirit of statistical mechanics we can assign a probability to these D_N's and obtain a probability distribution for F_s and ask for the most

We consider a special case, namely a weak potential in a spatially uniform system. This case is general enough to produce an "irreversible" equation, the Fokker-Planck equation, yet simple enough to examine both the *forward motion* (i.e., the development in time from uncorrelated initial conditions, a special case of the Green and Piccirelli initial condition) and the corresponding *reverse motion*. The evolution of F_1 for the forward motion is governed by the Fokker-Planck equation while the *corresponding* reverse motion is governed by an anti-Fokker-Planck equation.

II. BASIC EQUATIONS

We start our development with the BBKGY equations, Eq. (1), the first two of which, in the spatially uniform case, are

$$\frac{\partial F_1(\mathbf{p}_1,t)}{\partial t}=\frac{1}{v}\int dx_2\theta_{12}(x_1,x_2)F_2(x_1,x_2,t)\,, \tag{4a}$$

$$\frac{\partial F_2(x_1,x_2,t)}{\partial t}+\mathcal{H}_2(x_1,x_2)F_2(x_1,x_2,t) =\frac{1}{v}\int dx_3(\theta_{13}+\theta_{23})F_3(x_1,x_2,x_3,t)\,. \tag{4b}$$

We introduce the two particle, three particle—correlation functions g and h—by

$$F_2(x_1,x_2,t)=F_1(\mathbf{p}_1,t)F_1(\mathbf{p}_2,t)+g(x_1,x_2,t)\,, \tag{5a}$$

$$F_3(x_1,x_2,x_3,t)=F_1(\mathbf{p}_1,t)F_1(\mathbf{p}_2,t)F_1(\mathbf{p}_3,t)+F_1(\mathbf{p}_1,t)g(x_2,x_3,t)+F_1(\mathbf{p}_2,t)g(x_1,x_3,t)+F_1(\mathbf{p}_3,t)g(x_1,x_2,t)+h(x_1,x_2,x_3,t)\,, \tag{5b}$$

etc. With these definitions, Eqs. (4a) and (4b) are

$$\frac{\partial F_1(\mathbf{p}_1,t)}{\partial t}=\frac{1}{v}\int dx_2\theta_{12}g(x_1,x_2,t)\,, \tag{6a}$$

$$\frac{\partial g(x_1,x_2,t)}{\partial t}+[\mathcal{H}_1(x_1)+\mathcal{H}_1(x_2)]g(x_1,x_2,t) =\theta_{12}[F_1(\mathbf{p}_1,t)F_1(\mathbf{p}_2,t)+g(x_1,x_2,t)]+\frac{1}{v}\int dx_3\theta_{13}F_1(\mathbf{p}_1,t)g(x_2,x_3,t) +\frac{1}{v}\int dx_3\theta_{23}F_1(\mathbf{p}_2,t)g(x_1,x_3,t)+\frac{1}{v}\int dx_3(\theta_{13}+\theta_{23})h(x_1,x_2,x_3,t)\,. \tag{6b}$$

Define the operator $S_{-t}(x_1,x_2)$ in terms of the single-particle Liouville operator $\mathcal{H}_1$ by

$$S_{-t}(x_1,x_2)\equiv\exp\{-t[\mathcal{H}_1(x_1)+\mathcal{H}_1(x_2)]\}\,, \tag{7}$$

i.e., $S_{-t}(x_1,x_2)$ when operating on the point x_i ($i=1, 2$) propagates the point back in time along a *free-particle orbit* over a time interval t. Equation (6b) can be formally integrated along free-particle orbits to give

$$g(x_1,x_2,t)=S_{-(t-t_0)}(x_1,x_2)g(x_1,x_2,t_0)+\int_0^{t-t_0}dt'S_{-t'}(x_1,x_2)\Big\{\theta_{12}[F_1(\mathbf{p}_1,\,t-t')F_1(\mathbf{p}_2,\,t-t')+g(x_1,\,x_2,\,t-t')] +\frac{1}{v}\int dx_3\theta_{13}F_1(\mathbf{p}_1,\,t-t')g(x_2,\,x_3,\,t-t')+\frac{1}{v}\int dx_3\theta_{23}F_1(\mathbf{p}_2,\,t-t')g(x_1,\,x_3,\,t-t') +\frac{1}{v}\int dx_3(\theta_{13}+\theta_{23})h(x_1,\,x_2,\,x_3,\,t-t')\Big\}\,. \tag{8}$$

At this point we introduce the weak short-range potential and assume we can find a solution in the form

$$g(x_1,x_2,t)=g^0(x_1,x_2,t)+\epsilon g^{(1)}(x_1,x_2,t)+\cdots\,, \tag{9}$$
$$h(x_1,x_2,x_3,t)=h^0(x_1,x_2,x_3,t)+\epsilon h^{(1)}(x_1,x_2,x_3,t)+\cdots\,,$$

etc., where ϵ is an expansion parameter that measures the strength of the potential (actually a measure of the ratio of the average potential to the average relative kinetic energy). For our purpose it will be sufficient to consider

probable form for F_s. This has been considered by Grad (Ref. 6) who has shown that most likely the F_s are uncorrelated.

[6] H. Grad, J. Chem. Phys. 33, 1342 (1960).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$g^0(x_1,x_2,t_0)=h^0(x_1,x_2,x_3,t_0)=\cdots=0$. The zeroth- and first-order equations are then (dropping the ϵ notation)

$$g^0(x_1,x_2,t)=0\,,$$
$$g^{(1)}(x_1,x_2,t)=S_{-(t-t_0)}(x_1,x_2)g^{(1)}(x_1,x_2,t_0)+\int_0^{t-t_0}dt'S_{-t'}(x_1,x_2)\theta_{12}(x_1x_2)F_1(\mathbf{p}_1,t-t')F_1(\mathbf{p}_2,t-t')\,, \tag{10}$$

etc.

To this order, the equation for F_1 [Eq. (6a)] is

$$\frac{\partial F_1(\mathbf{p}_1,t)}{\partial t}=\frac{1}{v}\int dx_2\theta_{12}g^{(1)}(x_1,x_2,t)\,. \tag{11}$$

In Appendix A we prove that the set of Eqs. (10) and (11) are still reversible; the ϵ expansion has not destroyed the reversibility. This point is taken up again in Sec. IV.

III. RELAXATION OF THE CORRELATION FUNCTION

We now consider a special case, namely (taking $t_0=0$), $g^{(1)}(x_1,x_2,0)=0$.

(a) Consider first that $|\mathbf{q}_1-\mathbf{q}_2|<R$, where R is the range of the force. If we assume there exists a time τ, the "time of a collision," such that for essentially all relevant momenta

$$S_{-\tau}(x_1,x_2)\frac{\partial\varphi_{12}(|\mathbf{q}_1-\mathbf{q}_2|)}{\partial\mathbf{q}_1}$$
$$=\partial\varphi_{12}\left(\left|\mathbf{q}_1-\mathbf{q}_2-\frac{(\mathbf{p}_1-\mathbf{p}_2)}{m}\tau\right|\right)\Big/\partial\mathbf{q}_1=0\,,$$

then Eq. (10) reduces, for $t\gtrsim\tau$ to

$$g^{(1)}(x_1,x_2,t)$$
$$=\int_0^{\tau}dt'S_{-t'}(x_1,x_2)\theta_{12}F_1(\mathbf{p}_1,t-t')F_1(\mathbf{p}_2,t-t')\,,\qquad \text{for}\quad t\gtrsim\tau\,; \tag{12}$$

and, from (11) we have

$$F_1(\mathbf{p}_i,t-t')=F_1(\mathbf{p}_i,t)+O(\tau/\mathcal{T})\ \text{ for }\ 0\leqslant t'\leqslant\tau\,, \tag{13}$$

where $\mathcal{T}$ is the mean time between collisions.

To lowest order,

$$g_{\mathrm{FP}}{}^{(1)}(x_1,x_2,t)$$
$$=\int_0^{\tau}dt'S_{-t'}(x_1,x_2)\theta_{12}F_1(\mathbf{p}_1,t)F_1(\mathbf{p}_2,t)\,,\qquad \text{for}\quad t\gtrsim\tau\,. \tag{14}$$

Therefore, to this order, the functional form proposed by Bogoliubov develops, for $|\mathbf{q}_1-\mathbf{q}_2|<R$, in a time τ from the initial time. The subscript F-P on $g^{(1)}$ indicates that this is the form of $g^{(1)}$ that together with Eq. (11) is the Fokker-Planck equation (or, as Bogoliubov calls it, the Landau equation). The Fokker-Planck equation is irreversible in the sense that it obeys an H theorem.[7]

[7] A. Lenard, Ann Phys. (N. Y.) 10, 390 (1960).

(b) Consider $|\mathbf{q}_1-\mathbf{q}_2|>R$.

Suppose $\mathbf{p}_1$ and $\mathbf{p}_2$ are such that at no earlier time have the two points interacted, i.e., $|S_{-t}(x_1,x_2)\{\mathbf{q}_1-\mathbf{q}_2\}|>R$ for $0\leqslant t\leqslant\infty$; then $g^{(1)}(x_1,x_2,t)=0$ for all time.

If $\mathbf{p}_1$ and $\mathbf{p}_2$ are such that at an earlier time $\tau_0(x_1,x_2)$ the points are just starting to interact, i.e.,

$$|S_{-\tau_0}\{\mathbf{q}_1-\mathbf{q}_2\}|=R\,,$$

then Eq. (10) is

$$g^{(1)}(x_1,x_2,t)$$
$$=0\,,\quad t\leqslant\tau_0\,;$$
$$=\int_{\tau_0}^{t}dt'S_{-t'}(x_1x_2)\theta_{12}F_1(\mathbf{p}_1,t-t')F_1(\mathbf{p}_2,t-t')\,,\qquad \tau_0\leqslant t\leqslant\tau_0+\tau\,; \tag{15}$$
$$=\int_{\tau_0}^{\tau_0+\tau}dt'S_{-t'}\theta_{12}F_1(\mathbf{p}_1,t-t')F_1(\mathbf{p}_2,t-t')\,,\qquad t\gtrsim\tau_0+\tau\,.$$

The asymptotic form for $g^{(1)}$ is reached only after $t\gtrsim\tau_0+\tau$ which can be (for given $\mathbf{p}_1$ and $\mathbf{p}_2$) arbitrarily large for points $\mathbf{q}_1$ and $\mathbf{q}_2$ sufficiently far apart. It is interesting to notice that the previous history of the system, in terms of F_1, is stored in the correlation function of distant points; for, at any time t, there are pairs of points $(\mathbf{q}_1,\mathbf{q}_2)$ such that the corresponding $g^{(1)}$ depends on the value of F_1 at any given time between zero and t.

The asymptotic form of (15) can be written as

$$g^{(1)}(x_1,x_2,t)=\mathbf{J}(t-\tau_0)\cdot\mathbf{I}_{r_0}\,,\quad t\gtrsim\tau_0+\tau\,,$$
$$\mathbf{J}(t)=\left(\frac{\partial}{\partial\mathbf{p}_1}-\frac{\partial}{\partial\mathbf{p}_2}\right)F_1(\mathbf{p}_1,t)F_1(\mathbf{p}_2,t)\,, \tag{16}$$
$$\mathbf{I}_{r_0}=\int_{\tau_0}^{\tau_0+\tau}dt'S_{-t'}(x_1,x_2)\frac{\partial\varphi_{12}}{\partial\mathbf{q}_1}\,,$$

where we have again used Eq. (13) and, from the spherical symmetry of the force law and the fact that the collision is completed, $\mathbf{I}_{r_0}$ is in the direction of the distance of closest approach $\mathbf{r}_0$. Therefore, $g^{(1)}$ is nonzero if $\mathbf{J}$ has a component in the $\mathbf{r}_0$ direction. In equilibrium, $\mathbf{J}$ is in the direction of the relative momentum $\mathbf{P}=\mathbf{p}_2-\mathbf{p}_1$ which is normal to $\mathbf{r}_0$ so that $g^{(1)}=0$. We see then, in the nonequilibrium state, the range of $g^{(1)}$ can be arbitrarily large, but the range of $(\mathbf{p}_1,\mathbf{p}_2)$ which gives a nonzero value to $g^{(1)}$ goes down with increasing $|\mathbf{q}_1-\mathbf{q}_2|$. In Appendix B we show that the long range

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of $g^{(1)}$ does not cause the next approximation $g^{(2)}$ to become unbounded with time.

IV. THE REVERSE MOTION

In Sec. IIIa we considered the evolution of a system that at zero time was uncorrelated. In this section we shall describe the corresponding reverse motion. For this purpose we consider the evolution of a second system constructed at an arbitrary time $t_0>0$ that is identical to the first system but with all momenta reversed. This second system is initially correlated in a special way and it is this initial correlation which causes the reverse motion to be accomplished.

Consider again the initial condition $g^{(1)}(x_1,x_2,0)=0$. We have, from Eq. (10) with $t_0=0$

$$g^{(1)}(0|x_1,x_2,t) = \int_0^t dt' S_{-t'}(x_1,x_2)\theta_{12}F_1(0|\mathbf{p}_1,t-t')\times F_1(0|\mathbf{p}_2,t-t'), \quad (17)$$

where the zero preceding the vertical bar in $g^{(1)}$ and F_1 indicate the initial time was zero. In particular (suppressing $\mathbf{q}_1$, $\mathbf{q}_2$) we have

$$g^{(1)}(0|-\mathbf{p}_1,-\mathbf{p}_2,t) = \int_0^t dt' S_{-t'}(-\mathbf{p}_1,-\mathbf{p}_2)\theta_{12}(-\mathbf{p}_1,-\mathbf{p}_2)\times F_1(0|-\mathbf{p}_1,t-t')F_1(0|-\mathbf{p}_2,t-t'). \quad (18)$$

At time t_0 start another system off with initial conditions

$$F_1(t_0|\mathbf{p}_1,t)|_{t=t_0}=F_1(0|-\mathbf{p}_1,t_0), \quad (19a)$$

$$g^{(1)}(t_0|\mathbf{p}_1,\mathbf{p}_2,t)|_{t=t_0}=g^{(1)}(0|-\mathbf{p}_1,-\mathbf{p}_2,t_0). \quad (19b)$$

For $t\geq t_0$ we have from Eq. (10)

$$g^{(1)}(t_0|\mathbf{p}_1,\mathbf{p}_2,t) = S_{-(t-t_0)}(\mathbf{p}_1,\mathbf{p}_2)g^{(1)}(t_0|\mathbf{p}_1,\mathbf{p}_2,t_0) + \int_0^{t-t_0} dt' S_{-t'}(\mathbf{p}_1,\mathbf{p}_2)\theta_{12}(\mathbf{p}_1,\mathbf{p}_2)\times F_1(t_0|\mathbf{p}_1,t-t')F_1(t_0|\mathbf{p}_2,t-t'). \quad (20)$$

Using (19b) and (18) in (20) we have

$$g^{(1)}(t_0|\mathbf{p}_1,\mathbf{p}_2,t)=S_{-(t-t_0)}(\mathbf{p}_1,\mathbf{p}_2)\left\{\int_0^{t_0} dt' S_{-t'}(-\mathbf{p}_1,-\mathbf{p}_2)\theta_{12}(-\mathbf{p}_1,-\mathbf{p}_2)F_1(0|-\mathbf{p}_1,t_0-t')F_1(0|-\mathbf{p}_2,t_0-t')\right\} + \int_0^{t-t_0} dt' S_{-t'}(\mathbf{p}_1,\mathbf{p}_2)\theta_{12}(\mathbf{p}_1,\mathbf{p}_2)F_1(t_0|\mathbf{p}_1,t-t')F_1(t_0|\mathbf{p}_2,t-t'). \quad (21)$$

In the first term in Eq. (21) we can combine the S operators

$$S_{-(t-t_0)}(\mathbf{p}_1,\mathbf{p}_2)S_{-t'}(-\mathbf{p}_1,-\mathbf{p}_2)=S_{-(t-t_0-t')}(\mathbf{p}_1,\mathbf{p}_2)=S_{-(t'+t_0-t)}(-\mathbf{p}_1,-\mathbf{p}_2). \quad (22)$$

Splitting the range of integration in the first integral in (21) into

$$(0,t-t_0) \quad \text{and} \quad (t-t_0,t_0) \quad \text{for} \quad t_0\leq t\leq 2t_0,$$

the first integral is

$$\left\{\int_0^{t-t_0} dt' S_{-(t-t_0-t')}(\mathbf{p}_1,\mathbf{p}_2)+\int_{t-t_0}^{t_0} dt' S_{-(t'+t_0-t)}(-\mathbf{p}_1,-\mathbf{p}_2)\right\}\theta_{12}F_1F_1.$$

Changing time variables, Eq. (21) becomes

$$g^{(1)}(t_0|\mathbf{p}_1,\mathbf{p}_2,t)=\int_0^{t-t_0} dt' S_{-t'}(\mathbf{p}_1,\mathbf{p}_2)\theta_{12}(-\mathbf{p}_1,-\mathbf{p}_2)F_1(0|-\mathbf{p}_1,2t_0+t'-t)F_1(0|-\mathbf{p}_2,2t_0+t'-t) + \int_0^{2t_0-t} dt' S_{-t'}(-\mathbf{p}_1,-\mathbf{p}_2)\theta_{12}(-\mathbf{p}_1,-\mathbf{p}_2)F_1(0|-\mathbf{p}_1,2t_0-t'-t)F_1(0|-\mathbf{p}_2,2t_0-t'-t) + \int_0^{t-t_0} dt' S_{-t'}(\mathbf{p}_1,\mathbf{p}_2)\theta_{12}(\mathbf{p}_1,\mathbf{p}_2)F_1(t_0|\mathbf{p}_1,t-t')F_1(t_0|\mathbf{p}_2,t-t'), \quad \text{for} \quad t_0\leq t\leq 2t_0. \quad (23)$$

From the general reversibility argument (Appendix A) we would expect

$$F_1(t_0|\mathbf{p}_1,t)=F_1(0|-\mathbf{p}_1,2t_0-t), \quad (24a)$$

$$g^{(1)}(t_0|\mathbf{p}_1,\mathbf{p}_2,t)=g^{(1)}(0|-\mathbf{p}_1,-\mathbf{p}_2,2t_0-t), \quad \text{for} \quad t_0\leq t\leq 2t_0, \quad (24b)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

which satisfy the initial conditions (19a) and (19b). To show that this is the case, suppose (24a) is the solution of (23) and (11), then the first term in (23) cancels the last term and the remaining term is, by (18), $g^{(1)}(0|-\mathbf{p}_1, -\mathbf{p}_2, 2t_0-t)$ thus establishing (24b); and (24b) in (11) leads to (24a), i.e., Eq. (11) is

$$\frac{\partial F_1(t_0|\mathbf{p}_1,t)}{\partial t}=-\frac{1}{v}\int dx_2\theta_{12}(\mathbf{p}_1,\mathbf{p}_2)g^{(1)}(t_0|\mathbf{p}_1,\mathbf{p}_2,t)\,. \tag{25}$$

The right-hand side of (25) is

$$-\frac{1}{v}\int dx_2\theta_{12}(\mathbf{p}_1,\mathbf{p}_2)g^{(1)}(0|-\mathbf{p}_1,-\mathbf{p}_2,2t_0-t)=-\frac{1}{v}\int dx_2\theta_{12}(-\mathbf{p}_1,-\mathbf{p}_2)g^{(1)}(0|-\mathbf{p}_1,-\mathbf{p}_2,2t_0-t) \tag{25a}$$

and the right side of (25a) is, by Eq. (11), $\partial F_1(0|-\mathbf{p}_1, 2t_0-t)/\partial t$; we have for $t_0\leq t\leq 2t_0$, $\partial F_1(t_0|\mathbf{p}_1,t)/\partial t = \partial F_1(0|-\mathbf{p}_1, 2t_0-t)/\partial t$, or $F_1(t_0|\mathbf{p}_1,t)-F_1(t_0|\mathbf{p}_1,t_0)=F_1(0|-\mathbf{p}_1, 2t_0-t)-F_1(0|-\mathbf{p}_1, t_0)$ and, with initial condition (19a), this is (24a).

Over the time interval $t_0\leq t\leq 2t_0$, the equation for $F_1(t_0|\mathbf{p}_1,t)$ can be obtained from (25) and (23). Equation (23) can be written, using (24a) and (13), as

$$\begin{aligned} g^{(1)}(t_0|\mathbf{p}_1,\mathbf{p}_2,t)&=\int_0^{2t_0-t}dt'S_{-t'}(-\mathbf{p}_1,-\mathbf{p}_2)\theta_{12}(-\mathbf{p}_1,-\mathbf{p}_2)F_1(0|-\mathbf{p}_1,2t_0-t'-t)F_1(0|-\mathbf{p}_2,2t_0-t'-t)\\ &=-\int_0^{2t_0-t}dt'S_{-t'}(\mathbf{p}_1,\mathbf{p}_2)\theta_{12}(\mathbf{p}_1,\mathbf{p}_2)F_1(t_0|\mathbf{p}_1t)F_1(t_0|\mathbf{p}_2,t)\,. \end{aligned} \tag{26}$$

Equation (26), together with (25), is the anti-Fokker-Planck equation, i.e., the collision term is the negative of the Fokker-Planck collision term. If we call $\mathbf{q}_1-\mathbf{q}_2=\mathbf{r}$ we have

$$\partial F_1(t_0|\mathbf{p}_1,t)/\partial t=-\frac{1}{v}\int d\mathbf{p}_2d\mathbf{r}\left[\frac{\partial\varphi(|\mathbf{r}|)}{\partial\mathbf{r}}\cdot\left\{\frac{\partial}{\partial\mathbf{p}_1}-\frac{\partial}{\partial\mathbf{p}_2}\right\}\right]\int_0^{2t_0-t}dt'\partial\varphi\left(\left|\mathbf{r}+\frac{(\mathbf{p}_1-\mathbf{p}_2)}{m}t'\right|\right)\Big/\partial\mathbf{r}$$
$$\cdot\left\{\frac{\partial}{\partial\mathbf{p}_1}-\frac{\partial}{\partial\mathbf{p}_2}\right\}F_1(t_0|\mathbf{p}_1,t)F_1(t_0|\mathbf{p}_2,t)\,.$$

Changing $\mathbf{r}\rightarrow-\mathbf{r}$

$$\frac{\partial F_1(t_0|\mathbf{p}_1,t)}{\partial t}=-\frac{1}{v}\int d\mathbf{p}_2d\mathbf{r}\left[\frac{\partial\varphi(|\mathbf{r}|)}{\partial\mathbf{r}}\cdot\left\{\frac{\partial}{\partial\mathbf{p}_1}-\frac{\partial}{\partial\mathbf{p}_2}\right\}\right]\int_0^{2t_0-t}dt'\partial\varphi\left(\left|\mathbf{r}-\frac{(\mathbf{p}_1-\mathbf{p}_2)}{m}t'\right|\right)\Big/\partial\mathbf{r}$$
$$\cdot\left\{\frac{\partial}{\partial\mathbf{p}_1}-\frac{\partial}{\partial\mathbf{p}_2}\right\}F_1(t_0|\mathbf{p}_1,t)F_1(t_0|\mathbf{p}_2,t)\,, \tag{27}$$

which is the anti-Fokker-Planck equation for $t_0\leqslant t\leqslant 2t_0-\tau$.

At time $t=2t_0$, from (24a) and (24b) we obtain

$$g^{(1)}(t_0|\mathbf{p}_1,\mathbf{p}_2,2t_0)=0\,, \tag{28a}$$

$$F_1(t_0|\mathbf{p}_1,2t_0)=F_1(0|-\mathbf{p}_1,0)\,. \tag{28b}$$

The equation describing the motion for $t\geqslant 2t_0$ is then, from (11) and (10)

$$\frac{\partial F_1(2t_0|\mathbf{p}_1,t)}{\partial t}=-\frac{1}{v}\int dx_2\theta_{12}g^{(1)}(2t_0|\mathbf{p}_1,\mathbf{p}_2,t)\,, \tag{29a}$$

$$g^{(1)}(2t_0|\mathbf{p}_1,\mathbf{p}_2,t)$$
$$=\int_0^{t-2t_0}dt'S_{-t'}(\mathbf{p}_1,\mathbf{p}_2)\theta_{12}(\mathbf{p}_1,\mathbf{p}_2)$$
$$\times F_1(2t_0|\mathbf{p}_1,t)F_1(2t_0|\mathbf{p}_2,t)\,, \tag{29b}$$

where

$$g^{(1)}(2t_0|\mathbf{p}_1,\mathbf{p}_2,2t_0)=0\,,$$
$$F_1(2t_0|\mathbf{p}_1,t)|_{t=2t_0}=F_1(0|-\mathbf{p}_1,0)\,, \tag{29c}$$

and, therefore, after $t\geqslant 2t_0+\tau$ the equation for F_1 is again the Fokker-Planck equation and the system is again approaching equilibrium.

V. SUMMARY

From the BBKGY set of equations, we have derived an approximate set of equations for the weak force case, Eqs. (10) and (11); these have been shown to be reversible in Appendix A. In the special case that the initial $g^{(1)}=0$, the equation for F_1 evolves into the "irreversible" Fokker-Planck equation after a time τ (on the order of a time of a collision) and the system approaches equilibrium.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Suppose, on the other hand, the system is allowed to run for an arbitrary length of time t_0; then in order to describe the reverse motion, we consider a second system identical to the first at time t_0, but with all momenta reversed. The initial conditions on F_1 and $g^{(1)}$ for this second system are constructed from the F_1 and $g^{(1)}$ of the first system at t_0. The second system during the time interval $(t_0,2t_0)$ now performs exactly the reverse motion that the original system performed during the time $(0,t_0)$. The equation for F_1 for the second system during the time interval $(t_0, 2t_0-\tau)$ is the anti-Fokker-Planck equation and after the time $2t_0+\tau$ is the Fokker-Planck equation.

For the second system the dependence of $g^{(1)}$ on its initial value causes the reverse motion to be accomplished: "built into" the initial value of $g^{(1)}$ at pairs of points outside the range of the force is the earlier behavior of F_1 for the first system. The dependence of $g^{(1)}$ on its initial value would be missing if the momentum reversal were applied to the Fokker-Planck equation.

The final question of what to use in describing a given system is answered in the spirit of statistical mechanics by the argument that if all that is known initially about a system is F_1, then the most likely $g^{(1)}$ is zero and F_1 will most likely evolve according to the Fokker-Planck equation.[5]

APPENDIX A

Equations (10) and (11), with $t_0=0$, suppressing spatial coordinates in $g^{(1)}$ and S, are

$$\frac{\partial F_1(\mathbf{p}_1,t)}{\partial t}=-\frac{1}{v}\int d\mathbf{q}_2 d\mathbf{p}_2 \frac{\partial\varphi_{12}}{\partial\mathbf{q}_1}\cdot\left(\frac{\partial}{\partial\mathbf{p}_1}-\frac{\partial}{\partial\mathbf{p}_2}\right)g^{(1)}(\mathbf{p}_1,\mathbf{p}_2,t), \quad \text{(A1)}$$

$$g^{(1)}(\mathbf{p}_1,\mathbf{p}_2,t) = S_{-t}(\mathbf{p}_1,\mathbf{p}_2)g^{(1)}(\mathbf{p}_1,\mathbf{p}_2,0) + \int_0^t dt' S_{-t'}(\mathbf{p}_1,\mathbf{p}_2)\frac{\partial\varphi_{12}}{\partial\mathbf{q}_1}\cdot\left(\frac{\partial}{\partial\mathbf{p}_1}-\frac{\partial}{\partial\mathbf{p}_2}\right) \times F_1(\mathbf{p}_1,t-t')F_1(\mathbf{p}_2,t-t'). \quad \text{(A2)}$$

Consider $\mathfrak{F}(\mathbf{p}_1,t)$ and $\mathfrak{G}(\mathbf{p}_1,\mathbf{p}_2,t)$ to be the solutions of (A1) and (A2) with initial conditions $\mathfrak{F}(\mathbf{p}_1,0)$ and $\mathfrak{G}(\mathbf{p}_1,\mathbf{p}_2,0)$. In Eqs. (A1) and (A2) change $\mathbf{p}_i\rightarrow-\mathbf{p}_i$ and $t\rightarrow-t$; then using the fact that $S_{-t}(\mathbf{p}_1,\mathbf{p}_2)=S_t(-\mathbf{p}_1,-\mathbf{p}_2)$ we have

$$\frac{\partial F_1(-\mathbf{p}_1,-t)}{\partial t}=-\frac{1}{v}\int d\mathbf{q}_2 d\mathbf{p}_2 \frac{\partial\varphi_{12}}{\partial\mathbf{q}_1}\cdot\left(\frac{\partial}{\partial\mathbf{p}_1}-\frac{\partial}{\partial\mathbf{p}_2}\right) \times g^{(1)}(-\mathbf{p}_1,-\mathbf{p}_2,-t), \quad \text{(A3)}$$

$$g^{(1)}(-\mathbf{p}_1,-\mathbf{p}_2,-t) = S_{-t}(\mathbf{p}_1,\mathbf{p}_2)g^{(1)}(-\mathbf{p}_1,-\mathbf{p}_2,0) + \int_0^t dt' S_{-t'}(\mathbf{p}_1,\mathbf{p}_2)\frac{\partial\varphi_{12}}{\partial\mathbf{q}_1}\cdot\left(\frac{\partial}{\partial\mathbf{p}_1}-\frac{\partial}{\partial\mathbf{p}_2}\right) \times F_1(-\mathbf{p}_1,-t+t')F_1(-\mathbf{p}_2,-t+t'). \quad \text{(A4)}$$

Comparing Eqs. (A3) and (A4) with (A1) and (A2) we see that if we take as initial conditions in (A3) and (A4)

$$F_1(-\mathbf{p}_1,-t)\big|_{t=0}=\mathfrak{F}(\mathbf{p}_1,0),$$
$$g^{(1)}(-\mathbf{p}_1,-\mathbf{p}_2,-t)\big|_{t=0}=\mathfrak{G}(\mathbf{p}_1,\mathbf{p}_2,0),$$

then the solutions of (A3) and (A4) are

$$F_1(-\mathbf{p}_1,-t)=\mathfrak{F}(\mathbf{p}_1,t),$$
$$g^{(1)}(-\mathbf{p}_1,-\mathbf{p}_2,-t)=\mathfrak{G}(\mathbf{p}_1,\mathbf{p}_2,t),$$

or

$$F_1(\mathbf{p}_1,t)=\mathfrak{F}(-\mathbf{p}_1,-t),$$
$$g^{(1)}(\mathbf{p}_1,\mathbf{p}_2,t)=\mathfrak{G}(-\mathbf{p}_1,-\mathbf{p}_2,-t). \quad \text{(A5)}$$

Therefore, the approximation used to obtain Eqs. (A1) and (A2) have not destroyed the reversibility.

APPENDIX B

We show here that the long range of $g^{(1)}$ (see Sec. IIIb) does not cause the next approximation $g^{(2)}$ to become unbounded with increasing time. $g^{(2)}$ will contain a term

$$\frac{1}{v}\int_0^t dt' S_{-t'}(x_1,x_2)\int dx_3\theta_{13}F_1(\mathbf{p}_1,t-t')g^{(1)}(x_2,x_3,t-t') = -\frac{1}{v}\int_0^t dt'\int d\mathbf{q}_3 d\mathbf{p}_3\frac{\partial\varphi_{13}}{\partial\mathbf{q}_1}(|\mathbf{q}_1'-\mathbf{q}_3|)\cdot\frac{\partial F_1(\mathbf{p}_1,t-t')}{\partial\mathbf{p}_1} \times g^{(1)}(x_2',x_3,t-t'), \quad \text{(B1)}$$

where

$$x_i'=S_{-t'}(x_1,x_2)x_i; \quad i=1,2.$$

Figure 1 shows a configuration at time t' where the integrand in (B1) is nonzero.

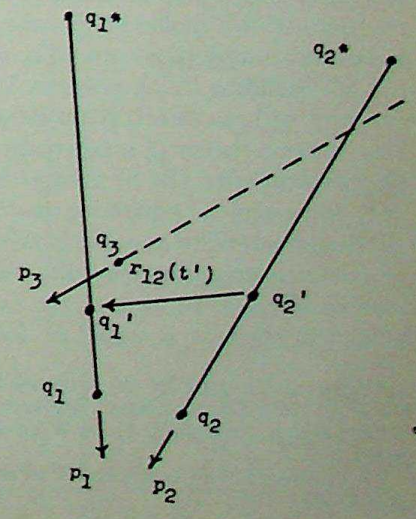

FIG. 1. An interacting configuration. (a) $\mathbf{q}_i^*=\mathbf{q}_i-\mathbf{p}_i t/m$; $i=1,2$. (b) $\mathbf{q}_3$ is within range of force of $\mathbf{q}_1'$ and (c) $\mathbf{p}_3$ is such that at an earlier time (but before particle 2 is at $\mathbf{q}_2^*$) particles 2 and 3 interact since $g^{(1)}\neq0$ at that time.

In terms of the relative momentum $\mathbf{P}_{32}$; $\mathbf{P}_{32}$ must be within a solid angle $\pi R^2/|\mathbf{r}_{23}(t')|^2$ in the direction $\mathbf{r}_{23}(t')$, which at large distances can be replaced by $\pi R^2/|\mathbf{r}_{12}(t')|^2$, where $\mathbf{r}_{12}(t')=\mathbf{r}_{12}-\mathbf{P}_{12}t'/m$ and $\mathbf{r}_{12}=\mathbf{q}_1-\mathbf{q}_2$, $\mathbf{P}_{12}=\mathbf{p}_1-\mathbf{p}_2$.

In (B1) changing the momentum integration to $\mathbf{P}_{32}$ we have

$$\int_0^t dt' \int d\Omega_{P_{32}}\alpha\,, \tag{B2}$$

$$\alpha=-\frac{1}{v}\int d\mathbf{q}_3 dP_{32}P_{32}^2\frac{\partial\varphi_{13}}{\partial\mathbf{q}_1}\cdot\frac{\partial F_1}{\partial\mathbf{p}_1}g^{(1)}.$$

To obtain the magnitude of (B2) we neglect the variation of α with time and treat it as constant with respect to the angles when it is nonzero. We then have

$$\alpha\int_0^t dt'\frac{\pi R^2}{|\mathbf{r}_{12}(t')|^2}$$
$$=\frac{\alpha\pi R^2}{r_{12}(P_{12}/m)(1-\cos^2\theta)^{1/2}}\left\{\tan^{-1}\left[\frac{P_{12}t/mr_{12}-\cos\theta}{(1-\cos^2\theta)^{1/2}}\right]-\tan^{-1}\left[\frac{-\cos\theta}{(1-\cos^2\theta)^{1/2}}\right]\right\}, \tag{B3}$$

where θ is the angle between $\mathbf{r}_{12}$ and $\mathbf{P}_{12}$. Equation (B3) approaches a limit as $t\to\infty$, according to

$$\frac{\alpha\pi R^2}{r_{12}(P_{12}/m)(1-\cos^2\theta)^{1/2}}\left\{\frac{\pi}{2}-\tan^{-1}\left[\frac{-\cos\theta}{(1-\cos^2\theta)^{1/2}}\right]-\frac{(1-\cos^2\theta)^{1/2}}{P_{12}t/mr_{12}}\right\}. \tag{B4}$$

Possibility of Synthesizing an Organic Superconductor*

W. A. Little
Department of Physics, Stanford University, Stanford, California

(Received 13 November 1963; revised manuscript received 27 January 1964)

London's idea that superconductivity might occur in organic macromolecules is examined in the light of the BCS theory of superconductivity. It is shown that the criterion for the occurrance of such a state can be met in certain organic polymers. A particular example is considered in detail. From a realistic estimation of the matrix elements and density of states in this polymer it is concluded that superconductivity should occur even at temperatures well above room temperature. The physical reason for this remarkable high transition temperature is discussed. It is shown further that the superconducting state of these polymers should be distinguished by certain unique chemical properties which could have considerable biological significance.

I. INTRODUCTION

IN the forward to Vol. 1 of his monographs on superfluids, F. London[1] questions whether a superfluid-like state might occur in certain macromolecules which play an important role in biochemical reactions. If this should be the case, an entirely new and important consideration would be added to the problem of understanding living systems. In view of the significance of such an effect, it appears appropriate at this time, when a theory of superconductivity, the Bardeen-Cooper-Schrieffer (BCS) theory[2] has been so remarkably successful in explaining much of the behavior of superconductors, to examine in the light of this whether or not a superconducting state might occur in certain macromolecules. In view of the extreme complexity of biological systems, it would be folly for a physicist to attempt to experiment in such an environment. Instead of attempting this, we shall tackle the problem on our own grounds. The BCS theory, while by no means complete and exact, has succeeded in providing a model with most of the essential features of a superconductor. In particular, it prescribes certain criteria for a system which, if satisfied, should lead to the superconducting state. Our approach is to consider how these criteria might be applied to the design of a particular organic molecule which, if its synthesis is possible, should show some of the essential features of a superconductor and, as we shall show, some remarkable chemical properties as well. One of the interesting features about the particular class of molecules we investigate in detail is that the molecules should be superconducting at room temperature and, indeed, to temperatures well above room temperatures. We can show on simple physical grounds why this is so and perhaps, with hindsight, why this was to be expected.

The idea of superconductivity in organic systems is not a new idea, however, there is a considerable amount

of confusion as to the exact meaning of this. The diamagnetic ring currents of aromatic molecules such as benzene, naphthalene, etc., are nondissipative currents similar in many respects to the persistent currents of superconducting rings and, have often been referred to as a form of superconductivity. However, the "superconductivity" of these molecules is not the same as the superconductivity of bulk materials. The reason, I believe, is the following. In macroscopically large superconductors, if superconductivity exists, then a finite fraction of the charge carriers, in general, the BCS pairs are in identically the same center-of-mass momentum state. This state then has a macroscopic occupation. In a magnetic field the canonical momentum of this state remains unchanged, but due to the vector potential term contained in it a current is induced and the energy of the state changes. For a macroscopically large superconductor the kinetic energy of the different center-of-mass momentum states of the pairs lie extremely close to one another, however, because the coherence energy of each state depends upon the square of the number of pairs in that state, the state which is macroscopically occupied is appreciably lower in energy than any of the neighboring states even in a moderate magnetic field. It is only by transitions in which practically all the pairs in the macroscopically occupied state simultaneously move to another state that a lower energy final state can be reached. This is obviously highly forbidden and, consequently, the system of pairs remains in the momentum state into which condensation originally occurred. Thus, it is the coherence energy which prevents the system from freely adjusting itself to take the lowest possible energy. In the aromatic ring compounds practically all the molecules are in their ground states. In a magnetic field the canonical momentum of the electrons in this state remain unchanged and diamagnetic currents flow in the molecule similar to those of a bulk superconductor. The energy of the different momentum states of the electrons in each molecule in this case are well separated though, because the molecules are of microscopic size. Thus, the momenta of the electrons do not change because for fields as large as those available in the laboratory, the state which evolves out of the original ground state still is lower in energy than any other in the presence of the field. If, however, the aromatic system is made arbitrarily large such as in graphite, bulk superconductivity does not result because as the system gets bigger, the different momentum states of the electrons approach each other in energy. Transitions can then occur between states and the induced currents are dissipated. So that in order to get superconductivity in a macromolecule or in a bulk material, something of the nature of a coherence energy is required. In conventional superconductors this is provided by the phonon-induced, electron-electron interaction; in attempting to devise a macromolecule which is to be superconducting one must provide, therefore, some mechanism similar to this. In our model we do this in the following manner.

II. MODEL SYSTEM

We shall consider a molecule consisting of two parts, a long chain called the "spine" in which electrons fill the various states and may or may not form a conducting system; and secondly, a series of arms or side chains attached to the spine as indicated in Fig. 1. We will show that by appropriate choice of the molecules which constitute the side chains, the virtual oscillation of charge in these side chains can provide an interaction between the electrons moving in the spine. This can be made a sufficiently attractive interaction so that the superconducting state results. We can show further that even if the spine by itself is initially an insulator due to the valence band being full and the conduction band empty, the addition of side chains can increase the electron-electron attraction to the point where it becomes energetically favorable to enter the superconducting state by mixing in states of the conduction band. The spine thus transforms from the insulating or semiconducting state directly to the superconducting metallic state upon the addition of the side chains.

Consider a long chain molecule as shown in the left half of Fig. 1. We will assume this is a conjugated chain of double and single bonds resonating between the two at each link. This corresponds in the band theory of metals to a band which is half filled and ideally is a metallic conductor. (See, however, Sec. III.) At the points P, P', $\cdots$, a regular array of side chain molecules B are attached. The individual side-chain molecules are chosen to have a low-lying excited state such that transitions from the ground state to the excited state correspond classically to an oscillation of charge from end to end of the molecule.

The electrons moving in the spine may be described

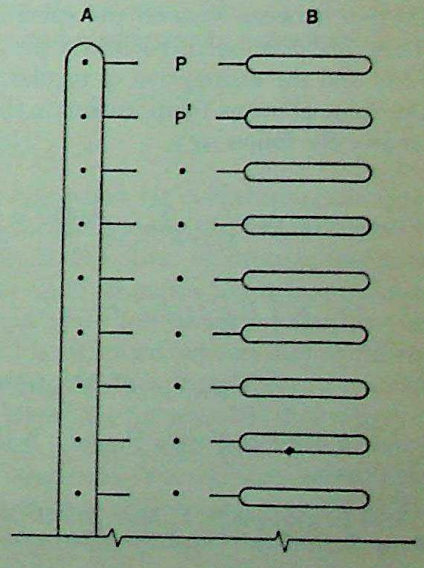

FIG. 1. Proposed model of a superconducting organic molecule. The molecule A is a long unsaturated polyene chain called the "spine." The molecules B are side chains attached to the spine at points P, P', ···.

in the tight-binding approximation[3] by eigenfunctions of the form

$$\phi_{k,m}(r)=\frac{1}{G^{1/2}}\sum_i e^{ikR_i}U_m(r-R_i)\,, \qquad (2.1)$$

where $U_m(r-R_i)$ is the wave function of an electron in a single atom located at R_i. G is the number of links in the chain and ϵ_k is the energy of this electron and we will assume cyclic boundary conditions. To avoid unnecessary complication we shall ignore the electron spin throughout the discussion except where necessary.

The wave function of the electrons in a single side-chain molecule in an eigenstate n we designate by $\psi_n(r_1,r_2,\cdots)$. Due to the interaction of one side chain upon its neighbors, the degeneracy of the levels of the group of side chains will be removed when the side chains are brought together as in Fig. 1. The band of levels of the system of side chains as a whole can be described then by a new wave function similar to (2.1) above.

$$X_{q,n}=\frac{1}{G^{1/2}}\sum_j e^{iqR_j}\psi_n(r_1-R_j;r_2-R_j\cdots)\,. \qquad (2.2)$$

The Coulomb interaction between the electrons in the spine and those on the side chain will provide an interaction between the electrons in the spine and the side-chain modes. Let this Coulomb interaction be $V_1=\sum_{i,j}V(r-R_i;r_1-R_j,r_2-R_j,\cdots)$ which will give rise to a typical interaction matrix element

$$\int\int\cdots\int\phi_{k'm'}{}^*(r)X_{q'm'}{}^*(r_1,r_2\cdots)$$
$$\times V_1X_{qn}(r_1,r_2\cdots)\phi_{km}(r)d^3rd^3r_1\cdots\,. \qquad (2.3)$$

In the model we shall consider, screening reduces the range of the Coulomb interaction so that one can safely disregard the contribution to the interaction from any but the neighboring side chains. Secondly, in our model there is negligible overlap between side chains, and also overlap between sites on the spine is relatively small. These features together with the properties of (2.1) and (2.2) and the assumption of regular substitution along the spine allow us to approximate the interaction (2.3) to give the following

$$V_{k'm',q'n',qn,km}=\frac{1}{G}\sum_{n''=-1,0,+1}\cos Qn''a\int\cdots$$
$$\times\int U_{m'}{}^*(r)\psi_{n'}{}^*(r_1-n''a,\cdots)$$
$$\times V_1\psi_n(r_1-n''a)U_m(r)\times d^3rd^3r_1\cdots\,, \qquad (2.4)$$

where $k'=k+Q$, $q'=q-Q$, and a is the spacing between side chains.

[3] See for example N. F. Mott and H. Jones, *The Theory of the Properties of Metals and Alloys* (Clarendon Press, Oxford, 1936).

It is convenient to write this as $(1/G)V(Q)$ for the moment. Then the complete spine side-chain interaction can be described in the representation of second quantization as

$$V_{\text{side chain}}=\frac{1}{G}\sum_{\substack{Q,n,n'\\k,m,m'}}V(Q)\Big(\sum_q c_{q-Q,n'}{}^\dagger c_{q,n}\Big)a_{k+Q,m'}{}^\dagger a_{km}\,, \qquad (2.5)$$

where the $a^\dagger$ and a are the creation and destruction operators for the electron in the spine, and $c^\dagger$ and c the corresponding operators for the side-chain modes. The particle-hole operator $\sum_q c_{q-Q,n'}{}^\dagger c_{qn}$ which occurs in (2.5) appears in a similar manner to the phonon creation operator $b_Q{}^\dagger$ in the phonon-electron interaction in a metal. The terms linear in this particle-hole operator which appear through the interaction (2.5) in the total Hamiltonian can be eliminated by the same type of transformation[4] which eliminates the terms linear in the phonon creation operator $b_Q{}^\dagger$ in the conventional theory. This leads to a side-chain induced electron-electron interaction V_2 *between* electrons in the spine of the form

$$V_2=\tfrac{1}{2}\sum_{k,k',Q}\left\{\frac{2V^2(Q)}{G}\,\frac{\hbar\omega_Q}{(\epsilon_{k+Q}-\epsilon_k)^2-(\hbar\omega_Q)^2}\right\}$$
$$\times a_{k+Q}{}^\dagger a_{k'-Q}{}^\dagger a_{k'}a_k\,. \qquad (2.6)$$

We have written $\hbar\omega$ for the difference $(E_{n'}-E_n)$ between the energy of the states of the side-chain modes and have considered for simplicity only one excited state n'. This is identical in form to the usual phonon-induced electron-electron coupling. We note that if $|\hbar\omega|\gg|(\epsilon_{k+Q}-\epsilon_k)|$ then the term in brackets reduces to an attractive interaction, $V\approx-2\langle|V(Q)|^2\rangle_{\text{av}}/G\hbar\omega$, where $\langle|V(Q)|^2\rangle_{\text{av}}$ is the average of the square of the interaction $V(Q)$.

In addition to this attractive term, the screened Coulomb interaction gives a repulsive term. The sum of these two is the net electron-electron interaction. Let this sum be $\langle V(Q)\rangle_{\text{av}}$; then the total Hamiltonian for the electrons in the spine is

$$\mathcal{H}=\sum_k(\epsilon_k-\mu)a_k{}^\dagger a_k$$
$$+\tfrac{1}{2}\sum_{k,k',Q}\langle V(Q)\rangle_{\text{av}}a_{k+Q}{}^\dagger a_{k'-Q}{}^\dagger a_{k'}a_k\,, \qquad (2.7)$$

where $\langle V(Q)\rangle_{\text{av}}$ is given above and μ is the Fermi energy.

The BCS theory then shows that a superconducting state is possible if the following equation can be satisfied for a nonzero gap, Δ:

$$-1=\sum_k\frac{V\tanh\frac{1}{2}\beta E_k}{2E_k}\,, \qquad (2.8)$$

where $E_k=[(\epsilon_k-\mu)^2+\Delta^2]^{1/2}$ and the sum is limited by $|\epsilon_k-\mu|<\hbar\omega$. V is the average over the region of Q where $\langle V(Q)\rangle_{\rm av}$ is attractive. The critical temperature is given by

$$kT_c=1.14\hbar\omega\exp[-1/N(0)V], \qquad (2.9)$$

where $N(0)$ is the density of states of one spin at the Fermi surface.

It is appropriate to dispose of a difficulty here which will arise shortly in considering a particular example of a molecule. In long-chain conjugated molecules the double and single bonds do not resonate freely between each position in the chain, but tend to localize so that a stationary periodic charge distribution and periodic bond length is established. This introduces a periodic potential of twice the atomic spacing in the chain which in turn produces a gap in the density of states halfway up the band. As there is one electron per atom in the band, this band is filled up to the new gap. The conjugated system is then no longer a metallic conductor but a semiconductor or insulator, i.e., the density of states at the Fermi surface $N(0)$ would be zero.[5] However, it is incorrect to interpret Eq. (2.9) as indicating that $T_c=0$ in this case, for Eq. (2.9) is only an approximation. Instead, one must go back to (2.8) and examine this to see whether in this case a solution is possible. In the next section we consider this in detail.

III. SUPERCONDUCTIVITY IN A SEMICONDUCTOR

Let us consider a somewhat idealized case of a semiconductor with a band structure as shown in Fig. 2. Before the introduction of the periodic potential which generates the gap, the energy of the states would have been given by that shown by the dashed line in the figure. Let us take the band gap as δ and for convenience we will assume the density of states near the band edge is the same in the two bands. If the lower band is completely filled and the upper empty, then the Fermi level will be halfway between the two bands. We will assume that $\hbar\omega$ is greater than δ.

Let $N(0)$ be the density of states at the Fermi surface for the system prior to the introduction of the periodic potential and let ϵ be the energy of these states measured with respect to the Fermi surface. The semiconductor band gap can then be conveniently introduced by changing the energy of each state ϵ to $\epsilon'=[\epsilon^2+(\delta/2)^2]^{1/2}$. We can now use Eq. (2.8) to see if the superconducting state can occur at any temperature. At $T=0°$K a

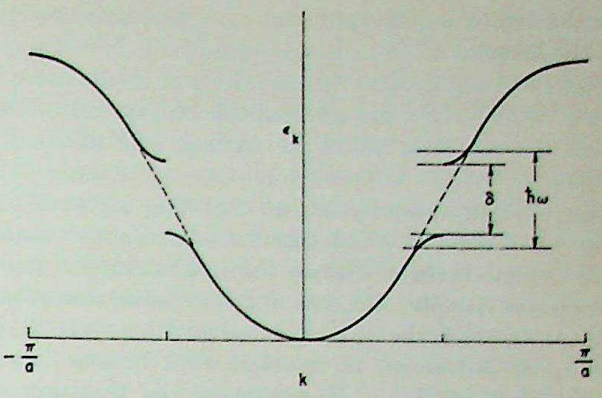

FIG. 2. Band structure of a conjugated chain semiconductor caused by the localization of the double bond. The energy $\hbar\omega$ is the energy of the transitions of the side chains.

superconducting state is possible if V is negative and

$$1<\sum_{\epsilon}\frac{|V|}{2[\epsilon^2+(\delta/2)^2]^{1/2}}, \qquad (3.1)$$

where the sum is limited by $|\epsilon'|<\hbar\omega$.

Transforming to an integral, we require

$$\frac{1}{N(0)|V|}<\int_0^x\frac{d\epsilon}{[\epsilon^2+(\delta/2)^2]^{1/2}}, \qquad (3.2)$$

where $x^2=(\hbar\omega)^2-(\delta/2)^2$ and $N(0)$ is defined above prior to the introduction of the gap.

$$\frac{1}{N(0)|V|}<\ln\left[\frac{[(\hbar\omega)^2-(\delta/2)^2]^{1/2}+\hbar\omega}{\delta/2}\right]. \qquad (3.3)$$

If $(\delta/2)^2\ll(\hbar\omega)^2$ then the criterion for obtaining the superconducting state is that

$$\delta<4\hbar\omega\exp\left[\frac{-1}{N(0)|V|}\right]. \qquad (3.4)$$

If this criterion can be satisfied, then the transition temperature can be obtained from the expression

$$\frac{1}{N(0)|V|}=\int_0^x\frac{\tanh\frac{1}{2}\beta_c\epsilon'}{\epsilon'}d\epsilon, \qquad (3.5)$$

which is the same expression for determining the temperature at which the energy gap of a superconductor becomes equal to $\delta/2$. The form of this expression is given graphically in the BCS paper. We only need note that T_c rapidly approaches the transition temperature for $\delta=0$ as $|V|N(0)$ is increased beyond that necessary to satisfy the criterion. So that if the criterion can be satisfied, then the transition temperature generally will be of the same order as the transition temperature of the metallic superconductor. We see then that a gap in the band structure does not necessarily exclude the superconducting state. Incidentally, this conclusion does

[5] Where one does not have alternating double and single bonds, but a double bond separated from the next by two single bonds, the band theory does not appear to work and one finds that the chain is an insulator instead of a metal. This empirical fact does not appear to have been explained, but seems to be a consequence of the same considerations of the metallic and insulating states discussed by N. F. Mott [Phil. Mag. 6, 287 (1961)], and W. Kohn [Phys. Rev. 133, A171 (1964)]. As this question is not quite settled we have limited ourselves to a conjugated chain which is known to behave as one would expect from the band theory.

not violate Yang's[6] statement that superconductivity or off-diagonal-long-range order (ODLRO) cannot occur in an insulator because his definition of an insulator is one in which there are no available empty states. Our point is that these states are, in fact, available in our model.

It is perhaps appropriate to note that a gap in the density of states such as that considered above would make the average side-chain induced interaction more strongly attractive because for interband transitions $(\epsilon_{k+Q}-\epsilon_k)$ would be at least δ and as can be seen from (2.6), the attractive term would thus become larger provided that $\delta<\hbar\omega$. If one takes the variation of $\langle V(Q)\rangle_{\rm av}$ with Q into account, the details of the above inequality are, of course, changed, but the general feature that the existence of superconductivity is determined by some such criterion remains.

IV. PARTICULAR EXAMPLE

As a particular example of a molecule of the type considered in Sec. II, we will consider in detail the molecule illustrated in Fig. 3. The spine is a conjugated chain of alternating double and single bonds. To this is attached a series of side-chain molecules as shown. Because of the great thickness of the benzene rings in the side chains, compared to the carbon-carbon spacing in the spine, it is not possible to attach a side chain to every carbon atom on the spine. This can be seen more clearly in Fig. 4 where the molecule is drawn to scale using the known values for the van der Waals radii of the constituent atoms. The changed periodicity of the new structure necessitates a slight modification of the wave function used in (2.1) and (2.2) above, but the modification is an obvious one which we will handle later. The side-chain molecule is part of a well-known dye molecule used for sensitizing photographic plates in the red, a diethyl-cyanine iodide, and it has been chosen because its absorption spectrum is known, and its ground and excited states are well understood.[7]

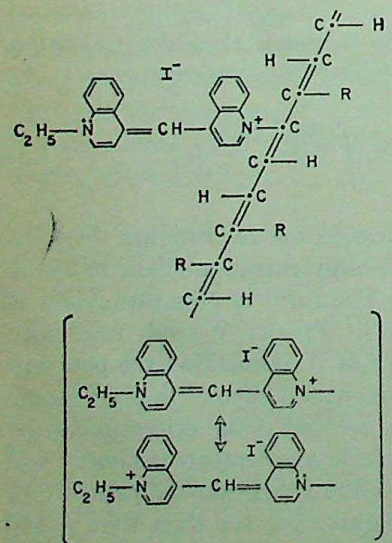

FIG. 3. Chemical structure of the proposed superconducting organic polymer. At each point R on the spine a similar side chain to the one shown is attached. These side chains are resonating hybrids of the two extreme structures shown in the inset. The positive charge resonates between the two nitrogen sites as illustrated.

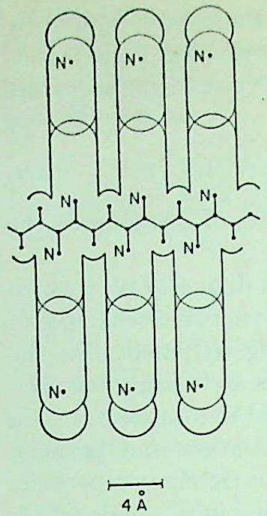

FIG. 4. Approximate scale drawing of the proposed superconducting organic polymer. The plane of the benzene rings in the side chains are oriented at right angles to the spine. The two nitrogen sites on each side chain are indicated, but the iodine site has been omitted for the sake of clarity.

Before estimating the matrix elements of the interaction of the side chains with the electrons in the spine, it is useful to consider first what effect screening will have upon the Coulomb interaction.

Screening

The Coulomb potential at a distance r from a charge which is placed in a conducting medium is screened by the rearrangement of the charges of the medium. The potential is then given approximately by $(e/r)e^{-\lambda r}$. The screening length $1/\lambda$ in a free-electron gas can be estimated by using the Thomas-Fermi method as shown by Mott and Jones.[4] From this one finds that $\lambda^2=(4me^2/\hbar^2)(3N_0/\pi)^{1/3}$ where N_0 is the number of electrons per unit volume. For the carbon atoms on the spine, one valence electron per atom is relatively free, and from the known size of the atom one can estimate N_0 and thus λ. We find that $1/\lambda$ is approximately 0.5 Å. This value varies extremely slowly with the number of valence electrons so that our choice of one free valence electron is not critical. We note then that the Coulomb interaction is screened out in an extremely short distance.

It should be noted too that screening can occur only where the charges of the medium are free to move, as for example, within an atom or along the conjugated series of atoms of the spine. Where the charges are not free to move indefinitely, then only a limited displacement of the charges occurs which merely modifies the Coulomb interaction by the dielectric constant of the medium, but does not screen it. These two cases must be born in mind in considering the Coulomb interaction and the side-chain interaction. Because the electrons are free to move in the spine one must use the screened Coulomb interaction for computing the Coulomb repulsion between the electrons in the spine. However,

the interaction between the electrons in the spine and the charges on the side chain is only partially screened because the side chain is insulated from the spine and a free movement of charge between the two cannot occur, i.e., the conjugation of the side chain does not extend to the spine. Here one must use the Coulomb interaction modified by the dielectric constant of the medium together with some screening due to the induced movement of charge in the spine.

Coulomb Repulsion

For steric reasons, it is not possible to attach a side chain to each carbon atom of the spine. Consequently, the Hamiltonian of the spine is not invariant under a displacement from one atom to the next as assumed in our earlier discussion. In our example, the unit cell is repeated only after four carbon atoms and thus, we are dealing here with a lattice with a basis of four atoms. The wave function of the spine is then

$$\phi_{km}=\frac{1}{(G)^{1/2}}\sum_{i}^{G}e^{ikR_i}\sum_{j=1}^{4}\alpha_{kj}U_m(r-r_{j,i}). \qquad (4.1)$$

R_i is now the position of the lattice point measured along the zig-zag line joining the carbon atoms and $r_{j,i}$ the position of the jth atom in the unit cell measured with respect to R_i. α_{kj} is a phase factor which one would expect would be very nearly $(1/4^{1/2})e^{ik(r_{j,i})}$, which is the value it would have if the Hamiltonian was perfectly invariant under a C−C displacement. The number of unit cells, G is now a quarter of the number of carbon atoms in the spine.

Let us now calculate the Coulomb repulsion between electrons in states given by (4.1):

$$V(Q)_{\text{Coulomb}}=\int\int\phi_{k-Q}^{*}(r_1)\phi_{k'+Q}^{*}(r_2)V(r_{12})\times\phi_{k'}(r_2)\phi_k(r_1)d^3r_1d^3r_2. \qquad (4.2)$$

Using (4.1) and the fact that the Coulomb interaction is screened from all except immediate neighboring ions, we obtain in the long-wave limit, i.e., $Q\approx 0$

$$V(0)_{\text{Coulomb}}=\frac{1}{4G}\left[\int|U(r_1-r_j)|^2V(r_{12})|U(r_2-r_j)|^2d^3r_{12}+\sum_{k=j\pm1}\int|U(r_1-r_j)|^2V(r_{12})|U(r_2-r_k)|^2d^3r_{12}\right]. \qquad (4.3)$$

The second term should be much smaller than the first because $V(r)$ is heavily screened. To a first approximation we shall ignore it compared to the first. A reasonable exact value of the dominant term could be obtained by using the known form of the sp carbon orbital and evaluating the integral, however, one can obtain a reasonable estimate of the approximate magnitude of the term by considering the electron density in the orbital as constant and occupying a volume of about half the volume of the atom. The integral is easily done and gives $6e^2/\lambda^2R^3$ where R is the van der Waals radius of the carbon atom. Using the value obtained above for λ and a van der Waals radius of 1.5 Å[8] we obtain a value of 6 eV for the integral. This seems to be a reasonable estimate for one might expect it to be comparable to the energy necessary to add one additional electron to a carbon atom. The energy necessary to form the C^- ion is known as the electron affinity A and is related to the ionization energy I and the electronegativity x of the atom by the relation[8] $(I+A)/5.4=x$ where I and A are expressed in electron volts. The ionization energy of carbon is 11.3 eV and x is 2.5 giving an electron affinity for carbon of 2.2 eV. This is of the same order of magnitude estimated above. Taking the larger value of 6 eV to be safe we find

$$V(0)_{\text{Coulomb}}\approx 1.5\text{ eV}/G. \qquad (4.4)$$

For larger values of Q the first term in (4.3) remains unchanged in the tight-binding approximation while the second term which we have neglected above is reduced by an additional factor of $\cos Qa$ where a is the carbon-carbon spacing. Over the whole range of Q, then we can take the Coulomb repulsion to be of the order of that given by (4.4)

Side-Chain Interaction

The wave function of the side chain must be modified in the same way as the wave function for the electrons of the spine. It is now

$$X_{qn}=\frac{1}{G^{1/2}}\sum_{i=1}^{G}e^{iqR_i}\sum_{j=1}^{4}\beta_{q,j}\psi_n(r-r_{j,i},\cdots). \qquad (4.5)$$

At the sites, j, where side chains are attached β is approximately $e^{iqr_{ji}}/2^{1/2}$, and zero where there are no side chains.

The side chain we have chosen is a resonating hybrid of the two extreme structures shown in the inset to Fig. 3. If the wave functions of these two extreme structures are ψ^+ and ψ^-, respectively, then the ground state, ψ_0 is $(1/\sqrt{2})(\psi_++\psi_-)$ and the excited state of interest to us, ψ_1 is the orthogonal hybrid structure $(1/\sqrt{2})(\psi_+-\psi_-)$. In the matrix element (2.4) we require $\psi_1^*\psi_0$ which is simply $\frac{1}{2}[|\psi_+|^2-|\psi_-|^2]$.

Using the new wave functions for the spine (4.1) and (4.5), Eq. (2.4) reduces to

$$V(Q)_{\text{side chains}}=\int\int\sum_{j=1}^{4}\sum_{n=-1}^{+1}\alpha_{k+Q,j}^{*}\alpha_{kj}|U_m(r-r_{ji})|^2\times V(r)e^{iQn4a\frac{1}{2}}\sum_{l=1}^{4}\beta_{q+Q,l}^{*}\beta_{q,l}\times\{|\psi_+(r_{l,i+n})|^2-|\psi_-(r_{l,i+n})|^2\}, \qquad (4.6)$$

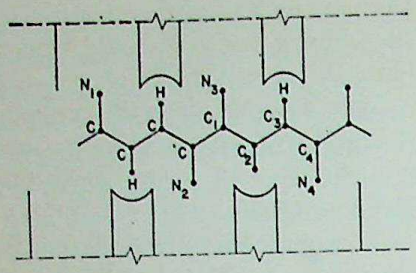

FIG. 5. Enlarged view of atoms of the spine of the proposed polymer.

where we have confined ourselves to a single atomic level m. The different k levels then describe the bands of the type discussed in Sec. III. We recall that j and l refer to each of the four atomic sites within the unit cell; and n has values 0 and ± 1 which refer to the same unit cell, i and the two adjacent cells, respectively.

In the superconducting state two types of matrix elements are important; those which describe scattering between states close to the Fermi surface with momentum transfer $Q \approx 0$ and those for scattering from one side of the Fermi surface to the other. The latter scattering involves a $Q \approx \pi/a$ because there is one electron per atom in the band originating from the fourth sp_3 orbital of the carbon atom. We shall estimate the side-chain interaction matrix element in the neighborhood of these values of the momentum transfer.

Firstly, the interaction between the spine and the iodine ion of the side chain cancels in the matrix element (4.6) because the ion is located at the same point in the two extreme structures of the hybrid. Secondly, in the ψ_- structure the positive charge is located on the nitrogen site which is remote from the spine, consequently, the interaction with this structure is weak. The only important contribution to the matrix element then, is that which is due to the positive charge on the nitrogen close to the spine in the ψ_+ structure, and the electron on each of the sites r_j.

In Fig. 5 we show an enlarged drawing of the spine and part of the side chains. In view of our earlier discussion of screening, it would be consistent to treat the interaction between the positive charge on nitrogen site N_3 (see Fig. 5) and carbon site 1 as virtually unscreened; the interaction with sites 2 and 3 as half screened and sites beyond this as completely screened. Our choice is based on the picture that the migration of negative charge from the vicinity of C_2 and C_3 towards C_1 would partially screen the field produced by the positive charge on N_3 so that at C_4 the interaction would be effectively reduced to zero. We arrive at the figure of $\frac{1}{2}$ for the screening of sites 2 and 3 because half of the atomic orbital adjacent to the nitrogen site on these sites is practically unscreened, while the opposite side is quite strongly screened. There is very little material between the nitrogen site and each of these three carbon sites, so that it seems reasonable to leave the Coulomb interaction with the dielectric constant that of free space. In Table I we tabulate the distances between the nitrogen site and each carbon site. We include also the matrix element for each site, j, in Eq. (4.5) computed for $Q=0$ and $Q=\pi/a$ using the approximate form of the α's and β's given after Eq. (4.1) and (4.5) and the unmodified Coulomb interaction limited in the manner described above.

TABLE I. Carbon-nitrogen distances and matrix elements.

Carbon site	Distance to N_3 (Å)	Matrix element $V(Q)$ (eV) $Q=0$	$Q=\pi/a$
1	1.5	0.76	0.41
2	2.5	0.47	0.11
3	3.0	0.47	0.11
4	(4.5)	0.76	0.41
▮		Total 2.46	1.04

It is reasonable to neglect the interaction with the positive charge on the remote nitrogen site on the ψ_- structure because the distance to the spine is about 14 Å and the interaction is further reduced by the dielectric constant of the material of the side chain. This dielectric constant must be similar to that of benzene which is about 2.2. This gives a total matrix element of 0.1 eV for $Q=0$ which we can neglect compared to the total computed in Table I considering the approximations we have made.

In order to calculate the side-chain induced electron-electron interaction, we must know the energy $\hbar\omega$ for the transitions of the side chains. For an isolated side-chain molecule of 1,1′-diethyl-4,4′-cyanine iodide the absorption maximum for the transition we are considering occurs at 600 mμ giving a value of 2 eV for $\hbar\omega$.[7]

In the polymer the side chains will interact with one another and change the frequency of oscillation to some extent, but as the molecules are quite well separated and the charges are quite well screened from one another, let us take the frequency to be about 2 eV nevertheless. Then the side-chain induced attraction $V \approx \langle 2V(Q)^2 \rangle_{\text{av}}/G\hbar\omega$ will be approximately -3.5 eV/G where we have taken the mean of the square of the interaction for $Q=0$ and $Q=\pi/a$ as given in Table I. This is greater than the Coulomb repulsion of 1.5 eV/G estimated in (4.4) so that the net interaction is an attractive one,

$$V \approx -2 \text{ eV}/G. \tag{4.7}$$

The reason this is so strongly attractive is that we have seen to it that the nitrogen sites lie close to the spine so that the matrix element (4.6) is large and at the same time have chosen a side chain with a fairly low-frequency transition so that $\hbar\omega$ is small.

Some idea of the superconducting transition temperature now can be obtained by estimating the density of states for the electrons in the spine, $N(0)$. This can be done in the following way. The spine itself is very similar to a conjugated polyene chain $\{CH=CH-\}_n$ except that the side chains replace certain of the hydrogens so that one can crudely estimate the density

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of states in the spine from a knowledge of it in a polyene chain. The benzene ring is essentially a triene {CH=CH−} tied back on itself in the form of a loop and can be described in terms of a simple band picture.[9,10] The first absorption at 250 mμ is believed to correspond to a transition of a π-electron from a $m=1$ to $m=2$ state which is approximately half the total width of the band. The total width of the band for benzene is thus ≈10 eV and should be approximately the same for the polyene chain. If we assume the ϵ versus k curve is parabolic up to the halfway point in the band (up to 5 eV), then the density of states of one spin at the Fermi surface is approximately $\frac{1}{5}G$ states/eV. This is probably a reasonable estimate of the density of states as it corresponds to an effective mass for the electrons in the spine of 0.7 the electron mass.

If there was no bond localization in the spine, then we could use Eq. (2.9) to estimate the superconducting transition temperature using (4.3) and the above density of states. One obtains a temperature ≈2200°K in this case! This extremely high transition temperature can be understood when it is realized that in the chosen structure it is an electronic oscillation which provides the coupling between the electrons rather than the oscillation of the nuclei as in a conventional superconductor. The simple argument of the isotope effect that the transition temperature for a phonon-coupled superconductor is proportional to $1/M^{1/2}$, where M is the isotopic mass of the nuclei indicates that for an electron-coupled superconductor the transition temperature should be a factor of $(M/m)^{1/2}$ (i.e., ≈300) times larger. This is, perhaps, too glib an answer for it is necessary to choose the over-all structure so as to obtain a sufficiently strong coupling matrix element (2.6). Our particular model illustrates this in detail.

If there is considerable bond localization in the spine, then our inequality (3.4) shows that the superconducting state can still occur if the semiconductor gap δ is somewhat less than 0.67 eV. If this is satisfied, the transition temperature in this case should still be several hundred °K.

For transition temperatures as high as this the coherence energy of the superconducting state becomes comparable to the chemical binding energy. This energy is approximately

$$W_0=-2N(0)(\hbar\omega)^2\exp[-2/(N(0)|V|)]. \quad (4.8)$$

In our example, the coherence energy is about 0.1 eV per unit cell of the chain. This is not very large, however, if one synthesized a polymer in which the density of states is large but $|V|$ is small so as to obtain the same transition temperature, then the coherence energy would become quite large. A coherence energy of as much as 1 eV per unit cell of the chain appears possible in such a polymer. As this energy is comparable to the resonance energy of the benzene ring, one should expect a considerable stabilization of the polymer on this account. It is interesting to note, too, that the destruction of superconductivity at one point in the chain raises the energy by the coherence energy per unit length times the coherence length ζ_0. The coherence length ζ_0 for these molecules should be about 30 Å as it is inversely proportional to T_c and $\zeta_0\approx10^4$ Å for conventional superconductors. Consequently, it would require a large amount of energy to destroy the superconductivity locally.

V. DISCUSSION

We believe that while the estimates for the various matrix elements in the above example are crude, they are not unrealistic. This forces upon us the remarkable conclusion that superconductivity could and should occur in structures such as this even at room temperatures. There are many other possible structures similar to the one shown involving a semiconducting chain for the spine and a dye-like molecule for the side chain which would also be superconducting. It is unlikely that our particular choice described above would be the easiest to synthesize or have the optimum superconducting properties, but it illustrates the possibility in a detailed manner.

In these molecules we should expect the usual electrical properties of a metallic superconductor, however, in order to observe such effects contact would have to be made to the ends of the spine. This could be a difficult problem to solve, but may be possible by cross-linking the spines so as to form a three-dimensional net of the filamentary molecules. Because of the large transition temperature, one would expect the critical field for the destruction of superconductivity to be very high compared to that of conventional superconductors. The highly divided filamentary structure of a bulk sample of the polymer should mask any appreciable Meissner effect. Perhaps the most interesting feature of these molecules, however, lies in the phase correlation of the electron pairs throughout the molecule. This phase correlation should impose certain restraints upon the ability of the molecule to react chemically with other such molecules. The reason is that in order to form a covalent bond, the electrons must interfere constructively in the region of positive potential. Consequently, the relative phase of the electrons forming the bond are important. Such an effect has been discussed briefly by Ambegaokar and Baratoff[11] in regard to tunneling between conventional superconductors in the Josephson effect. The superconducting state is unique in that this long-range phase correlation, "off-diagonal-long-range-order" (ODLRO)[6] distinguishes it from the normal or insulating states. This we have shown can occur even

in our structure which is essentially a one-dimensional chain, which is in striking contrast to a classical one-dimensional interacting chain such as the Ising chain which cannot exhibit long-range order.[12] Because of this ODLRO, which is a property of the molecule as a whole and the above chemical properties which are related to it, these molecules will have the property of reacting as a single entity which is precisely what London[1] was seeking to understand in regard to biologically important macromolecules.

In regard to the possible biological significance of our results, it is appropriate to mention a theorem which was established by Wigner[13] on the probability of a quantum mechanical system reproducing itself. He succeeded in showing that under two reasonable assumptions, this probability is essentially zero. The relevant assumption is that his "collision matrix" S, which generates the final state from the initial state, is assumed to be a random matrix. This assumption may be violated in the superconducting state because of the singular nature of the pair distribution associated with ODLRO. It would be useful to reexamine Wigner's theorem to see whether a *superconducting* quantum system would be capable of reproducing. The curious chemical selectivity mentioned earlier suggests that this may be the case.

ACKNOWLEDGMENTS

I should like to thank Derek Griffiths for many useful discussions and critical comments during the preparation of this work. I should also like to thank William Fairbank, Bascomb Deaver, and Felix Bloch for many stimulating conversations over the past few years related to this problem.

Note added in proof. It is appropriate to clarify a point in regard to the band structure of our chosen model. The partial charges on the nitrogen sites of the side chains produce a periodically varying potential along the spine with a fundamental period of $4a$. This produces a gap at $k=\pi/4a$ but no gap at $\pi/2a$ where the Fermi surface lies. The reason there is no gap at $\pi/2a$ is that in the tight binding approximation, where one can consider an electron as sampling the potential at all points within a particular orbital before moving on, the effective potential of each orbital may be taken as that of the appropriate carbon nucleus. From a calculation similar to that of Table II, one can easily show that there is then no Fourier component of period $2a$ and therefore no gap at the Fermi surface. The only effect which tends to produce a semiconductor gap (i.e., one at the Fermi surface) is the tendency for the double bond to localize at alternate sites. This was considered in Sec. III, where we showed that for a fixed semiconductor gap, the superconducting state should occur if a particular inequality could be satisfied. The band gap produced by bond alternation, however, is not fixed, but depends upon the amplitude of the periodic distortion; consequently, the actual gap and distortion must be determined in a self-consistent manner. In this case our earlier arguments do not apply and whether the superconducting state or the semiconductor state occurs depends upon which has the lower energy. Longuet-Higgins and Salem [Proc. Roy. Soc. (London) **A251**, 172 (1959)] have calculated the stabilization energy for a polyene with alternation of bond lengths and obtain an energy of 0.019 kcal/mole per bond ($\approx$0.001 eV/bond) for the semiconductor state. We have calculated it for the superconducting state [Eq. (4.8)] and obtain ($\approx$0.025 eV/bond) so that, in our model, the superconducting state should be favored.

Finally, our calculation has shown that a phase transition from the normal to the superconducting state should occur even in our one-dimensional system. This is unusual [see, for example, L. van Hove, Physica **16**, 137 (1950)] and one may question whether our result follows because the BCS theory, upon which it is based, is not sufficiently exact. We have some reason for believing that our conclusions are valid nevertheless, but this point requires further investigation.

Cavitation in Liquid Helium*

R. D. Finch, R. Kagiwada, M. Barmatz, and I. Rudnick
University of California, Los Angeles, California

(Received 27 January 1964)

Ultrasonic cavitation has been induced in liquid helium over the temperature range 1.2 to 2.3°K, using a pair of identical transducers. The transducers were calibrated using a reciprocity technique and the cavitation threshold was determined at 90 kc/sec. It was found that this threshold has a sharp peak at the λ point, but is at all temperatures quite low, with an approximate range of 0.001–0.01 atm. The significance of these results is discussed.

INTRODUCTION

ESTIMATES of the tensile strengths of liquids based on the assumption that it is possible to rupture molecular bonds, are considerably higher than measured values. For example, in the case of water at room temperatures such predictions of tensile strength vary from 500 to 10 000 atm while empirical values range from a fraction of an atmosphere to 280 atm.[1,2] To explain these discrepancies it has been proposed that true rupture does not occur in practice but that the applied tension is relieved by the sudden growth of relatively large cavities from microscopic nuclei. It is possible to nucleate cavitation in normal liquids by the following principal agencies: (1) minute gas or vapor filled bubbles, mechanically or electrolytically created, (2) inclusions of gas or vapor in cracks on solid surfaces, (3) solid particles unwetted by the liquid, (4) cosmic rays and radioactivity.

The last mentioned agency was first suggested since even degassed distilled liquids have relatively low thresholds.[3] There is now a growing body of phenomena in which cosmic rays and radioactivity nucleate cavitation.[4–10]

It has been pointed out by Beams[11] that the variety of possible nuclei is much restricted in liquid helium since it cannot contain bubbles filled with anything but its own vapor, it is a very efficient wetting agent and due to its low viscosity and density cannot readily carry solid particles in suspension. If cavitation in liquid helium is nucleated, then the most likely agency would be cosmic rays.

When the vapor above liquid helium I is pumped away, evaporative cooling occurs, and bubbles rise through the liquid. On reaching the λ point the bubbling stops and below this temperature the liquid, helium II, has excellent heat transfer properties, causing the disappearance of bubbles.[12] This and other manifestations of superfluidity make it especially interesting for cavitation studies.

The tensile strength of helium II was first measured by Misener and Herbert[13] in the temperature range 1.092–2.147°K using a bellows technique. They concluded that if helium II has a tensile strength it could not exceed 0.3 atm. Beams[11] measured the tensile strength of helium II by a spinning capillary method and by a piston and cylinder method at a temperature of about 1.9°K. He found the negative pressures necessary for rupture were 0.14±0.02 atm with the first method and about one-half of this value with the second method. Since these values are much less than theoretical estimates, Beams concluded that there must have been nuclei present. During preliminary experiments for the design of a liquid-helium bubble chamber Fairbank *et al.*[14] applied negative pressures of about 100 mm to helium II and obtained photographs of bubbles. No tracks were found but there were some "double" bubbles, which Fairbank *et al.* conjectured might have some relationship to quantized vortices.

The uncertainties in these experiments arose from difficulties in the measurement of small negative pressures and in the detection of the onset of cavitation. Relatively low negative pressures can be readily applied and measured using ultrasonic techniques. Further, ultrasonic cavitation gives rise to a characteristic noise which is generated by the collapse of cavities during the positive pressure phase. This noise, when amplified, affords a sensitive means of detecting the onset of cavitation.

APPARATUS

The object of the present experiments was, then, to measure the threshold of ultrasonic cavitation in

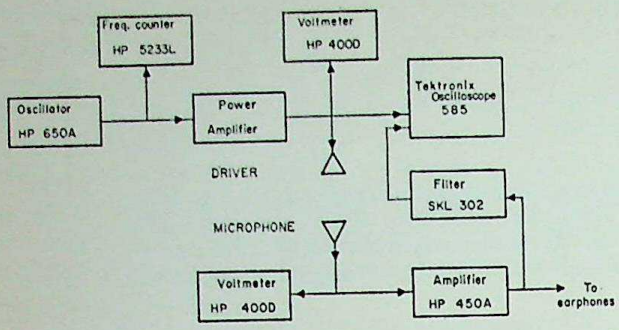

FIG. 1. Block diagram of driver and microphone circuits. With identical PZT-4 transducers as driver and microphone it was possible to deduce acoustic pressures directly from measurements of driver and microphone voltages using a reciprocity technique. The cavitation threshold was determined by the onset of noise from the microphone as heard through earphones and as displayed on an oscilloscope.

liquid helium over a temperature range. To do this two transducers were employed, one to act as a driver and the other as a microphone. A block diagram of the driving and microphone circuits is given in Fig. 1. As will be explained later, it was possible to measure acoustic pressures simply by monitoring the driver and microphone voltages, while the threshold could be detected with cavitation noise, heard in earphones and seen on an oscilloscope trace.

The two transducers were identical disks of Clevite PZT-4 ceramic, $\frac{1}{2}$ in. in radius and in thickness, with electrodes on the flat faces. The resonant frequencies of the transducers were both within 0.2% of 91.15 kc/sec in liquid helium and their capacitances were also the same to within 0.5%. Tests made with a third transducer showed that their sensitivities as microphones were also essentially the same. They were supported by threads (for vibration isolation) from a metal cradle with their opposed faces parallel, there being a separation of some 4.5 cm between them, as seen in Fig. 2. This figure also shows a carbon resistor which when immersed in helium formed one arm of a bridge so that by monitoring the off-balance current an accurate indication of temperature change was possible. The assembly shown, in Fig. 2, was suspended vertically in a standard low-temperature double-Dewar system. The assembly could be viewed through parallel vertical slits in the silvering of the Dewars. Temperatures were determined by measuring vapor pressure using Wallace and Tiernan gauges.

PRELIMINARY OBSERVATIONS OF CAVITATION

When the driving voltage was increased from zero there came a point at which intermittent bursts of noise could be hear in the earphones. This point corresponded to the cavitation threshold and could also be observed as "noise" on an oscilloscope trace of the microphone output after it had been filtered to eliminate the 91-kc/sec driving frequency. With further increase of the driving current the bursts became a steady white noise hiss, characteristic of ultrasonic cavitation, this noise being easily distinguished from that of boiling above the λ point, when the appearance of relatively large rising bubbles could be correlated with "burbling" sounds. With driving currents an order of magnitude or so higher than at threshold the cavitation noise was sufficiently loud to be heard outside the cryostat with an unaided ear. At these power levels the cavities were visible as transient bubbles of about $\frac{1}{2}$–1 mm in diameter, uniformly distributed throughout the volume between the transducers. This was the case whichever transducer was driven. It should be noted, however, that it was not easy to see these bubbles due to the low refractive index of liquid helium, and the use of photography was not practical since the cryostat could not readily accommodate optical systems of any size. With these reservations in mind it may be stated that no "double" bubbles were seen. An examination was made with an RCA 6810-A photomultiplier (cathode sensitivity: 60 μA/lumen, current gain: 12.5×10^6) but no sonoluminescence could be detected at any temperature in the operating range.

MEASUREMENT OF CAVITATION THRESHOLDS

It has been shown by Maclean[15] that using the laws of reciprocity for a four-terminal network it is possible to determine the sensitivity of a reversible transducer using only one other identical transducer. Following

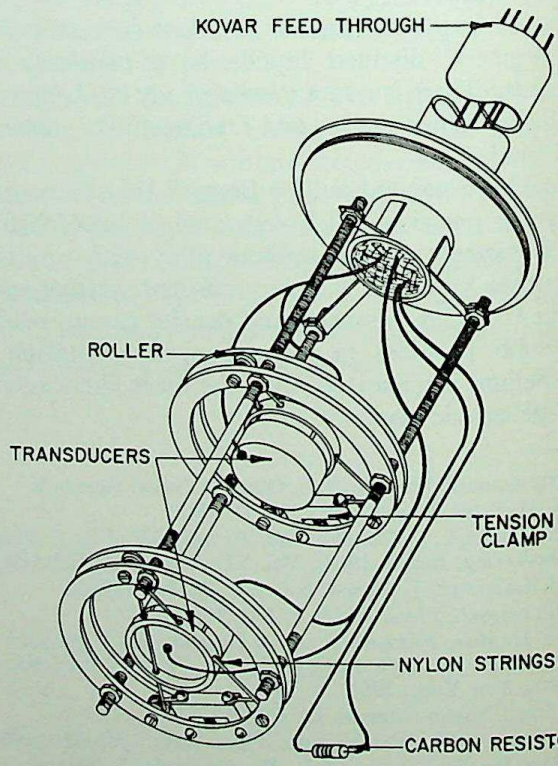

FIG. 2. Driver and microphone suspension. The PZT-4 transducers were 1 in. in diam and $\frac{1}{2}$ in. in thickness. A carbon resistor, used to determine temperature stability, is seen below the lower transducer.

[15] W. R. Maclean, J. Acoust. Soc. Am. 12, (1940).

the principles laid down by Maclean it may be shown that for two identical transducers:

$$M_0=[(V_2/I_1)(1/Q)]^{1/2}, \quad (1)$$

where M_0=sensitivity of a transducer used as a microphone in esu of potential/dyne/cm². V_2 and I_1 are, respectively, the microphone open circuit potential difference and driving current in esu as indicated in Fig. 3. Q is given by

$$Q=P_2/U_1S,$$

where P_2=acoustic pressure (dynes/cm²) at the microphone face, U_1=particle velocity at the driver face (cm/sec) and S=area of a transducer face (cm²).

In the present case a standing wave is set up in the volume between the transducers. However, since the driver has a high impedance the particle velocity U_1 will not differ appreciably from the free field particle velocity U_F. Suppose that due to the nondirectionality of the beam the pressure in a progressive wave is reduced by a factor r in traveling once between the transducers. The pressure at the microphone, P_2, will then be given by

$$P_2=2P_Fr/(1-r^2),$$

where P_F is the free field pressure at the driver. Thus, in this case,

$$Q=(\rho c/S)[2r/(1-r^2)],$$

where ρ and c are the density and sound velocity of liquid helium, respectively. In Fig. 3 C_T represents the capacitance of the transducer and C_g the capacitance of the cable. The capacitances of the cables had essentially the same value (within 0.5% of 524 μF) showing no appreciable change over the operating temperature ranges. Under these circumstances $V_2'I_1'=V_2I_1$ and $I_1'=V_1'Z_D$, where Z_D is the combined impedance of a transducer and its cable. A further test was made to confirm that Z_D did not vary with temperature. Hence, substituting in Eq. (1) for Q and taking values of V_2' and I_1' appropriate to the onset of cavitation then the

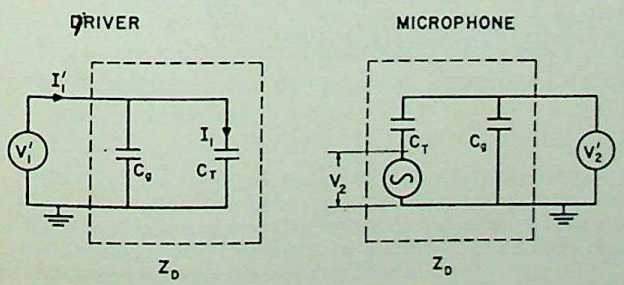

FIG. 3. Four terminal reciprocity network. C_t: capacitance of a transducer. C_g: cable capacitance. C_t and C_g were identical to within ½% for both transducers. Z_d: combined impedance of a transducer and its cable. V_2: generated microphone voltage. V_2': measured microphone voltage. I_1: actual driving current. I_1': measured driving current. V_1' measured driving voltage.

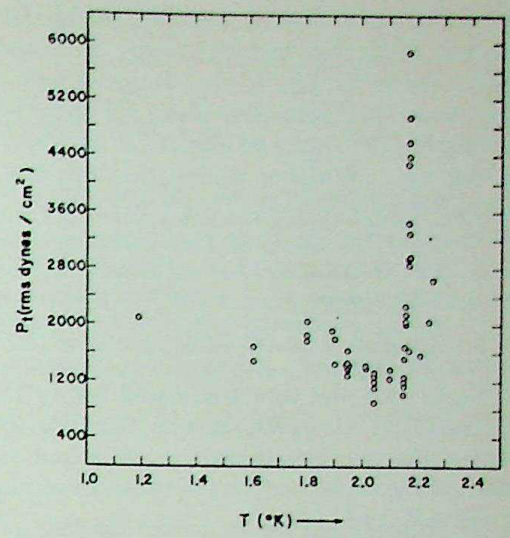

FIG. 4. Cavitation thresholds. The principal feature is a sharp peaking to a maximum value at the λ point (2.172°K). This rise all occurs within 0.01°K below the λ point. At other temperatures the threshold is comparable to the liquid pressure head, which varied smoothly from about 1600 to 1100 dynes/cm² at the driver face during the experiment.

pressure at the microphone, Pm, will be:

$$P_m=\left(\frac{\rho c}{S}\frac{2r}{(1-r^2)}\frac{10^7}{Z_D}\right)^{1/2}(V_1V_2)^{1/2},$$

where V_1 and V_2 are expressed in volts and Z_D in ohms. The pressure at the driver is then the cavitation threshold, P_t, given by

$$P_t=\frac{(1+r^2)}{2r}\left(\frac{\rho c}{S}\frac{2r}{(1-r^2)}\frac{10^7}{Z_D}\right)^{1/2}(V_1V_2)^{1/2}. \quad (2)$$

The ratio r was measured by applying pulses of about 100-μsec width to the driver, without removing the assembly from the helium, displaying the microphone voltage on the oscilloscope and measuring the ratio of successive reflected pulses. This gave r^2, which was found to be 0.69 by averaging a number of measurements, so that $r=0.83$. Then, taking $\rho=0.146$ gm/cm³, $c=2.38\times10^4$ cm/sec, $S=5.07$ cm², and $Z_D=2.75\times10^3$ Ω, from Eq. (2), $P_t=3.72\times10^3(V_1V_2)^{1/2}$. Thus the threshold at any temperature could be deduced directly from two voltage readings.

The procedure adopted was to increase the driving voltage until cavitation noise could just be heard continuously. Then by gradually reducing the driving voltage a point was reached with careful tuning where a burst of noise could not be heard more than once every five seconds. The voltage readings were then made. Certain precautions had to be observed to obtain consistent readings. To begin with, care was taken to ensure that particles of frozen air did not get into the helium. Secondly, it was found that the process of temperature stabilization (achieved by balancing the heat input from the transducer against the pumping

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

rate) had to be truly effective and the threshold measurement not made too hurriedly after stabilization. The results shown in Fig. 4 were obtained only after the temperature had remained stable for some ten to fifteen minutes. The liquid level was 7.2 cm above the face of the top transducer during this run and the bottom transducer was used as the driver.

Some calorimetric measurements were carried out by timing the temperature rise from 1.53 to 1.73°K with the sound pressure maintained just above threshold level, and then with no sound at all. The time intervals in the two cases did not differ by more than about 5%, so that the threshold could not be determined accurately. However, it was found that the total power flux due to self-heating and sound across the surface of the transducer was of the order of magnitude of one mW/cm^2.

DISCUSSION OF RESULTS

In the first place, it is necessary to establish that the phenomenon observed was truly cavitation and not boiling at the surface of the transducer. In order to boil helium II it is necessary to generate a heat current of sufficient magnitude to convert the liquid surrounding the source into helium I after which the boiling occurs. A number of workers have found that this heat current is of the order of 1 W/cm^2 [16,17] and that heat currents of the same order of magnitude are required for nucleate boiling of helium I.[18] In the present experiments the heat current at threshold was of the order of a mW/cm^2. Only when driving the transducer at full power could the heat flux have attained 1 W/cm^2. This is strong evidence that boiling was not present, a conclusion corroborated by a number of facts. For instance the white noise obtained was quite distinct from the sounds of nucleate boiling and typical of ultrasonic cavitation. Again, at high ultrasonic power transient bubbles could be seen uniformly distributed in the space between the transducers, even when driving the upper one. Whereas if the phenomenon were boiling the vapor phase might be expected to occur in the locality of the driving transducer or as stable bubbles rising from it.

A significant aspect of the results is the fact that the threshold is very low at all temperatures. Apart from the λ point the situation is similar to the case of gassy water where the threshold is determined by the static pressure head. However, the methods for estimating the tensile strength of a normal liquid may not be applicable in the case of helium, so that the values of 4 atm and over, as cited by Beams[11] should be treated with some reserve.

The other remarkable feature of the results is the sharp peak at the λ point. Many of the properties of liquid helium show pronounced effects in this vicinity, especially the thermal properties. There is for instance the well-known behavior of the specific heat which rises sharply to very high values at the λ point. One possible tentative explanation of this apparent correlation between the threshold and thermal properties can be given in terms of the Seitz theory of the bubble chamber.[19]

As has been mentioned in the Introduction, of the agents that are known to nucleate cavitation in normal liquids, cosmic rays and radioactivity are the most likely to be operative in liquid helium. That the passage of high-energy particles in liquid helium can give rise to bubbles is evidenced by the successful operation of helium bubble chambers. According to Seitz, the particle produces highly localized energy deposits or "thermal spikes" in the liquid. The thermal spikes then cause the growth of microbubbles whose equilibrium size is partly determined by the thermal properties of the liquid. Possibly it is these microbubbles which nucleate the cavitation event. If the threshold is a function of nucleus size, as in normal liquids, then a relationship might be expected between the threshold and the thermal properties.

Theory of an Optical Maser*

WILLIS E. LAMB, JR.
Yale University, New Haven, Connecticut
(Received 13 January 1964)

A theoretical model for the behavior of an optical maser is presented in which the electromagnetic field is treated classically, and the active medium is made up of thermally moving atoms which acquire nonlinear electric dipole moments under the action of the field according to the laws of quantum mechanics. The corresponding macroscopic electric polarization of the medium acts as a source for an electromagnetic field. The self-consistency requirement that a quasistationary field should be sustained by the induced polarization leads to equations which determine the amplitudes and frequencies of multimode oscillation as functions of the various parameters characterizing the maser. Among the results obtained are: threshold conditions, single-mode output as a function of cavity tuning, frequency pulling and pushing, mode competition phenomena including frequency locking, production of combination tones, and population pulsations. A more approximate discussion of maser action using rate equations is also given in which the concept of "hole burning" plays a role.

1. INTRODUCTION

THIS paper gives a theoretical description of the operation of multimode maser oscillators. The type of approach is particularly suitable for gaseous optical masers of the type suggested by Schawlow and Townes,[1] and first realized experimentally by Javan, Bennett, and Herriott,[2] but the equations should also find use in the description of some features of solid-state optical masers.

2. BASIS FOR CALCULATION

We consider a high-Q multimode cavity in which there is a given *classical* electromagnetic field acting on a material medium which consists of a collection of atoms described by the laws of quantum mechanics. No attempt is made to consider noise due to spontaneous emission and thermal, density, or quantum fluctuations. The high degree of spectral purity observed by Javan and co-workers[3] suggests that these should be good approximations.

The effect of the electromagnetic field on the atoms in the cavity is to produce a macroscopic electric polarization $\mathbf{P}(\mathbf{r},t)$ of the medium. This acts as a source for the electromagnetic field in accordance with Maxwell's equations. The conditions for self-consistency (that the field produced should be equal to the field assumed) determine the amplitudes and frequencies of the possible oscillations. The calculations will include nonlinear effects, so that phenomena of frequency pulling and pushing, mode competition, frequency locking, etc., can be described.

The thermal motion of an atom during its natural decay time may carry it several wavelengths through the standing wave pattern of the electromagnetic field. As a result, the atom "sees" Doppler-shifted optical frequencies which depend on its trajectory. This important circumstance considerably influences the behavior of the Javan-Bennett-Herriott maser. When, however, thermal motion is neglected the equations of the paper can be used in a model calculation for an ideal solid-state optical maser.

We will assume that only two atomic states a and b contribute to the maser action. As a related simplification the vector character (polarization) of the electromagnetic field will be ignored. In order to ensure that our analysis should apply, it would be desirable to have the optical configuration favor one plane of polarization, as with windows of the Brewster's angle type. The more complicated problem of a general state of polarization will be dealt with in another paper.

A cavity of the Fabry-Perot type used by Javan, Bennett, and Herriott has, of course, a continuum of modes because it is not enclosed by reflecting walls. However, it follows from work of Fox and Li[4] that there are discrete sets of quasimodes for which the diffractive leakage from the tube is small. The cavity modes of highest Q are the even symmetric ones whose circular frequencies are given by

$$\Omega_n = \pi n c/L, \tag{1}$$

where c is the velocity of light, L is the distance between the reflecting plates ($L \sim 100$ cm) and n is a large integer, typically of order 2×10^6. Fox and Li have shown that the modes of next highest Q are those possessing odd radial symmetry, which, for typical geometry differ by about 1 Mc/sec from the former modes. Our discussion will be specifically, but not inevitably, aimed at the modes of highest Q.

* This work was supported in part by the U. S. Air Force Office of Scientific Research. The main results of the paper were reported at the Third International Conference on Quantum Electronics, Paris, February, 1963. Lectures on some of the material were given at the 1963 Varenna Summer School.

3. ELECTROMAGNETIC FIELD EQUATIONS

We write Maxwell's equations in mks units as

$$\begin{aligned} &\mathrm{div}\mathbf{D}=0 \quad \mathrm{curl}\mathbf{E}=-\partial\mathbf{B}/\partial t \\ &\mathrm{div}\mathbf{B}=0 \quad \mathrm{curl}\mathbf{H}=\mathbf{J}+\partial\mathbf{D}/\partial t, \end{aligned} \tag{2}$$

where

$$\mathbf{D}=\epsilon_0\mathbf{E}+\mathbf{D}, \quad \mathbf{B}=\mu_0\mathbf{H}, \quad \mathbf{J}=\sigma\mathbf{E}. \tag{2a}$$

To an approximation whose validity will be discussed in another paper, the array of excited atoms may be regarded as a medium with an electrical state described by a macroscopic polarization $\mathbf{P}(\mathbf{r},t)$ (electric dipole moment density). In order to avoid a complicated boundary value problem, it is convenient to assume the presence of a lossy medium with an Ohmic conductivity σ adjusted to give the desired damping of a normal mode. The electric field then obeys a wave equation

$$\mathrm{curl}\,\mathrm{curl}\mathbf{E}+\mu_0\sigma\partial\mathbf{E}/\partial t+\mu_0\epsilon_0\partial^2\mathbf{E}/\partial t^2=-\mu_0\partial^2\mathbf{P}/\partial t^2. \tag{3}$$

In the subsequent calculations the main effect of the space dependence of $\mathbf{E}(x,y,z,t)$ comes from the motion of the excited atoms through the field which leads to amplitude modulation of the fields seen by the atoms. The analysis of Fox and Li for the even symmetric modes indicates that the electric field does not vary rapidly across the tube diameter. Accordingly we take only the axial variation of $\mathbf{E}$ into account. Then curl curl$\mathbf{E}$ is replaced by $-\partial^2E/\partial z^2$, where z is the axial coordinate, and E is the transverse electric field. For the nth normal mode (unnormalized), we have eigenfunctions

$$U_n(z)=\sin K_n z, \tag{4}$$

with wave number

$$K_n=n\pi/L, \tag{5}$$

where n is a large integer.

In the presence of a given polarization $P(z,t)$, quasi-stationary forced oscillations of the electric field can be expanded in normal mode eigenfunctions

$$E(z,t)=\textstyle\sum_n A_n(t)U_n(z), \tag{6}$$

where the amplitudes $A_n(t)$ obey a differential equation of a forced, damped simple harmonic oscillator

$$\frac{d^2A_n}{dt^2}+\left(\frac{\sigma}{\epsilon_0}\right)\frac{dA_n}{dt}+\Omega_n^2A_n=-\left(\frac{1}{\epsilon_0}\right)\frac{d^2P_n(t)}{dt^2}, \tag{7}$$

in which $P_n(t)$ is the space Fourier component of $P(z,t)$

$$P_n(t)=\frac{2}{L}\int_0^L dzP(z,t)\sin K_n z. \tag{8}$$

Since $P_n(t)$ will be very nearly monochromatic at an optical frequency[5] (o.f.) ν, we replace its second time derivative by $-\nu^2P_n$ on the right side of Eq. (7). Adjusting the fictional conductivity σ to give the desired Q_n of the nth mode, we write

$$\sigma=\epsilon_0\nu/Q_n. \tag{9}$$

Then $A_n(t)$ obeys

$$\frac{d^2A_n}{dt^2}+\left(\frac{\nu}{Q_n}\right)\frac{dA_n}{dt}+\Omega_n^2A_n=\left(\frac{\nu^2}{\epsilon_0}\right)P_n. \tag{10}$$

In the typical gaseous optical maser, the separation of the principal modes $\Delta\sim150$ Mc/sec is much larger than the cavity mode band width $\nu/Q\sim1$ Mc/sec. Hence we may hope to neglect time Fourier components of $A_n(t)$ and $P_n(t)$ which are at frequencies far from the cavity resonance frequency Ω_n, and write[6]

$$A_n(t)=E_n(t)\cos(\nu_n t+\varphi_n(t)), \tag{11}$$

and

$$\begin{aligned} P_n(t)=C_n(t)\cos(\nu_n t+\varphi_n(t)) \\ +S_n(t)\sin(\nu_n t+\varphi_n(t)), \end{aligned} \tag{12}$$

where the amplitudes $E_n(t)$ and phases $\varphi_n(t)$, as well as the in-phase and quadrature coefficients $C_n(t)$ and $S_n(t)$ are slowly varying functions of t which, together with the frequencies ν_n, are still to be determined. The expressions (11) and (12) are put into Eq. (10) with only the first time derivatives of $E_n(t)$ and $\varphi_n(t)$ retained. Equating the coefficients of $\cos(\nu_n t+\varphi_n)$ and $\sin(\nu_n t+\varphi_n)$ separately to zero, and further neglecting small terms involving $\nu_n\dot{E}_n/Q_n$, $\dot{\varphi}_n\dot{E}_n$ and $\nu_n\dot{\varphi}_nE_n/Q_n$, and recognizing that $\nu_n+\dot{\varphi}_n$ is very close to Ω_n, we find the self-consistency equations

$$(\nu_n+\dot{\varphi}_n-\Omega_n)E_n=-\tfrac{1}{2}(\nu/\epsilon_0)C_n \tag{13}$$

and

$$\dot{E}_n+\tfrac{1}{2}(\nu/Q_n)E_n=-\tfrac{1}{2}(\nu/\epsilon_0)S_n, \tag{14}$$

which serve to determine the amplitudes, frequencies and phases of the o.f. radiation once the polarization state of the medium is known in terms of the $E_n(t)$.

4. POLARIZATION OF THE MEDIUM

The maser action arises from the establishment of a negative temperature distribution for the two excited states a and b of the atoms constituting the medium as shown in Fig. 1. The ground state, far below a and b, is not shown. Consider what happens to an atom which at time t_0 is excited by some process (electron bombardment, collision of the second kind, absorption of resonance radiation, decay from some higher excited

[5] We adopt the convention that all symbols for frequencies should denote circular frequencies. A numerical value, e.g., 150 Mc/sec, however, denotes an ordinary frequency. A decay constant like γ_a which denotes a reciprocal life time $1/\tau_a$ often plays the role of a circular frequency. Numerical values of γ_a will be given as ordinary frequencies.

[6] The representation of an arbitrary function $A_n(t)$ in the form (11) in terms of a variable amplitude $E_n(t)$ and phase $\varphi_n(t)$ is not unique. Despite this, because of the use of the rotating wave approximation it seems possible through Eqs. (13) and (14) to determine both amplitude and phase. [The positive frequency part of (11) is a complex function very closely equal to $A_n^{(+)}(t)=E_n(t)\exp-i(\nu_n t+\varphi_n(t))$ which does have a unique amplitude and phase.]

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

state, etc.) into the upper maser state a. Let the atom be at position $\mathbf{r}_0$ at t_0, and have velocity $\mathbf{v}$. For the present, we neglect collisions, so that at time $t>t_0$ the atom will be at $\mathbf{r}=\mathbf{r}_0+\mathbf{v}(t-t_0)$. If there is an o.f. electric field $\mathbf{E}(\mathbf{r},t)$ in the cavity, the atom sees a time-dependent field $E(\mathbf{r}_0+\mathbf{v}t-\mathbf{v}t_0, t)$ for $t>t_0$. Associated with this field is a time-dependent perturbation energy whose matrix element is

$$\hbar V(t)=-\wp E(\mathbf{r}_0+\mathbf{v}t-\mathbf{v}t_0, t), \tag{15}$$

where $\wp$ (assumed real) is the matrix element for the electric dipole moment of the atom between states a and b. The perturbation causes the atomic wave function to become a time-dependent linear combination $a(t)\psi_a+b(t)\psi_b$. The quantum-mechanical average value of the electric dipole operator for the atom is $(a^*b+ab^*)\wp$.

To follow the time-dependent wave function (in the subspace of ψ_a and ψ_b), we start from the equations of time-dependent perturbation theory

$$\begin{aligned} i\dot{a}&=W_a a+V(t)b-\tfrac{1}{2}i\gamma_a a,\\ i\dot{b}&=W_b b+V(t)a-\tfrac{1}{2}i\gamma_b b, \end{aligned} \tag{16}$$

in which the radiative decay of states a and b is described by phenomenological terms containing the decay constants γ_a and γ_b for the two states. Here $\hbar W_a$ and $\hbar W_b$ are the unperturbed energies of states a and b, and the matrix element of the perturbation $V(t)$ is given by Eq. (15).

If the motion of the atom were neglected, and if the maser were working in a single cavity mode, $V(t)$ would be monochromatic, and the rotating wave approximation would allow the Eqs. (16) to be integrated exactly. Even so, there are great algebraic simplifications to be gained by going over to a density matrix description[7] of an ensemble of atoms consisting of all those of a given category which are produced during all times $t_0<t$. A theory of maser action in this case has already been given[8] which is valid when the signals are strong enough to fully saturate the transition $a\leftrightarrow b$. For multimode operation, such an exact solution can no longer be obtained. However, the simpler theory can help with the interpretation of our rather complicated equations, and it will be discussed in Secs. 16–20.

When atomic motion through the electromagnetic field is taken into account an atom does not see a monochromatic perturbation even in single-mode operation. The equations can only be solved in a perturbation expansion of the solution in powers of the $E_n(t)$. It is still advantageous to use the density matrix method, considering first only those atoms characterized by

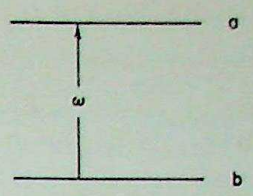

FIG. 1. Two excited energy levels a and b between which the maser action takes place. The levels have a resonance transition frequency $\omega>0$, and are given phenomenological decay constants γ_a and γ_b. The excitation of the states is described by the functions $\lambda_\alpha(r_0,t_0,v)$ which are introduced in Eq. (22).

a, $\mathbf{r}_0$, t_0, $\mathbf{v}$. The density matrix

$$\begin{aligned} \rho(a,\mathbf{r}_0,t_0,\mathbf{v},t)&=\begin{pmatrix} |a|^2 & ab^* \\ a^*b & |b|^2 \end{pmatrix}\\ &=\begin{pmatrix} \rho_{aa} & \rho_{ab} \\ \rho_{ba} & \rho_{bb} \end{pmatrix} \end{aligned} \tag{17}$$

obeys an equation of motion

$$\dot{\rho}=-i[\mathcal{H},\rho]-\tfrac{1}{2}(\Gamma\rho+\rho\Gamma), \tag{18}$$

where Γ is the diagonal matrix

$$\Gamma=\begin{pmatrix} \gamma_a & 0 \\ 0 & \gamma_b \end{pmatrix} \tag{19}$$

and the Hamiltonian matrix $\mathcal{H}$ is

$$\mathcal{H}=\begin{pmatrix} W_a & V(t) \\ V(t) & W_b \end{pmatrix}, \tag{20}$$

with $V(t)$, as given by Eq. (15), having a complicated time dependence because of atomic motion. A solution of Eq. (18) which satisfies the initial conditions

$$\rho(a,\mathbf{r}_0,t_0,\mathbf{v},t_0)=\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \tag{21}$$

is required. The average electric dipole moment corresponding to this density matrix ρ is $\wp(\rho_{ab}+\rho_{ba})$.

To obtain the macroscopic polarization $P(\mathbf{r},t)$ we have to combine the contributions of all atoms which arrive at $\mathbf{r}$ at time t, no matter when or where they were excited to state a, and also a similar contribution from atoms excited initially to state b. Let $\lambda_\alpha(\mathbf{r}_0,t_0,\mathbf{v})$ be the number of atoms excited to state $\alpha=a, b$ per unit time per unit volume. We have

$$\begin{aligned} P(\mathbf{r},t)=\wp\sum_{\alpha=a,b}\int_{-\infty}^{t}dt_0\int d\mathbf{r}_0\int d\mathbf{v}\lambda_\alpha(\mathbf{r}_0,t_0,\mathbf{v})\\ \times[\rho_{ab}(\alpha,\mathbf{r}_0,t_0,\mathbf{v},t)+\rho_{ba}(\alpha,\mathbf{r}_0,t_0,\mathbf{v},t)]\\ \times\delta(\mathbf{r}-\mathbf{r}_0-\mathbf{v}(t-t_0)). \end{aligned} \tag{22}$$

In practice, $\lambda_\alpha(\mathbf{r}_0,t_0,\mathbf{v})$ will be a slowly varying function

[7] W. E. Lamb, Jr. and T. M. Sanders, Jr., Phys. Rev. 119, 1901 (1960), especially pp. 1902–1903; L. R. Wilcox and W. E. Lamb, Jr., *ibid.* 119, 1915 (1960), especially p. 1928.

Digitized by Arya Samaj Foundation Chennai and eGangotri

of $\mathbf{r}_0$ so that it can be replaced by $\lambda_\alpha(\mathbf{r},t_0,\mathbf{v})$. After integration over $\mathbf{r}_0$

$$P(\mathbf{r},t)=\wp\sum_{\alpha=a,b}\int_{-\infty}^{t}dt_0\int d\mathbf{v} \tag{23}$$
$$\times\lambda_\alpha(\mathbf{r},t_0,\mathbf{v})[\rho_{ab}(\alpha,\ \mathbf{r}-\mathbf{v}(t-t_0),\ t_0,\ \mathbf{v},\ t)+\text{conj.}].$$

Similarly, we will have use for a density matrix describing an ensemble of atoms which arrive at $\mathbf{r}$ with velocity $\mathbf{v}$ at time t regardless of their place $\mathbf{r}_0$, time t_0 or state $\alpha=a,\ b$ of excitation. This will be denoted by

$$\rho(\mathbf{r},\mathbf{v},t)=\sum_{\alpha=a,b}\int_{-\infty}^{t}dt_0\int d\mathbf{r}_0\lambda_\alpha(\mathbf{r}_0,t_0,\mathbf{v})$$
$$\times\rho(\alpha,\mathbf{r}_0,t_0,\mathbf{v},t)\delta(\mathbf{r}-\mathbf{r}_0-\mathbf{v}t+\mathbf{v}t_0). \tag{24}$$

The density matrix resulting from (24) by integration over all velocities will be denoted by $\rho(\mathbf{r},t)$.

5. INTEGRATION OF THE EQUATIONS OF MOTION

The matrix equation of motion for the density matrix $\rho(\alpha,\mathbf{r}_0,t_0,\mathbf{v},t)$ has components

$$\dot\rho_{ab}=-i\omega\rho_{ab}-\gamma_{ab}\rho_{ab}+iV(t)(\rho_{aa}-\rho_{bb}),$$
$$\dot\rho_{aa}=-\gamma_a\rho_{aa}+iV(t)(\rho_{ab}-\rho_{ba}), \tag{25}$$
$$\dot\rho_{bb}=-\gamma_b\rho_{bb}-iV(t)(\rho_{ab}-\rho_{ba}),$$
$$\rho_{ba}=\rho_{ab}^*, \tag{26}$$

where

$$\gamma_{ab}=\tfrac{1}{2}(\gamma_a+\gamma_b) \tag{26a}$$

and

$$\omega=W_a-W_b>0. \tag{27}$$

We consider first the case of excitation to the upper maser state a. At $t=t_0$, $\rho_{aa}=1$ and $\rho_{bb}=\rho_{ab}=\rho_{ba}=0$. The solution to any desired order in the perturbation $V(t)$ can be obtained by iteration. There are contributions to $\rho_{ab}=\rho_{ba}^*$ in first and third order, to ρ_{bb} in second order, and to ρ_{aa} in zeroth and second order. Thus, in zeroth order,

$$\rho_{aa}^{(0)}(a,\mathbf{r}_0,t_0,\mathbf{v},t)=\exp-\gamma_a(t-t_0) \tag{28}$$

and the first-order contribution to ρ_{ab} is

$$\rho_{ab}^{(1)}(a,\mathbf{r}_0,t_0,\mathbf{v},t)$$
$$=i\int_{t_0}^{t}dt'V(t')\exp[(\gamma_{ab}+i\omega)(t'-t)+\gamma_a(t_0-t')], \tag{29}$$

while the third-order contribution is

$$\rho_{ab}^{(3)}(a,\mathbf{r}_0,t_0,\mathbf{v},t)=i\int_{t_0}^{t}dt'V(t')$$
$$\times[\rho_{aa}^{(2)}(a,\mathbf{r}_0,t_0,\mathbf{v},t')-\rho_{bb}^{(2)}(a,\mathbf{r}_0,t_0,\mathbf{v},t')]$$
$$\times\exp(\gamma_{ab}+i\omega)(t'-t), \tag{30}$$

where

$$\rho_{aa}^{(2)}(a,\mathbf{r}_0,t_0,\mathbf{v},t')$$
$$=-\int_{t_0}^{t'}dt''\int_{t_0}^{t''}dt'''V(t'')V(t''')$$
$$\times\{\exp[\gamma_a(t''-t')+(\gamma_{ab}+i\omega)(t'''-t'')$$
$$+\gamma_a(t_0-t''')]+\text{conj.}\}, \tag{31}$$

and similarly

$$\rho_{bb}^{(2)}(a,\mathbf{r}_0,t_0,\mathbf{v},t')$$
$$=+\int_{t_0}^{t'}dt''\int_{t_0}^{t''}dt'''V(t'')V(t''')$$
$$\times\{\exp[\gamma_b(t''-t')+(\gamma_{ab}+i\omega)(t'''-t'')$$
$$+\gamma_a(t_0-t''')]+\text{conj.}\}. \tag{32}$$

6. FIRST-ORDER THEORY

In order to convert the expression (29) for $\rho_{ab}^{(1)}$ into a macroscopic polarization, we must first calculate

$$\rho_{ab}^{(1)}(a,\mathbf{r},\mathbf{v},t)$$
$$=\int_{-\infty}^{t}dt_0\rho_{ab}^{(1)}(a,\ \mathbf{r}_0=\mathbf{r}-\mathbf{v}t+\mathbf{v}t_0,\ t_0,\ \mathbf{v},\ t) \tag{33}$$

as in Eq. (24).

The perturbation $V(t')$ acting at time t' on the atom specified by $\mathbf{r}_0$, t_0, $\mathbf{v}$ is $-(\wp/\hbar)E(\mathbf{r}_0+\mathbf{v}(t'-t_0),t')$, but for Eq. (33) we require this for an atom characterized by $\mathbf{r}_0=\mathbf{r}-\mathbf{v}t+\mathbf{v}t_0$, $\mathbf{v}$, t_0, for which the effective perturbation

$$V(t')=-(\wp/\hbar)E(\mathbf{r}-\mathbf{v}(t-t'),t') \tag{34}$$

does not depend on t_0. We may then perform the above integration over t_0 if we treat λ_a as a slowly varying function of t_0 and evaluate it at t. For the first-order terms, we have to deal with an expression of the form

$$\int_{-\infty}^{t}dt_0\int_{t_0}^{t}dt'F(t,t')e^{\gamma_a(t_0-t')}.$$

By an interchange[9] of the order of integrations this becomes

$$\int_{-\infty}^{t}dt'\int_{-\infty}^{t'}dt_0F(t,t')e^{\gamma_a(t_0-t')}=(1/\gamma_a)\int_{-\infty}^{t}dt'F(t,t'). \tag{35}$$

Let us assume now that the maser oscillator is running simultaneously in M cavity modes, so that

$$E(\mathbf{r},t)=\sum_{\mu=1}^{M}E_\mu(t)U_\mu(\mathbf{r})\cos(\nu_\mu t+\varphi_\mu(t)), \tag{36}$$

[9] In each double integral an integration is carried over the same triangular area in the t_0, t' plane.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

where $E_\mu(t)$ and $\varphi_\mu(t)$ are slowly varying functions of time. We make a rotating wave approximation by keeping only exponential factors like $\exp i(\omega-\nu_\mu)t'$ and neglecting rapidly varying exponentials like $\exp i(\omega+\nu_\mu)t'$. Then $\rho_{ab}{}^{(1)}(a,\mathbf{r},\mathbf{v},t)=$

$$-\tfrac{1}{2}i\left(\frac{\wp}{\hbar}\right)\left[\frac{\lambda_a(\mathbf{r},v,t)}{\gamma_a}\right]\sum_{\mu=1}^{M}\int_{-\infty}^{t}dt'E_\mu(t')\times U_\mu(\mathbf{r}-\mathbf{v}(t-t'))\exp-i(\nu_\mu t+\varphi_\mu(t'))\times\exp[-\gamma_{ab}+i(\nu_\mu-\omega)](t-t'). \quad (37)$$

We also assume that the amplitudes $E_\mu(t')$ and phases $\varphi_\mu(t')$ do not vary much in a time $1/\gamma_{ab}$, so that they can be evaluated at time t. With a change of variable of integration from t' to $\tau'=t-t'$, we find

$$\rho_{ab}{}^{(1)}(a,\mathbf{r},\mathbf{v},t)=-\tfrac{1}{2}i\left(\frac{\wp}{\hbar}\right)\left[\frac{\lambda_a(\mathbf{r},\mathbf{v},t)}{\gamma_a}\right]\sum_{\mu=1}^{M}E_\mu(t)\exp-i(\nu_\mu t+\varphi_\mu(t))\times\int_0^\infty d\tau' U_\mu(\mathbf{r}-\mathbf{v}\tau')\exp-(\gamma_{ab}+i(\omega-\nu_\mu))\tau'. \quad (38)$$

The corresponding contribution to the polarization of the medium is

$$P^{(1)}(a,\mathbf{r},\mathbf{v},t)=-\tfrac{1}{2}i(\wp^2/\hbar)[\lambda_a(\mathbf{r},\mathbf{v},t)/\gamma_a]\times\sum_\mu E_\mu(t)\left\{\exp-i(\nu_\mu t+\varphi_\mu)\int_0^\infty d\tau' U_\mu(\mathbf{r}-\mathbf{v}\tau')\times\exp-(\gamma_{ab}+i(\omega-\nu_\mu))\tau'\right\}+\text{conj.} \quad (39)$$

Let us first assume that the excitation rate density has the form[10]

$$\lambda_\alpha(\mathbf{r},\mathbf{v},t)=W(\mathbf{v})\Lambda_\alpha(\mathbf{r},t)\quad\alpha=a,b, \quad (40)$$

where $W(\mathbf{v})$ is the normalized velocity distribution function and $\Lambda_\alpha(\mathbf{r},t)$ is the number of atoms excited to state α per unit volume and time. Because we are assuming a spatial dependence of the electric field only on z, we may change over from a three- to a one-dimensional description. Then the velocity distribution $W(v)$ refers to the z component v of $\mathbf{v}$, and $\mathbf{r}$ is replaced by z.

It will be noted that the quantity $P(a,z,v,t)$ is proportional to $\Lambda_a(z,t)/\gamma_a$. When we now consider the contribution of atoms excited to the lower maser state b there is a complication which we did not meet in the case of a excitation. Spontaneous decay of atoms in the upper maser level a may be one of the excitation mechanisms for state b. This could be plausibly represented by replacing the excitation rate density $\lambda_b(z,v,t)$ by $\lambda_b(z,v,t)+f\gamma_a\rho_{aa}(z,v,t)$, where f is the branching ratio (decay from a to b)/(total decay from a) and λ_b now describes only "external" excitation processes.

In order to reduce somewhat the complexity of the subsequent equations we will now proceed as if f were zero. The effects of cascade excitation $a\rightarrow b$ will be discussed by an approximate method in Sec. 20. With this simplification it turns out, as one would expect, that for b excitation $P(b,z,v,t)$ is exactly like (39) except for an over-all sign change and interchange of a and b. Hence, the total polarization $P(z,v,t)=P(a,z,v,t)+P(b,z,v,t)$ is proportional to a quantity

$$N(z,t)=[(\Lambda_a(z,t)/\gamma_a)-(\Lambda_b(z,t)/\gamma_b)], \quad (41)$$

which we will call the "excitation density." This is simply the excess density of active atoms in a steady state in the absence of optical oscillations.

The first-order polarization

$$P^{(1)}(z,t)=\wp\int_{-\infty}^{\infty}dvW(v)[\rho_{ab}{}^{(1)}(a,z,v,t)+\rho_{ab}{}^{(1)}(b,z,v,t)+\text{conj.}] \quad (42)$$

is also proportional to $N(z,t)$. For use in Eqs. (13), (14) a spatial Fourier projection on the nth cavity mode is next to be made

$$P_n{}^{(1)}(t)=(2/L)\int_0^L dzP^{(1)}(z,t)U_n(z). \quad (43)$$

The product $U_n(z)U_\mu(z-v\tau')$ which occurs in (43) may be written as

$$\sin K_n z\sin K_\mu(z-v\tau')=\tfrac{1}{2}\cos\{(K_n-K_\mu)z+K_\mu v\tau'\}-\tfrac{1}{2}\cos\{(K_n+K_\mu)z-K_\mu v\tau'\}. \quad (44)$$

The last term will not contribute appreciably to the z integration (43) because the excitation density $N(z,t)$ changes little in an o.f. wavelength. Since the velocity distribution is normally an even function of v only that part of the remainder of (44) which is even in v will contribute to the polarization, i.e.,

$$\tfrac{1}{2}[\cos(K_n-K_\mu)z]\cos Kv\tau',$$

where the subscript μ has been dropped in the last factor since all of the modes considered have very nearly the same wave number $K=\nu/c$.

We find

$$P_n{}^{(1)}(t)=-\tfrac{1}{2}i(\wp^2/\hbar)\sum_\mu E_\mu\exp-i(\nu_\mu t+\varphi_\mu).N_{n-\mu}\times\int_{-\infty}^{\infty}dvW(v)[\mathfrak{D}(\omega-\nu_\mu+Kv)]+\text{conj.}, \quad (45)$$

where

$$\mathfrak{D}(\omega)=1/(\gamma_{ab}+i\omega) \quad (46)$$

[10] It would be easy to modify the theory to allow the atoms excited to state b to have a different velocity distribution from those excited to state a.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

is a convenient abbreviation for a frequently occurring denominator and where

$$N_{n-\mu}(t)=\frac{1}{L}\int_0^L dz N(z,t)\cos\left[(n-\mu)\frac{\pi z}{L}\right] \quad (47)$$

is a spatial Fourier component of the excitation density $N(z,t)$. It should be noted that (45) has a very simple interpretation in terms of Doppler shifts of the atomic transition frequencies by Kv due to the atomic motion. This simplicity will be lost when nonlinear effects are considered.

For the following detailed calculations a Maxwellian distribution

$$W(v)=(u\pi^{1/2})^{-1}\exp-(v^2/u^2) \quad (48)$$

will be assumed. The speed parameter u is related to an effective temperature T by the equation

$$\tfrac{1}{2}mu^2=k_BT, \quad (49)$$

where m is the atomic mass and k_B is the Boltzmann constant. If it should develop that a Maxwellian distribution is not realized in practice, some obvious changes in the later work can be made.

With Eq. (48) the integration over v may profitably be done on (39) before that over τ', and we find

$$P_n^{(1)}(t)=-\tfrac{1}{2}(\wp^2/\hbar Ku)\times\Big[\sum_{\mu=1}^{M}E_\mu(t)\exp-i(\nu_\mu t+\varphi_\mu(t))\times N_{n-\mu}(t)Z(\nu_\mu-\omega)+\text{conj.}\Big], \quad (50)$$

where $Z(\nu-\omega)$ is an abbreviation for

$$Z(\nu-\omega,\gamma_{ab},Ku)=iKu\int_0^\infty d\tau\exp\left[i(\nu-\omega)\tau-\gamma_{ab}\tau-\tfrac{1}{4}K^2u^2\tau^2\right], \quad (51)$$

which is a complex function well known in the theory of Doppler broadening.[11] The function Z is, in fact, a function of a single complex variable ζ

$$Z(\zeta)=2i\int_{-\infty}^{i\zeta}dt\exp-(t^2+\zeta^2), \quad (52)$$

where

$$\zeta=\xi+i\eta, \quad (53)$$

with

$$\xi=(\nu-\omega)/Ku, \quad (54)$$

and

$$\eta=\gamma_{ab}/Ku. \quad (55)$$

It is fortunate that extensive tables[12] of the real part Z_r and the imaginary part Z_i of $Z(\xi+i\eta)$ are now available.

$P_n^{(1)}(t)$ is a linear function of the complex electric fields $E_\mu(t)\exp-i\nu_\mu t-i\varphi_\mu(t)$ of the cavity modes and, apart from amplitude modulation arising from a possible slow time variation of the excitation density $N(z,t)$ contains the same frequencies as the cavity field.

To determine amplitude and frequency (or phase) of the oscillations, we write out the contributions of $P_n^{(1)}$ to C_n and S_n of Eqs. (13), (14). These are

$$S_n^{(1)}=-(\wp^2/\hbar Ku)\bar{N}Z_i(\nu_n-\omega)E_n, \quad (56)$$

$$C_n^{(1)}=-(\wp^2/\hbar Ku)\bar{N}Z_r(\nu_n-\omega)E_n, \quad (57)$$

where

$$\bar{N}=N_0(t)=(1/L)\int_0^L dzN(zt), \quad (58)$$

which will be called the "excitation," is the average of the excitation density over the cavity. We have now reverted to the notation of Eq. (51) for the Z function, but to shorten equations have dropped the parameters γ_{ab} and Ku which appear as arguments in (51).

In this approximation, without nonlinear terms, we can only hope to obtain the condition for starting of oscillations and their frequency at threshold. Furthermore, if the conditions are such that several modes can oscillate, they do so independently of each other and hence can be considered separately. The amplitude equation (14) gives

$$\dot{E}_n=-\tfrac{1}{2}(\nu/Q_n)E_\mu-\tfrac{1}{2}(\nu/\epsilon_0)S_n^{(1)} \quad (59)$$

or for a steady state, for which $\dot{E}_n=0$,

$$(\wp^2/\epsilon_0\hbar Ku)\bar{N}Z_i(\nu_n-\omega)=1/Q_n. \quad (60)$$

To first order in $\eta=\gamma_{ab}/Ku$, we have

$$Z(\xi,\eta)\simeq(1-2i\eta\xi)\left[-2\int_0^\xi e^{x^2}dx+i\pi^{1/2}\right]e^{-\xi^2}-2i\eta. \quad (61)$$

Hence for pure Doppler line shape the condition (60) for the onset of oscillations in the nth mode may be written as

$$2\pi^{1/2}[e^2/(4\pi\epsilon_0\hbar u)]\times(\wp/e)^2\lambda\bar{N}\exp-(\nu_n-\omega)^2/(Ku)^2=1/Q_n, \quad (62)$$

where $\lambda=2\pi/K$ is the wavelength. In these units,

$$e^2/(4\pi\epsilon_0\hbar c)\approx 1/137 \quad (63)$$

is the fine structure constant, so the left-hand side of (62) is the product of this and four other dimensionless factors: c/u, $2\pi^{1/2}$, $\exp-(\nu_n-\omega)^2/(Ku)^2$ and $(\wp/e)^2\lambda\bar{N}$ which is the net number of active atoms in a cylinder of cross sectional area $(\wp/e)^2$ and length λ. As the frequency detuning $\nu_n-\omega$ increases, the excitation $\bar{N}$ required to initiate oscillations increases in proportion to $\exp+(\nu_n-\omega)^2/(Ku)^2$. The frequency of oscillation is

determined by Eq. (13) in which we may set $\dot{\varphi}_n=0$ without loss of generality. Using Eq. (57), we find

$$\nu_n=\Omega_n+(\nu/2)(\wp^2\bar{N}/\epsilon_0\hbar Ku)Z_r(\nu_n-\omega). \quad (64)$$

It is convenient to use the threshold condition (60) to express $\bar{N}$ in terms of Q_n. We find

$$\nu_n-\Omega_n=\tfrac{1}{2}(\nu/Q_n)[Z_r(\nu_n-\omega)/Z_i(\nu_n-\omega)] \quad (65)$$

or in the approximation $\gamma_{ab}/Ku\ll 1$

$$\nu_n-\Omega_n=-\left(\frac{1}{\pi^{1/2}}\right)\left(\frac{\nu}{Q_n}\right)\int_0^{\xi_n}dx e^{x^2}. \quad (66)$$

If the integral (66) is expanded to first order in $\xi_n=(\nu_n-\omega)/Ku$ we obtain

$$(\nu_n-\Omega_n)/(\omega-\nu_n)\approx(1/\pi^{1/2})(\nu/QKu)=\mathcal{S}, \quad (67)$$

which implies "linear pulling," i.e., the detuning of ν_n from the cavity frequency Ω_n is proportional to the amount $\omega-\nu_n$ by which the oscillator frequency ν_n is removed from the atomic resonance frequency ω. The right-hand side of (67) ($\mathcal{S}$="stabilization factor"[13]) is about 1/800 for typical values of the parameters used in Sec. 2.

The more accurate expression (65) indicates a "nonlinear pulling" such that the oscillator frequency is nearer to the atomic frequency than it would be for linear pulling. To the next order in $(\Omega_n-\omega)/Ku$, but still for $\gamma_{ab}\ll Ku$, we find

$$(\nu_n-\Omega_n)/(\omega-\nu_n)\simeq[1+\tfrac{1}{3}(\Omega_n-\omega)^2/(Ku)^2]\mathcal{S}. \quad (68)$$

7. THIRD-ORDER TERMS

We now carry out a similar calculation for the third-order quantity $P_n^{(3)}(t)$ using Eqs. (8), (23), (30), (31) and (32). The integration of $\lambda_n(z,v,t_0)\rho_{ab}^{(3)}(a,z,t_0,v,t)$ over times t_0 of excitation involves integrals like

$$\int_{-\infty}^{t}dt_0\int_{t_0}^{t}dt'\int_{t_0}^{t'}dt''\int_{t_0}^{t''}dt'''F(t,t',t'',t''')\exp-\gamma_a(t'''-t_0),$$

which by a repeated interchange of orders of integration can be reduced to

$$(1/\gamma_a)\int_{-\infty}^{t}dt'\int_{-\infty}^{t'}dt''\int_{-\infty}^{t''}dt'''F(t,t',t'',t''').$$

Again, we keep only exponential factors in the time integration which are able to have resonance, and find after changes of variables

$$\tau'=t-t', \quad \tau''=t'-t'', \quad \tau'''-t''-t''' \quad (69)$$

and some algebraic manipulations

$$\begin{aligned}\rho_{ab}^{(3)}(z,v,t)=\tfrac{1}{8}i\wp^3\hbar^{-3}N(z,t)\sum_\mu\sum_\rho\sum_\sigma E_\mu E_\rho E_\sigma\Big\{&[\exp-i(\nu_\mu t+\varphi_\mu)+i(\nu_\rho t+\varphi_\rho)-i(\nu_\sigma t+\varphi_\sigma)]\\
&\times\int_0^\infty d\tau'\int_0^\infty d\tau''\int_0^\infty d\tau'''U_\mu(z-v\tau')U_\rho(z-v\tau'-v\tau'')U_\sigma(z-v\tau'-v\tau''-v\tau''')\\
&\times\{\exp-[(\gamma_{ab}-i\nu_\mu+i\nu_\rho-i\nu_\sigma+i\omega)\tau'+(\gamma_a+i\nu_\rho-i\nu_\sigma)\tau''+(\gamma_{ab}+i\omega-i\nu_\sigma)\tau'''\}\\
&+[\exp-i(\nu_\mu t+\varphi_\mu)-i(\nu_\rho t+\varphi_\rho)+i(\nu_\sigma t+\varphi_\sigma)]\\
&\times\int_0^\infty d\tau'\int_0^\infty d\tau''\int_0^\infty d\tau'''U_\mu(z-v\tau')U_\rho(z-v\tau'-v\tau'')U_\sigma(z-v\tau'-v\tau''-v\tau''')\\
&\times[\exp-[(\gamma_{ab}-i\nu_\mu-i\nu_\rho+i\nu_\sigma+i\omega)\tau'+(\gamma_a-i\nu_\rho+i\nu_\sigma)\tau''+(\gamma_{ab}-i\omega+i\nu_\sigma)\tau'''\Big\}\end{aligned}$$

$$+\text{same with } a \text{ and } b \text{ interchanged.} \quad (70)$$

In calculation of the Fourier projection $P_n^{(3)}(t)$ integrals of the form

$$\left(\frac{2}{L}\right)\int_0^L dz N(zt)U_n(z)U_\mu(z-v\tau')U_\rho(z-v\tau'-v\tau'')U_\sigma(z-v\tau'-v\tau''-v\tau''')$$

appear. The product of the four sine functions can be reduced to

$$\tfrac{1}{8}[\cos(K_\rho-K_\sigma+K_\mu-K_n)z\cos Kv(\tau'''-\tau')+\cos(K_\rho-K_\sigma-K_\mu+K_n)z\cos Kv(\tau'''+\tau')$$
$$+\cos(K_\rho+K_\sigma-K_\mu-K_n)z\cos Kv(\tau'+2\tau''+\tau''')].$$

[13] The term "stabilization factor" (≈cavity band width/atom bandwidth) was previously used in a theory of the ammonia beam maser (Ref. 8, p. 460) where its numerical value was large compared to unity.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

apart from rapidly oscillating terms and those odd in v. The integration over v may now be carried out, and we find

$$P_n^{(3)}(t)=\tfrac{1}{32}i\wp^4\hbar^{-3}\sum_\mu\sum_\rho\sum_\sigma E_\mu E_\rho E_\sigma\Big\{[\exp-i(\nu_\mu t+\varphi_\mu)+i(\nu_\rho t+\varphi_\rho)-i(\nu_\sigma t+\varphi_\sigma)]$$
$$\times\int_0^\infty d\tau'\int_0^\infty d\tau''\int_0^\infty d\tau'''[N_{(\rho-\sigma+\mu-n)}\exp-\tfrac{1}{4}(Ku)^2(\tau'''-\tau')^2+N_{(\rho-\sigma-\mu+n)}\exp-\tfrac{1}{4}(Ku)^2(\tau'''+\tau')^2$$
$$+N_{(\rho+\sigma-\mu-n)}\exp-\tfrac{1}{4}(Ku)^2(\tau'+2\tau''+\tau''')^2][\exp-(\gamma_{ab}-i\nu_\mu+i\nu_\rho-i\nu_\sigma+i\omega)\tau'$$
$$-(\gamma_a+i\nu_\rho-i\nu_\sigma)\tau''-(\gamma_{ab}+i\omega-i\nu_\sigma)\tau'''][\exp-i(\nu_\mu t+\varphi_\mu)-i(\nu_\rho t+\varphi_\rho)+i(v_\sigma t+\varphi_\sigma)]$$
$$\times\int_0^\infty d\tau'\int_0^\infty d\tau''\int_0^\infty d\tau'''[N_{(\rho-\sigma+\mu-n)}\exp-\tfrac{1}{4}(Ku)^2(\tau'''-\tau')^2+N_{(\rho-\sigma-\mu+n)}\exp-\tfrac{1}{4}(Ku)^2(\tau'''+\tau')^2$$
$$+N_{(\rho+\sigma-\mu-n)}\exp-\tfrac{1}{4}(Ku)^2(\tau'+2\tau''+\tau''')^2][\exp-(\gamma_{ab}-i\nu_\mu-i\nu_\rho+i\nu_\sigma+i\omega)\tau'-(\gamma_a-i\nu_\rho+i\nu_\sigma)\tau''$$
$$-(\gamma_{ab}-i\omega+i\nu_\sigma)\tau''']\Big\}+\text{same with }\gamma_a\text{ and }\gamma_b\text{ interchanged}+\text{complex conjugate.}\quad(71)$$

One of the most important characteristics of the third-order polarization is that it has constituents which oscillate at all possible frequencies $\nu_\mu\mp\nu_\rho\pm\nu_\sigma$. The combination of signs appearing here is correlated with use of the rotating wave approximation. Terms with frequencies such as $\nu_\mu+\nu_\rho+\nu_\sigma$ (near the third harmonic) are thereby neglected.

The formidable expression (71) can be simplified in either of two limiting cases: (a) no atomic motion ($u=0$), or (b) "Doppler limit," i.e., Ku much larger than γ_{ab} and various frequency differences such as $\nu_\mu+\nu_\rho-2\nu_\sigma$, etc. In the absence of atomic motion, one finds after some rewriting

$$P_n^{(3)}(t)=\tfrac{1}{32}i\hbar^{-3}\wp^4\sum_\mu\sum_\rho\sum_\sigma E_\mu E_\rho E_\sigma[\exp-i(\nu_\mu t+\varphi_\mu)+i(\nu_\rho t+\varphi_\rho)-i(\nu_\sigma t+\varphi_\sigma)]$$
$$\times[N_{(\rho-\sigma+\mu-n)}+N_{(\rho-\sigma-\mu+n)}+N_{(\rho+\sigma-\mu-n)}]\cdot\mathfrak{D}(\nu_\rho-\nu_\mu-\nu_\sigma+\omega)$$
$$\times[\mathfrak{D}_a(\nu_\rho-\nu_\sigma)+\mathfrak{D}_b(\nu_\rho-\nu_\sigma)][\mathfrak{D}(\omega-\nu_\sigma)+\mathfrak{D}(\nu_\rho-\omega)]+\text{conjugate},\quad(72)$$

where $\mathfrak{D}(\omega)$ was defined by Eq. (46) and

$$\mathfrak{D}_\alpha(\omega)=1/(\gamma_\alpha+i\omega),\quad\alpha=a,b.\quad(73)$$

The "Doppler limit" is appropriate for many possible gaseous optical masers, and for most of the remainder of this paper we will be dealing only with this case. Then

$$\exp-\tfrac{1}{4}(Ku)^2(\tau'''-\tau')^2$$

acts like a delta function of $\tau'''-\tau'$ and the integration over τ''' can be done in the form

$$\int_0^\infty d\tau'\int_0^\infty d\tau'''G(\tau',\tau''')\exp-\tfrac{1}{4}(Ku)^2(\tau'''-\tau')^2\simeq\frac{2\pi^{1/2}}{Ku}\int_0^\infty d\tau' G(\tau',\tau').\quad(74)$$

The other Gaussian factors do not have their full peaks in the range of integration, and give contributions which we neglect because they lead to expressions with higher powers of Ku in the denominator. Then, after performing the simple integrations over τ' and τ'', we find

$$P_n^{(3)}(t)=\tfrac{1}{32}i\pi^{1/2}[\wp^4/(\hbar^3Ku)]\sum_\mu\sum_\rho\sum_\sigma E_\mu E_\rho E_\sigma N_{(\rho-\sigma+\mu-n)}\{\mathfrak{D}(\omega-\tfrac{1}{2}\nu_\mu+\tfrac{1}{2}\nu_\rho-\nu_\sigma)[\mathfrak{D}_a(\nu_\rho-\nu_\sigma)+\mathfrak{D}_b(\nu_\rho-\nu_\sigma)]$$
$$\times[\exp-i(\nu_\mu-\nu_\rho+\nu_\sigma)t-i(\varphi_\mu-\varphi_\rho+\varphi_\sigma)]+\mathfrak{D}(-\tfrac{1}{2}\nu_\mu-\tfrac{1}{2}\nu_\rho+\nu_\sigma)[\mathfrak{D}_a(\nu_\sigma-\nu_\rho)+\mathfrak{D}_b(\nu_\sigma-\nu_\rho)]$$
$$\times[\exp[-i(\nu_\mu+\nu_\rho-\nu_\sigma)t-i(\varphi_\mu+\varphi_\rho-\varphi_\sigma)]]\}+\text{complex conjugate.}\quad(75)$$

By interchanging ρ and σ in the second group of terms, this may be written more compactly as

$$P_n^{(3)}(t)=\tfrac{1}{32}i\pi^{1/2}[\wp^4/(\hbar^3Ku)]\sum_\mu\sum_\rho\sum_\sigma E_\mu E_\rho E_\sigma[\exp[-i(\nu_\mu-\nu_\rho+\nu_\sigma)t-i(\varphi_\mu-\varphi_\rho+\varphi_\sigma)]]$$
$$\times[N_{(\rho-\sigma+\mu-n)}\mathfrak{D}(\omega-\tfrac{1}{2}\nu_\mu+\tfrac{1}{2}\nu_\rho-\nu_\sigma)+N_{(\sigma-\rho+\mu-n)}\mathfrak{D}(-\tfrac{1}{2}\nu_\mu-\tfrac{1}{2}\nu_\sigma+\nu_\rho)][\mathfrak{D}_a(\nu_\rho-\nu_\sigma)+\mathfrak{D}_b(\nu_\rho-\nu_\sigma)]$$
$$+\text{complex conjugate.}\quad(76)$$

8. SINGLE FREQUENCY OPERATION

For this case, the triple summation over μ, ρ, and σ reduces to a single term

$$P_n^{(3)}(t)=\tfrac{1}{16}i\pi^{1/2}\bar{N}[\wp^4/(\hbar^3\gamma_a\gamma_b Ku)]\times\gamma_{ab}[\mathfrak{D}(\omega-\nu_n)+\mathfrak{D}(0)]E_n^{(3)}\exp-i(\nu_n t+\varphi_n)+\text{complex conjugate.} \quad (77)$$

For use in Eqs. (13), (14) we need the in-phase and quadrature components of this

$$C_n^{(3)}(t)=\tfrac{1}{8}\pi^{1/2}\bar{N}[\wp^4/(\hbar^3\gamma_a\gamma_b Ku)]\times\gamma_{ab}(\omega-\nu_n)\mathfrak{L}(\omega-\nu_n)E_n^3 \quad (78)$$

and

$$S_n^{(3)}(t)=\tfrac{1}{8}\pi^{1/2}\bar{N}[\wp^4/(\hbar^3\gamma_a\gamma_b Ku)]\times[1+\gamma_{ab}^2\mathfrak{L}(\omega-\nu_n)]E_n^3, \quad (79)$$

where the Lorentzian function is denoted by

$$\mathfrak{L}(\omega-\nu)=[\gamma_{ab}^2+(\omega-\nu)^2]^{-1}. \quad (80)$$

The amplitude determining Eq. (13) is then of the form[14]

$$\dot{E}_n=\alpha_n E_n-\beta_n E_n^3, \quad (81)$$

where

$$\alpha_n=-\tfrac{1}{2}(\nu/Q_n)+\tfrac{1}{2}\nu\bar{N}[\wp^2/(\epsilon_0\hbar Ku)]Z_i(\nu_n-\omega), \quad (82)$$

$$\beta_n=(\nu/16)\pi^{1/2}\bar{N}[\wp^4/(\epsilon_0\hbar^3\gamma_a\gamma_b Ku)]\times[1+\gamma_{ab}^2\mathfrak{L}(\nu_n-\omega)]. \quad (83)$$

It is useful to employ the starting condition (60) to express the coefficients α_n, β_n (and others which appear later) in terms of a ratio

$$\mathfrak{N}=\bar{N}/\bar{N}_T \quad (84)$$

called the "relative excitation" where $\bar{N}_T$ is the excitation required for threshold oscillations when the cavity frequency Ω_n is tuned to the peak ω of the atomic resonance curve. We find

$$\alpha_n=\tfrac{1}{2}(\nu/Q_n)\{[Z_i(\nu_n-\omega)/Z_i(0)]\mathfrak{N}-1\} \quad (85)$$

and

$$\beta_n=\tfrac{1}{16}\pi^{1/2}(\nu/Q_n)[\mathfrak{N}\wp^2/(\hbar^2\gamma_a\gamma_b Z_i(0))]\times[1+\gamma_{ab}^2\mathfrak{L}(\nu_n-\omega)]. \quad (86)$$

A stable steady state occurs for an intensity of oscillations

$$E_n^2=\alpha_n/\beta_n, \quad (87)$$

which is easily related to the relative excitation with the help of Eqs. (85) and (86).

The frequency determining equation (again $\dot{\varphi}_n$ may be taken zero) is

$$\nu_n=\Omega_n-\tfrac{1}{2}(\nu/(\epsilon_0 E_n))[C_n^{(1)}+C_n^{(3)}]. \quad (88)$$

Since the frequency of oscillation ν_n will differ little from the cavity resonance frequency Ω_n, the right side of Eq. (88) may, to a sufficiently good approximation, be evaluated for $\nu_n=\Omega_n$. We may then write

$$\nu_n=\Omega_n+\sigma_n+\rho_n E_n^2, \quad (89)$$

where

$$\sigma_n=\tfrac{1}{2}\nu[\wp^2\bar{N}/(\epsilon_0\hbar Ku)]Z_r(\Omega_n-\omega) \quad (90)$$

and

$$\rho_n=+\tfrac{1}{16}\pi^{1/2}\nu[\wp^4\bar{N}/(\epsilon_0\hbar^2\gamma_a\gamma_b Ku)]\times\gamma_{ab}(\Omega_n-\omega)\mathfrak{L}(\Omega_n-\omega) \quad (91)$$

or expressing these coefficients in terms of the relative excitation (84)

$$\sigma_n=\tfrac{1}{2}(\nu/Q_n)\mathfrak{N}Z_r(\Omega_n-\omega)/Z_i(0) \quad (92)$$

and

$$\rho_n=+\tfrac{1}{16}\pi^{1/2}(\nu/Q_n)\mathfrak{N}[\wp^2/(\hbar^2\gamma_a\gamma_b Z_i(0))]\times\gamma_{ab}(\Omega_n-\omega)\mathfrak{L}(\Omega_n-\omega) \quad (93)$$

so that

$$\rho_n E_n^2=\rho_n\alpha_n/\beta_n=\tfrac{1}{2}(\nu/Q_n)\{[Z_i(\Omega_n-\omega)/Z_i(0)]\mathfrak{N}-1\}\gamma_{ab}(\Omega_n-\omega)/[2\gamma_{ab}^2+(\Omega_n-\omega)^2]. \quad (94)$$

The frequency now depends on the relative excitation (and hence on the power level) as well as on the detuning, i.e., there is frequency "pushing" as well as "pulling."

Equations (89), (92), and (94) indicate that for

$$(\Omega_n-\omega)^2+2\gamma_{ab}^2<-\gamma_{ab}(\Omega_n-\omega)Z_i(\Omega_n-\omega)/Z_r(\Omega_n-\omega) \quad (95)$$

an increase of excitation should move the frequency in the direction from ω toward Ω_n. For small detuning the right side of (95) is approximately $\frac{1}{2}\pi^{1/2}\gamma_{ab}Ku$.

The dependence of power level on excitation and detuning is given by Eq. (87). Using the value of $Z_i(\xi_n,\eta)$ for $\mathfrak{N}=0$, this equation may be written approximately as

$$(\wp E_n)^2/(\hbar^2\gamma_a\gamma_b)=8\left\{\left[\exp-\frac{(\Omega_n-\omega)^2}{(Ku)^2}\right]-\mathfrak{N}^{-1}\right\}\Big/[1+\gamma_{ab}^2\mathfrak{L}(\Omega_n-\omega)]. \quad (96)$$

This expression agrees with the linear approximation (62) in predicting threshold for relative excitation

$$\mathfrak{N}=\bar{N}/\bar{N}_T=\exp(\Omega_n-\omega)^2/(Ku)^2 \quad (97)$$

when there is detuning. Because of its derivation from a third order perturbation theory, Eq. (96) should not be trusted unless it predicts a value of the "saturation

[14] It is easy to see that the coefficient α_n is simply related to the gain (negative absorption) coefficient of the medium at frequency ν_n for small signals. However, the gain coefficient for a strong signal cannot be safely inferred from Eq. (81), since standing rather than traveling waves were assumed in its derivation. A theory of a traveling wave maser along the lines of this paper will be given later.

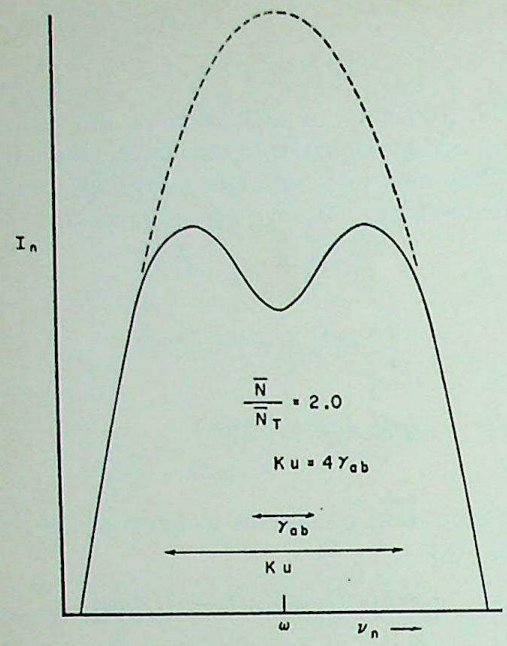

FIG. 2. Relative intensity of oscillation as a function of detuning. The solid curve, drawn for parameters $\bar{N}=2\bar{N}_T$ and $Ku=4\gamma_{ab}$ represents Eq. (96). The dotted curve indicates the Doppler gain profile of the numerator of (96).

parameter"[15]

$$I_n=\tfrac{1}{2}(\wp E_n)^2/(\hbar^2\gamma_a\gamma_b) \tag{98}$$

much less than unity.

The numerator in Eq. (96) has a peak for resonant tuning $\Omega_n=\omega$, but the denominator, which comes from the nonlinear term involving the coefficient β_n also has a peak when $\Omega_n=\omega$. Under certain conditions, the over-all curve of $E_n^2=\alpha_n/\beta_n$ versus detuning $\Omega_n-\omega$ should have a flattened peak at resonance, or even a dip between two maxima. The condition for the appearance of two maxima is

$$(\gamma_{ab}/Ku)^2<\tfrac{1}{2}\{1-\exp-[(\Omega_n{}^*-\omega)^2/(Ku)^2]\}, \tag{99}$$

where $\Omega_n{}^*-\omega$ is the detuning required to stop oscillations at the given level of excitation. The double peak[16] (see Fig. 2) should thus be seen somewhat above threshold, i.e., for relative excitation

$$\mathfrak{N}>1/[1-2(\gamma_{ab}/(Ku))^2]. \tag{100}$$

Under this degree of relative excitation, the electric field at central tuning is given by

$$I_n=\tfrac{1}{2}(\wp E_n)^2/(\hbar^2\gamma_a\gamma_b)\approx 4(\gamma_{ab}/(Ku))^2\ll 1 \tag{101}$$

so that the neglect of higher orders of perturbation theory should not be too serious, provided, as we assume, that $\gamma_{ab}\ll Ku$.

[15] The significance of this quantity is shown more clearly in Sec. 18.

[16] This dip has recently been observed. R. A. McFarlane, W. R. Bennett, and W. E. Lamb, Appl. Phys. Letters **2**, 189 (1963); A. Szöke and A. Javan, Phys. Rev. Letters **10**, 521 (1963).

TABLE I. This shows the twenty-seven possible values of the summation indices μ, ρ, σ which appear in Eq. (76) for "three"-mode oscillation. The fourth column gives the corresponding frequencies $\nu_\mu-\nu_\rho+\nu_\sigma$. The last column contains numerical values for the amount by which these frequencies exceed ν_1. We have taken $\nu_2-\nu_1=150$ Mc/sec and $\nu_3-\nu_2=151$ Mc/sec in order to simulate (but greatly to exaggerate) nonlinear pulling effects.

μ	ρ	σ	$\nu_\mu-\nu_\rho+\nu_\sigma$	Typical $\delta\nu$ (Mc/sec)
1	1	1	ν_1	0
1	1	2	ν_2	150
1	1	3	ν_3	301
1	2	1	$2\nu_1-\nu_2$	−150
1	2	2	ν_1	0
1	2	3	$\nu_1+\nu_3-\nu_2$	151
1	3	1	$2\nu_1-\nu_3$	−301
1	3	2	$\nu_1+\nu_2-\nu_3$	−151
1	3	3	ν_1	0
2	1	1	ν_2	150
2	1	2	$2\nu_2-\nu_1$	300
2	1	3	$\nu_2+\nu_3-\nu_1$	451
2	2	1	ν_1	0
2	2	2	ν_2	150
2	2	3	ν_3	301
2	3	1	$\nu_1+\nu_2-\nu_3$	−151
2	3	2	$2\nu_2-\nu_3$	−1
2	3	3	ν_2	150
3	1	1	ν_3	301
3	1	2	$\nu_2+\nu_3-\nu_1$	451
3	1	3	$2\nu_3-\nu_1$	602
3	2	1	$\nu_1+\nu_3-\nu_2$	151
3	2	2	ν_3	301
3	2	3	$2\nu_3-\nu_2$	452
3	3	1	ν_1	0
3	3	2	ν_2	150
3	3	3	ν_3	301

The physical interpretation of the dip is discussed in Secs. 17 and 18 from several points of view.

9. MULTIPLE MODE OPERATION

As the excitation is increased beyond that required for threshold of single frequency oscillation, other frequencies appear in the output of an optical maser oscillator. We wish to use the expression (76) for the nonlinear polarization in the electromagnetic field equations (13), (14) in order to account for the observed phenomena.

The first theory of an oscillator capable of multifrequency operation was given by van der Pol[17] in 1921–22. The necessary nonlinear features were provided by cubic terms in the current-voltage characteristic of a triode vacuum tube. The tank had two *R-L-C* circuits with resonance frequencies Ω_1 and Ω_2. Van der Pol found that steady oscillations could occur only at frequencies near Ω_1 or Ω_2, but that simultaneous steady operation at the two frequencies was impossible. There were hysteresis phenomena, i.e., the choice of steady state of oscillation depended on the past history of the circuit parameters.

Multicavity magnetrons provide very important

examples of oscillators capable of multifrequency operation, and here again the normal pattern is that an oscillation existing at one frequency tends to suppress one at another frequency.

There is, of course, a very close connection between van der Pol's work and ours. Where he dealt with a nonlinear triode characteristic for a vacuum tube, we are concerned with the nonlinear response of an assembly of atomic systems which obey the laws of quantum mechanics. A one-to-one correspondence can be set up between the two problems. The Fabry-Perot cavity modes correspond to the resonant constituents of van der Pol's plate circuit. As we will see, however, the effective tube characteristics of the optical medium differ qualitatively from that assumed by van der Pol, and hence the optical maser behaves in a very different fashion with respect to multifrequency operation than the oscillator in van der Pol's original model.

Rather than deal next with the case of two-frequency operation, it will perhaps save space to consider first the more general case of three-frequency operation. Probably most of the interesting phenomena for optical gaseous masers can be understood without dealing explicitly with more than three frequencies. After the more general equations have been obtained, we can easily drop terms and discuss two frequency oscillation as a special and simpler case.

We consider the expression (76) for the third-order polarization, in which the indices μ, ρ, σ, and n can each take on values 1, 2, and 3. It is useful to have the ingredients of the summands in tabular form. The entries in the fourth column of Table I give the frequencies of the various summands in $P_n^{(3)}$ identified by the μ, ρ, and σ values in the first three columns. It will be noted that besides the three frequencies ν_1, ν_2, and ν_3 assumed in the cavity excitation, there are nine additional frequencies present in the polarization of the medium. Hence there must be fields in the cavity at these new frequencies, and the desired self-consistency for three-frequency operation is in jeopardy. However, under certain conditions which will be determined later, the fields at the new frequencies do not produce appreciable effects, even though the frequencies lie close to cavity resonance, so that the calculation can be made as planned.

As is already apparent from the single-frequency case, the oscillation frequencies ν_n are typically very close to the cavity frequencies Ω_n, which are equally spaced and separated by

$$\Delta \approx 150 \text{ Mc/sec.} \tag{102}$$

Hence three of the new frequencies: $2\nu_2-\nu_3$, $\nu_1+\nu_3-\nu_2$, and $2\nu_2-\nu_1$ are very close to the three main frequencies ν_1, ν_2, and ν_3, respectively, and the corresponding terms are carried along in the calculations. The remaining frequencies can be ignored as long as the oscillator is appreciably below threshold for four-frequency operation.

Any pulling of ν_n from Ω_n is typically measured in kc/sec and hence the ν_n are not detuned from Ω_n by an appreciable fraction either of the cavity bandwidths ν/Q_n which are about 1 Mc/sec, or of the radiative decay constants γ_a, γ_b, or γ_{ab} which may be 10 Mc/sec or more. The entries in columns 5, 6, and 7 of Table II occur in the frequency denominators in Eq. (76) and are there to be combined with imaginary numbers $-i\gamma_a$, $-i\gamma_b$, or $-i\gamma_{ab}$. We have neglected the small terms arising from frequency pulling. Thus $\nu_2-\nu_1$ is freely replaced by Δ of Eq. (102), etc. A symbol like ν_{12} denotes a frequency halfway between ν_1 and ν_2, etc.,

$$\nu_{12}=\tfrac{1}{2}(\nu_1+\nu_2), \text{ etc.} \tag{103}$$

The entries in the last two columns of Table II are the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

integers characterizing the spatial Fourier components (47) of the excitation density which are needed for the evaluation of the contribution to (76) arising from the indices μ, ρ, σ, and n.

The combinations (μ,ρ,σ) which contribute third order polarizations at frequency ν_1 are (1,1,1), (1,2,2), (1,3,3), (2,2,1), and (3,3,1) while (2,3,2) gives a contribution near ν_1. Each summand has a product of two-resonance denominators. The dominant terms are (1,1,1), (1,2,2), and (1,3,3) since they do not necessarily contain inverse powers of Δ. The other terms have at least one power of Δ in the denominator. All terms will ultimately be expanded to order $1/\Delta^2$.

We find

$$P_1^{(3)}(t)=\tfrac{1}{16}i\pi^{1/2}[\wp^4/\hbar^3Ku)][\{E_1^3\bar{N}(\gamma_{ab}/(\gamma_a\gamma_b))(\mathfrak{D}(\omega-\nu_1)+\mathfrak{D}(0))$$
$$+E_1E_2^2\bar{N}(\gamma_{ab}/(\gamma_a\gamma_b))(\mathfrak{D}(\omega-\nu_{12})+\mathfrak{D}(\Delta/2))+E_1E_3^2\bar{N}(\gamma_{ab}/(\gamma_a\gamma_b))(\mathfrak{D}(\omega-\nu_2)+\mathfrak{D}(\Delta))$$
$$+E_2^2E_1[\tfrac{1}{2}N_2\mathfrak{D}(\omega-\nu_1)+\tfrac{1}{2}\bar{N}\mathfrak{D}(\Delta/2)][\mathfrak{D}_a(\Delta)+\mathfrak{D}_b(\Delta)]+E_3^2E_1[\tfrac{1}{2}N_4\mathfrak{D}(\omega-\nu_1)+\tfrac{1}{2}\bar{N}\mathfrak{D}(\Delta)]$$
$$\times[\mathfrak{D}_a(2\Delta)+\mathfrak{D}_b(2\Delta)]\}\exp-i(\nu_1t+\varphi_1)+\tfrac{1}{2}E_2^2E_3[N_2\mathfrak{D}(\omega-\nu_{12})+\bar{N}\mathfrak{D}(\Delta)][\mathfrak{D}_a(\Delta)+\mathfrak{D}_b(\Delta)]$$
$$\times\exp-i((2\nu_2-\nu_3)t-(2\varphi_2-\varphi_3))]+\text{complex conjugate.} \quad (104)$$

The in-phase coefficient $C_1^{(3)}$ is then

$$C_1^{(3)}=\tfrac{1}{8}\pi^{1/2}[\wp^4/(\hbar^3Ku)][E_1^3\bar{N}(\gamma_{ab}/(\gamma_a\gamma_b))(\omega-\nu_1)\mathfrak{L}(\omega-\nu_1)+E_1E_2^2\bar{N}(\gamma_{ab}/(\gamma_a\gamma_b))[(\omega-\nu_{12})\mathfrak{L}(\omega-\nu_{12})+(2/\Delta)]$$
$$+E_1E_3^2\bar{N}(\gamma_{ab}/(\gamma_a\gamma_b)[(\omega-\nu_2)\mathfrak{L}(\omega-\nu_2)+(1/\Delta)]+E_2^2E_1N_2\gamma_{ab}(\omega-\nu_1+\Delta)\mathfrak{L}(\omega-\nu_1)/\Delta^2$$
$$+\tfrac{1}{4}E_3^2E_1N_4\gamma_{ab}(\omega-\nu_1+2\Delta)\mathfrak{L}(\omega-\nu_1)/\Delta^2+E_2^2E_3\Delta^{-2}\{N_2\gamma_{ab}(\omega-\nu_{12}+\Delta)\mathfrak{L}(\omega-\nu_{12})\cos\psi$$
$$+[N_2(\gamma_{ab}^2-(\omega-\nu_{12})\Delta)\mathfrak{L}(\omega-\nu_{12})-\bar{N}]\sin\psi\}], \quad (105)$$

where the "relative phase angle" ψ is defined as

$$\psi=(2\nu_2-\nu_1-\nu_3)t+(2\varphi_2-\varphi_1-\varphi_3). \quad (106)$$

The quadrature coefficient $S_1^{(3)}$ is given by

$$S_1^{(3)}=\tfrac{1}{8}\pi^{1/2}[\wp^4/(\hbar^3Ku)]\{E_1^3\bar{N}[\gamma_{ab}^2\mathfrak{L}(\omega-\nu_1)+1]/(\gamma_a\gamma_b)+E_1E_2^2\bar{N}[\gamma_{ab}^2\mathfrak{L}(\omega-\nu_{12})+4\gamma_{ab}^2\Delta^{-2}]/(\gamma_a\gamma_b)$$
$$+E_1E_3^2\bar{N}[\gamma_{ab}^2\mathfrak{L}(\omega-\nu_2)+\gamma_{ab}^2\Delta^{-2}]/(\gamma_a\gamma_b)+E_2^2E_1\Delta^{-2}[N_2(\gamma_{ab}^2-(\omega-\nu_1)\Delta)\mathfrak{L}(\omega-\nu_1)-2\bar{N}]$$
$$+\tfrac{1}{4}E_3^2E_1\Delta^{-2}[N_4(\gamma_{ab}^2-2(\omega-\nu_1)\Delta)\mathfrak{L}(\omega-\nu_1)-2\bar{N}]+E_2^2E_3\Delta^{-2}[[N_2(\gamma_{ab}^2-(\omega-\nu_{12})\Delta)\mathfrak{L}(\omega-\nu_{12})-\bar{N}]\cos\psi$$
$$-N_2\gamma_{ab}(\omega-\nu_{12}+\Delta)\mathfrak{L}(\omega-\nu_{12})\sin\psi]\}. \quad (107)$$

There are similar expressions for the other coefficients which appear in the self-consistent field equations (13) and (14).

The generalization of Eq. (81) takes the form

$$\dot{E}_1=\alpha_1E_1-\beta_1E_1^3-\theta_{12}E_1E_2^2-\theta_{13}E_1E_3^2-(\eta_{23}\cos\psi+\xi_{23}\sin\psi)E_2^2E_3,$$
$$\dot{E}_2=\alpha_2E_2-\beta_2E_2^3-\theta_{21}E_2E_1^2-\theta_{23}E_2E_3^2-(\eta_{13}\cos\psi+\xi_{23}\sin\psi)E_1E_2E_3, \quad (108)$$
$$\dot{E}_3=\alpha_3E_3-\beta_3E_3^3-\theta_{31}E_3E_1^2-\theta_{32}E_3E_2^2-(\eta_{21}\cos\psi+\xi_{21}\sin\psi)E_2^2E_1.$$

The coefficients α_n and β_n were already calculated in the single-frequency case, and are given by Eqs. (82) and (83). The other coefficients are given by

$$\theta_{12}=\tfrac{1}{16}\pi^{1/2}\nu(\wp^4/(\epsilon_0\hbar^3Ku))\{\bar{N}\gamma_{ab}^2(\gamma_a\gamma_b)^{-1}[\mathfrak{L}(\omega-\nu_{12})+4\Delta^{-2}]-2\bar{N}\Delta^{-2}+N_2\Delta^{-2}[\gamma_{ab}^2-(\omega-\nu_1)\Delta]\mathfrak{L}(\omega-\nu_1)\}, \quad (109)$$

$$\theta_{13}=\tfrac{1}{16}\pi^{1/2}\nu(\wp^4/(\epsilon_0\hbar^3Ku))\{\bar{N}\gamma_{ab}^2(\gamma_a\gamma_b)^{-1}[\mathfrak{L}(\omega-\nu_2)+\Delta^{-2}]-\tfrac{1}{2}\bar{N}\Delta^{-2}+\tfrac{1}{4}N_4\Delta^{-2}[\gamma_{ab}^2-2(\omega-\nu_1)\Delta]\mathfrak{L}(\omega-\nu_1)\}, \quad (110)$$

$$\eta_{23}=\tfrac{1}{16}\pi^{1/2}\nu(\wp^4/(\epsilon_0\hbar^3Ku\Delta^2))\{N_2[\gamma_{ab}^2-(\omega-\nu_{12})\Delta]\mathfrak{L}(\omega-\nu_{12})-\bar{N}\}, \quad (111)$$

$$\xi_{23}=-\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3Ku\Delta^2)^{-1}N_2\gamma_{ab}(\omega-\nu_{12}+\Delta)\mathfrak{L}(\omega-\nu_{12}), \quad (112)$$

$$\theta_{21}=\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3Ku)^{-1}\{\bar{N}\gamma_{ab}^2(\gamma_a\gamma_b)^{-1}[\mathfrak{L}(\omega-\nu_{12})+4\Delta^{-2}]+N_2\Delta^{-2}[\gamma_{ab}^2+(\omega-\nu_2)\Delta]\mathfrak{L}(\omega-\nu_2)-2\bar{N}\Delta^{-2}\}, \quad (113)$$

$$\theta_{23}=\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3Ku)^{-1}\{\bar{N}\gamma_{ab}^2(\gamma_a\gamma_b)^{-1}[\mathfrak{L}(\omega-\nu_{23})+4\Delta^{-2}]+N_2\Delta^{-2}[\gamma_{ab}^2-(\omega-\nu_2)\Delta]\mathfrak{L}(\omega-\nu_2)-2\bar{N}\Delta^{-2}\}, \quad (114)$$

$$\xi_{13}=-\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3Ku\Delta^2)^{-1}N_2\gamma_{ab}[(\omega-\nu_{23}-\Delta)\mathfrak{L}(\omega-\nu_{23})+(\omega-\nu_{12}+\Delta)\mathfrak{L}(\omega-\nu_{12})], \quad (115)$$

$$\eta_{13}=\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3Ku\Delta^2)^{-1}\{N_2[\gamma_{ab}^2+(\omega-\nu_{23})\Delta]\mathfrak{L}(\omega-\nu_{23})+N_2[\gamma_{ab}^2-(\omega-\nu_{12})\Delta]\mathfrak{L}(\omega-\nu_{12})+2\bar{N}\}, \quad (116)$$

$$\theta_{31}=\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3Ku)^{-1}\{\bar{N}\gamma_{ab}^2(\gamma_a\gamma_b)^{-1}[\mathfrak{L}(\omega-\nu_2)+\Delta^{-2}]+\tfrac{1}{4}N_4\Delta^{-2}[\gamma_{ab}^2+2(\omega-\nu_3)\Delta]\mathfrak{L}(\omega-\nu_3)-\tfrac{1}{2}\bar{N}\Delta^{-2}\}, \quad (117)$$

$$\theta_{32}=\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3Ku)^{-1}\{\bar{N}\gamma_{ab}^2(\gamma_a\gamma_b)^{-1}[\mathfrak{L}(\omega-\nu_{23})+4\Delta^{-2}]+N_2\Delta^{-2}[\gamma_{ab}^2+(\omega-\nu_3)\Delta]\mathfrak{L}(\omega-\nu_3)-2\bar{N}\Delta^{-2}\}, \quad (118)$$

$$\eta_{21}=\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3Ku\Delta^2)^{-1}\{N_2[\gamma_{ab}^2+(\omega-\nu_{23})\Delta]\mathfrak{L}(\omega-\nu_{23})-\bar{N}\}, \quad (119)$$

$$\xi_{21}=-\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3Ku\Delta^2)^{-1}N_2\gamma_{ab}(\omega-\nu_{23}-\Delta)\mathfrak{L}(\omega-\nu_{23}). \quad (120)$$

$$\tau_{21}=-\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3Ku)^{-1}\{\bar{N}(\gamma_a\gamma_b)^{-1}[\gamma_{ab}(\omega-\nu_{12})\mathfrak{L}(\omega-\nu_{12})-2\gamma_{ab}\Delta^{-1}]+N_2\Delta^{-2}\gamma_{ab}(\omega-\nu_2-\Delta)\mathfrak{L}(\omega-\nu_2)\}, \quad (126)$$

$$\tau_{23}=-\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3Ku)^{-1}\{\bar{N}(\gamma_a\gamma_b)^{-1}[\gamma_{ab}(\omega-\nu_{23})\mathfrak{L}(\omega-\nu_{23})+2\gamma_{ab}\Delta^{-1}]+N_2\Delta^{-2}\gamma_{ab}(\omega-\nu_2+\Delta)\mathfrak{L}(\omega-\nu_2)\}, \quad (127)$$

$$\tau_{31}=-\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3Ku)^{-1}\{\bar{N}(\gamma_a\gamma_b)^{-1}[\gamma_{ab}(\omega-\nu_2)\mathfrak{L}(\omega-\nu_2)-\gamma_{ab}\Delta^{-1}]+\tfrac{1}{4}N_4\Delta^{-2}\gamma_{ab}(\omega-\nu_3-2\Delta)\mathfrak{L}(\omega-\nu_3)\}, \quad (128)$$

$$\tau_{32}=-\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3Ku)^{-1}\{\bar{N}(\gamma_a\gamma_b)^{-1}[\gamma_{ab}(\omega-\nu_{23})\mathfrak{L}(\omega-\nu_{23})-2\gamma_{ab}\Delta^{-1}]+N_2\Delta^{-2}\gamma_{ab}(\omega-\nu_3-\Delta)\mathfrak{L}(\omega-\nu_3)\}. \quad (129)$$

10. TWO-FREQUENCY OPERATION

We may here drop all terms referring to the third frequency ν_3. There are now no "combination tones" in near resonance with Ω_1 and Ω_2. The amplitudes E_1 and E_2 are determined by the differential equations

$$\dot{E}_1=\alpha_1E_1-\beta_1E_1^3-\theta_{12}E_1E_2^2,$$
$$\dot{E}_2=\alpha_2E_2-\theta_{21}E_2E_1^2-\beta_2E_2^3, \quad (130)$$

where the coefficients α_n, β_n, θ_{12}, and θ_{21} are now given by Eqs. (82), (83), (109), and (113).

Introducing the squared amplitudes

$$X=E_1^2 \quad \text{and} \quad Y=E_2^2, \quad (131)$$

Eqs. (126) become

$$\dot{X}=2X(\alpha_1-\beta_1X-\theta_{12}Y),$$
$$\dot{Y}=2Y(\alpha_2-\theta_{21}X-\beta_2Y). \quad (132)$$

The condition for a steady state of oscillation is $\dot{X}=0$, $\dot{Y}=0$ and may represent graphically in an X-Y plane by the point of intersection of the two straight lines

$$L_1: \quad \beta_1X+\theta_{12}Y=\alpha_1,$$
$$L_2: \quad \theta_{21}X+\beta_2Y=\alpha_2, \quad (133)$$

if there is one in the first quadrant, together with the single-frequency solutions

$$X=\alpha_1/\beta_1, \quad Y=0 \quad \text{and} \quad X=0, \quad Y=\alpha_2/\beta_2. \quad (134)$$

The differential equations (132) allow us to follow the temporal behavior of the state X, Y of oscillation in the phase plane X, Y. Through any point in this plane (except stationary points) there passes a curve which indicates the path followed by the representative point (X,Y) on its way to a stable state of oscillation. The parametric equations of the curves are $X=X(t)$, $Y=Y(t)$ with the time t as parameter. From the differential equations it is seen that each curve has a vertical tangent when it crosses the first of the straight lines (133), and a horizontal tangent when it crosses the second straight line. This principle facilitates a very simple, if qualitative, graphical integration of the differential equations (132) for the paths of the phase points in the cases discussed below.

The various possibilities are depicted[18] in Figs. 3–5 where it is assumed that both α_1 and α_2 are positive,

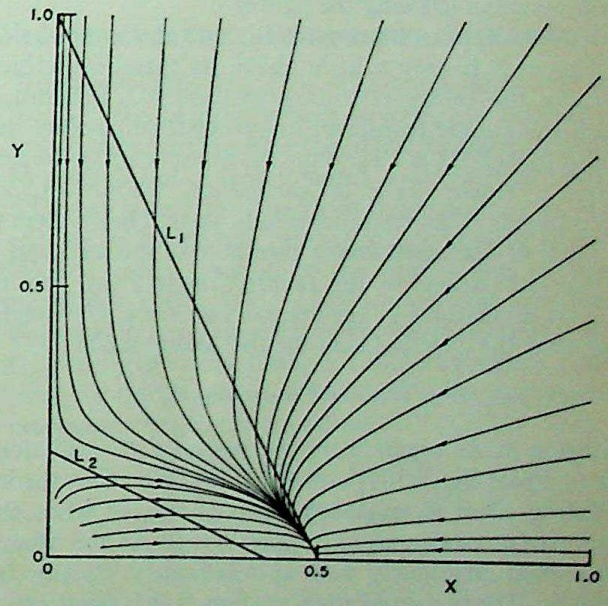

FIG. 3. Phase curves showing the transient behavior of two-mode oscillation. The straight lines L_1 and L_2 of Eq. (133) are taken to have coefficients $\alpha_1=1$, $\alpha_2=0.4$, $\beta_1=\beta_2=2$, $\theta_{12}=\theta_{21}=1$. The slope of a phase curve is zero when it crosses line L_2 and infinite when it crosses line L_1. Although both modes are above threshold, the favored X oscillation is able to quench the Y oscillation.

[18] The phase paths of Figs. 2-4 were kindly integrated on an analog computer by Dr. B. Wise of the Engineering Science Laboratory, Oxford, to whom the author is very indebted.

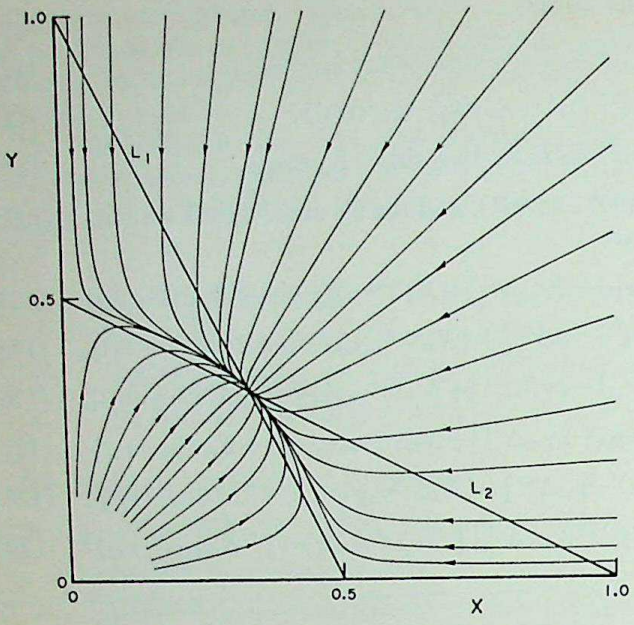

FIG. 4. Diagram similar to Fig. 3, except that the gain parameter for the second mode has been raised to $\alpha_2=1$. Simultaneous oscillations at both frequencies occur at the single stable steady state. Both Figs. 3 and 4 correspond to "weak" coupling.

so that the two modes are individually above threshold. The coefficients β_n are necessarily positive if the optical medium is an active one, and while the mode competition coefficients θ could conceivably have the opposite sign, they have been assumed positive (and equal to each other) in drawing the figures.

Figure 3 applies when mode 1 is well above threshold, but mode 2 is only a little above its threshold, either because the cavity resonance frequency Ω_2 is detuned from the atomic transition frequency ω or possibly because $Q_2<Q_1$. It is clear that the point $(\alpha_1/\beta_1,0)$ represents a stable state of oscillation, while $(0,\alpha_2/\beta_2)$ corresponds to an unstable steady state. Hence there is a range of operation above threshold of modes 1 and 2 where oscillations in the favored mode 1 are able to inhibit oscillations at the second frequency. One might say that the effective gain for the second mode

$$\alpha_2'=\alpha_2-\theta X=\alpha_2-\theta\alpha_1/\beta_1$$

is being made negative by the presence of oscillations at ν_1. From Eqs. (109) and (113) it is seen that the inhibiting effect is enhanced when $\nu_{12}=\omega$, or when the two cavity modes are on opposite sides of the atomic transition frequency, and approximately equally far from it. The physical interpretation of this effect which clearly involves o.f. saturation will be brought out more clearly in Sec. 18.

As the excitation increases, α_2' will eventually become positive, and the relevant diagrams are Figs. 4 and 5. The former applies when $\beta_1\beta_2>\theta^2$ (weak coupling) and the latter when $\beta_1\beta_2<\theta^2$ (strong coupling).

The two cases of weak and strong coupling give very different behaviors. For weak coupling the point of intersection of the two straight lines gives stable steady-state operation, while the single-frequency operating points are unstable. The optical maser oscillates simultaneously at two frequencies under these conditions. For strong coupling, on the other hand, the point of intersection of the two straight lines represents an unstable steady state and would not be realized in practice. All other points in the state diagram evolve into one or the other of the single-frequency operation points. Which of the two is reached depends on the past history of the state of oscillation. In other words, there is hysteresis.

In the Doppler broadened gaseous optical maser Eqs. (83), (109), and (113) indicate that the case of weak coupling is naturally favored, since $\beta_1\beta_2$ tends to be greater than $\theta_{12}\theta_{21}$. Hence, with possible exceptions such as the one discussed in the next section, double frequency operation is preferred. However, when van der Pol's theory of a double resonance feed back triode oscillator is transcribed into our notation, one finds that in his case $\theta=2\beta$. This results from his assumption of a term $(E_1\cos\nu_1 t+E_2\cos\nu_2 t)^3$ in the triode output current. After discarding terms which have frequencies far from ν_1 and ν_2, this becomes

$$\tfrac{3}{4}(E_1^3+2E_1E_2^2)\cos\nu_1 t+\tfrac{3}{4}(E_2^3+2E_2E_1^2)\cos\nu_2 t,$$

which leads to the stated relation $\theta=2\beta$. The van der Pol oscillator prefers operation at a single frequency and exhibits hysteresis phenomena, as in the case of strong coupling. Evidently the atomic medium of an optical

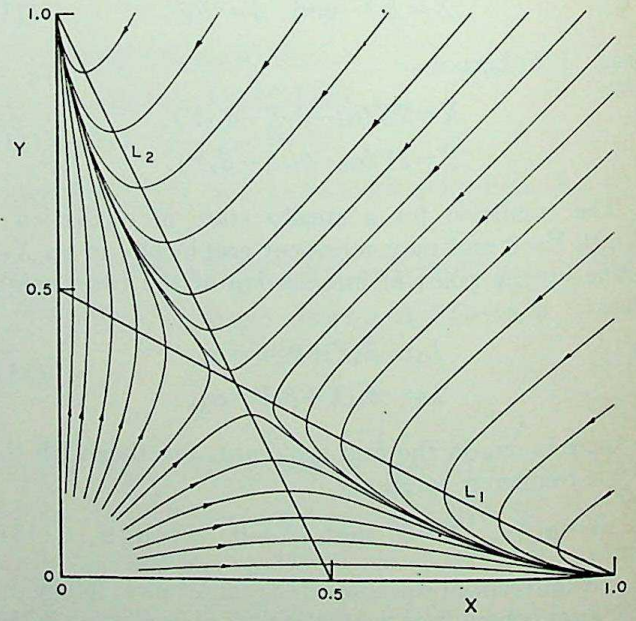

FIG. 5. Phase curves showing the transient behavior of two-mode oscillation when the straight lines L_1 and L_2 of Eq. (133) are taken to have the coefficients $\alpha_1=\alpha_2=1$, $\beta_1=\beta_2=1$, $\theta_{12}=\theta_{21}=2$ (strong coupling). There are two possible stable steady states, each corresponding to single-frequency operation. The particular state reached depends on the initial conditions. Hysteresis phenomena would occur if the parameters characterizing the oscillator were slowly changed.

maser differs from van der Pol's triode oscillator because the nonlinear response of the atoms to frequencies ν_1 and ν_2 has a resonant character not assumed of the triode. It will become clearer from the discussion of Sec. 18 that two groups of atoms with different velocity are driving the two oscillations with only a limited degree of interference. One could easily make a comparable model of the van der Pol type with *two* triodes each with its own tank circuit. A small amount of coupling between the two oscillators would produce intermode effects described by the θ coefficients in the weak-coupling case.

There is also a further case in which the two straight lines coincide, i.e., when $\alpha_1/\alpha_2=\beta_1/\theta=\theta/\beta_2$. In that case, there is a neutral steady state for the representative point lying anywhere on the line within the first quadrant. In practice, the state of operation when this condition is nearly satisfied should be very sensitive to microphonic disturbances.

11. INTENSITIES AND FREQUENCIES IN TWO-MODE OPERATION

The two-mode steady-state solution of (130) is given by

$$\begin{aligned} E_1^2&=(\beta_2\alpha_1-\theta_{12}\alpha_2)/(\beta_1\beta_2-\theta_{12}\theta_{21}),\\ E_2^2&=(\beta_1\alpha_2-\theta_{21}\alpha_1)/(\beta_1\beta_2-\theta_{12}\theta_{21}),\end{aligned} \tag{135}$$

where, as explained before, the right-hand sides may be evaluated for $\nu_1=\Omega_1$ and $\nu_2=\Omega_2$ without appreciable error. The frequencies are obtained by dropping inapplicable terms from Eqs. (121)–(123). We may set $\dot\varphi_1=\dot\varphi_2$ without loss of generality, and find

$$\begin{aligned} \nu_1&=\Omega_1+\sigma_1+\rho_1E_1^2+\tau_{12}E_2^2,\\ \nu_2&=\Omega_2+\sigma_2+\rho_2E_2^2+\tau_{21}E_1^2,\end{aligned} \tag{136}$$

where the right-hand sides are to be evaluated for $\nu_n=\Omega_n$, and the E_n^2 are as given in (135).

These equations are fairly complicated, and probably can be used in full generality only for a numerical analysis[19] of very detailed data on optical maser operation. Such a study would be simplified if the values of the E's could be inferred experimentally, since that would effectively reduce the dependence of Eqs. (136) on cavity tuning. For the present we will merely work out the frequencies for the important case of "midtuning" where $\nu_{12}=\frac{1}{2}(\nu_1+\nu_2)=\omega$, $\omega-\nu_1=\frac{1}{2}\Delta$ and $\nu_2-\omega=\frac{1}{2}\Delta$. If we regard Δ as being much greater than the γ's, we then may approximate the coefficients appearing in Eqs. (135)–(136) as follows:

$$\beta_1\simeq\beta_2\simeq\theta_{12}\simeq\theta_{21}\simeq\tfrac{1}{16}\pi^{1/2}\wp^4\bar N(\epsilon_0\hbar^3Ku\gamma_a\gamma_b)^{-1}=\beta, \tag{137}$$

$$\rho_2\approx-\rho_1=2\gamma_{ab}\Delta^{-1}\beta=\rho, \tag{138}$$

$$\tau_{12}\approx-\tau_{21}\approx-\rho, \tag{139}$$

and assuming $Q_1=Q_2=Q$, the gain parameters become

$$\alpha_1\approx\alpha_2\simeq\tfrac{1}{2}\nu Q_n^{-1}\{\Re[Z_i(\tfrac{1}{2}\Delta)/Z_i(0)]-1\}=\alpha. \tag{140}$$

The intensities are $E_1^2=E_2^2=\frac{1}{2}\alpha/\beta$, and the frequencies are

$$\begin{aligned} \nu_1&=\Omega_1+\sigma_1-\rho\alpha/\beta,\\ \nu_2&=\Omega_2+\sigma_2+\rho\alpha/\beta,\end{aligned} \tag{141}$$

so that the beat frequency is

$$\nu_2-\nu_1\simeq\Delta+(\sigma_2-\sigma_1)+4\gamma_{ab}\alpha/\Delta. \tag{142}$$

It will be seen that in the approximations of Eq. (137) we have $\beta_1\beta_2=\theta_{12}\theta_{21}$, and hence in order to decide whether the coupling is "weak" or "strong" it is necessary to evaluate the coefficients β and θ more exactly. In case of exact midtuning, one finds that $\beta^2-\theta^2$ has the same sign as $\bar N+N_2$. Ordinarily this would be positive since $\bar N$ must be positive for oscillations to occur. However, it is possible in principle to arrange to have $\bar N>0$ and $N_2<-\bar N$ by having $N(z)>0$ in the middle two quarters of the tube length, and $N(z)<0$ in the end quarters. In practice the last requirement could be met by adjusting the gas discharge conditions near the ends so that the lower maser atomic level is more populated than the upper one. In He-Ne masers an increase of tube diameter near the ends might be helpful in this respect. Diffusion of Ne metastables to the walls is thereby reduced, and electron excitation of the lower maser level is increased.

12. NORMAL THREE-FREQUENCY OPERATION

Equations (108) and (121)–(123) are fairly complicated, but can be readily used to discuss a number of special cases, as indicated in the following three sections.

In general, unless care is taken to adjust the cavity tuning very accurately, the three frequencies ν_1, ν_2, and ν_3 will be such that the relative phase angle ψ of Eq. (106) is a linear function of the time. Then the last terms in Eqs. (108), (121)–(123) are periodic functions of time, and in some approximation their effects average out. If we neglect these terms, we can get a steady-state solution for the intensities E_1^2, E_2^2, E_3^2 from the system of inhomogeneous linear equations

$$\begin{aligned} \alpha_1&=\beta_1E_1^2+\theta_{12}E_2^2+\theta_{13}E_3^2,\\ \alpha_2&=\beta_2E_2^2+\theta_{21}E_1^2+\theta_{23}E_3^2,\\ \alpha_3&=\beta_3E_3^2+\theta_{31}E_1^2+\theta_{32}E_2^2,\end{aligned} \tag{143}$$

and for the frequencies ν_1, ν_2, ν_3 from

$$\begin{aligned} \nu_1&=\Omega_1+\sigma_1+\rho_1E_1^2+\tau_{12}E_2^2+\tau_{13}E_3^2,\\ \nu_2&=\Omega_2+\sigma_2+\rho_2E_2^2+\tau_{21}E_1^2+\tau_{23}E_3^2,\\ \nu_3&=\Omega_3+\sigma_3+\rho_3E_3^2+\tau_{31}E_1^2+\tau_{32}E_2^2,\end{aligned} \tag{144}$$

again taking $\dot\varphi_1=\dot\varphi_2=\dot\varphi_3=0$. Since the coefficients in Eqs. (143) and (144) are slowly varying functions of frequency, it will suffice first to determine the E_n^2 from

[19] Such an analysis is being made by Dr. R. L. Fork and Dr. M. A. Pollack. The author is very grateful to them for helpful discussions on this and other parts of the manuscript.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

(143) and then to calculate the ν_n's from (144). The equations are a fairly obvious generalization of those for the two frequency case. It will be noted that operation with $E_1^2 \neq 0$, $E_2^2 \neq 0$ can inhibit normal oscillation at ν_3 until, with increasing excitation,

$$\alpha_3' = \alpha_3 - \theta_{31}E_1^2 - \theta_{32}E_2^2 \tag{145}$$

becomes positive.

Further discussion of pulling, pushing, and mode competition for this case will be left to readers requiring a numerical analysis of their data.

13. COMBINATION TONES

As mentioned in Secs. 7, 9, the third-order polarization $P_n^{(3)}(t)$ of the active medium has constituents which oscillate at all possible frequencies of the form $\nu_\mu - \nu_\rho + \nu_\sigma$. Even for "two"-frequency oscillation, there are additional frequencies $2\nu_2 - \nu_1 \equiv \nu_3'$ and $2\nu_1 - \nu_2 \equiv \nu_0'$ in the polarization which are very close to resonance with the principal cavity modes just above and below the two Ω_1 and Ω_2 of main interest. As a consequence of Maxwell's equations, fields at frequencies ν_3' and ν_0' necessarily exist in the cavity and can appear in the output. Well below the threshold for normal three-frequency oscillation, E_3 (and also E_0) will be much smaller than E_1 and E_2. We also assume $\gamma_{ab} \ll \Delta \ll Ku$ and $\nu_2 \simeq \omega$ so that

$$\eta_{21} \simeq -\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3 Ku\Delta^2)^{-1}[\bar{N}+2N_2], \tag{146}$$
$$\xi_{21} \simeq 0.$$

For a steady state, the third Eq. (108) then gives

$$E_3 \simeq \eta_{21}E_2^2E_1[\alpha_3 - \theta_{31}E_1^2 - \theta_{32}E_2^2]^{-1}\cos\psi. \tag{147}$$

The relative phase angle ψ is determined by Eq. (123) to have $\sin\psi \simeq 0$, whence $|\cos\psi| \simeq 1$, and

$$E_3 \approx -\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3 Ku\Delta^2)^{-1} \times[\alpha_3 - \theta_{31}E_1^2 - \theta_{32}E_2^2]^{-1}|\bar{N}+2N_2|E_2^2E_1. \tag{148}$$

This expression is intended to be used under excitation conditions for which the denominator is negative. When the excitation increases, and the factor involving α_3 turns positive, the neglected nonlinear terms in E_3 would have to be taken into account in order to describe the previously discussed normal three-frequency operation.

In order to obtain the combination tone $(2\nu_2 - \nu_1)$ experimentally, one should adjust the cavity tuning so Ω_2 is slightly above the atomic transition frequency ω, thereby making Ω_1 a little nearer resonance than Ω_3. The excitation should be increased until "two"-frequency operation is obtained, but not yet genuine three-frequency operation.

Under these conditions, the θ's in Eq. (148) contain a factor Δ^{-2} and to simplify the discussion they will now be neglected. Equation (148) then has a factor in its denominator

$$\alpha_3 \approx -\tfrac{1}{2}(\nu/Q_3)/G_3, \tag{149}$$

where the gain factor G_3 is given approximately by

$$G_3 \approx [1-(\bar{N}/\bar{N}_T)(Z_i(\Delta)/Z_i(0))]^{-1}, \tag{150}$$

if one is not too near to threshold for normal three-frequency operation. Equations (148)–(150), within their domain of validity, indicate that E_3 is smaller than E_1 by a factor

$$E_3/E_1 \approx \tfrac{1}{8}\pi^{1/2}\wp^4E_2^2(\epsilon_0\hbar^3 Ku\Delta^2)^{-1}Q_3G_3|\bar{N}+2N_2|. \tag{151}$$

Using Eq. (62) for $n=3$, this can be expressed in a convenient form

$$E_3/E_1 = \tfrac{1}{4}[\tfrac{1}{2}(\wp E_2)^2/(\hbar^2\gamma_a\gamma_b)][(\gamma_a\gamma_b)/\Delta^2]G_3 \times|1+(2N_2/\bar{N})|\exp(\Delta/Ku)^2, \tag{152}$$

which shows how the amplitude of the combination tone depends on G_3, and on the saturation parameter as given by Eq. (96) for $n=2$. It should be noted that Eq. (152) could vanish if the spatial distribution of the excitation density is such that $2N_2+\bar{N}=0$. (If the excitation is confined to the central region of the Fabry-Perot tube, N_2 and $\bar{N}$, by Eqs. (47), (58) have opposite signs.) An experimental study of the above phenomena might facilitate determination of some of the quantities which enter into our equations but for which direct experimental values are not yet available.

14. FREQUENCY LOCKING PHENOMENA

It has been observed by Javan[20] and by Fork[19] that when the cavity tuning is gradually changed in normal three-frequency operation so that the separation of the beat notes $\nu_2 - \nu_1$ and $\nu_3 - \nu_2$ approaches a small value (typically of order 1 kc/sec), a frequency jump occurs. This phenomenon can be easily understood by reference to Eqs. (121)–(123). For simplicity, we neglect the small frequency pushing associated with the terms involving ρ_{nm} and τ_{nm}, since the nonlinear pulling terms σ_n already give sufficient generality to the frequency relationships. By subtracting the sum of Eqs. (121)–(123) from twice Eq. (122), we find a differential equation for the relative phase angle ψ of Eq. (106) in the form

$$\dot{\psi} = \sigma + A\sin\psi + B\cos\psi, \tag{153}$$

where

$$\sigma = 2\sigma_2 - \sigma_1 - \sigma_3, \tag{154}$$

and A and B are slowly varying quantities which depend on the E_n, ξ_{nm}, and η_{nm}. We evaluate the ξ_{nm} and η_{nm} with the usual approximations $\gamma_{ab} \ll \Delta \ll Ku$. Then

$$\eta_{23} \simeq \eta_{21} \simeq -\tfrac{1}{16}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3 Ku\Delta^2)^{-1}\{\bar{N}+2N_2\},$$
$$\eta_{13} \simeq \tfrac{1}{8}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3 Ku\Delta^2)\{\bar{N}-2N_2\}, \tag{155}$$
$$\xi_{23} \simeq \xi_{21} \simeq \xi_{13} \simeq 0.$$

Because of the nearly symmetrical tuning of ν_1 and ν_3

[20] A. Javan, private communications for which the author is very grateful.

Digitized by Arya Samaj Foundation Chennai and eGangotri

we may set $E_1=E_3$ and find

$$A\approx\tfrac{1}{8}\pi^{1/2}\nu\wp^4(\epsilon_0\hbar^3Ku\Delta^2)^{-1}\times\{(\bar{N}+2N_2)E_2^2+2(\bar{N}-2N_2)E_1^2\}, \quad (156)$$

$B\approx 0$.

The differential equation

$$\dot{\psi}=\sigma+A\sin\psi+B\cos\psi \quad (157)$$

has an implicit solution

$$t(\psi)=\int_{\psi_0}^{\psi}dx/(\sigma+A\sin x+B\cos x), \quad (158)$$

where ψ_0 is the value of ψ at $t=0$. The character of the function $\psi(t)$ depends critically on whether

$$(A^2+B^2)^{1/2}<|\sigma| \quad \text{or} \quad (A^2+B^2)^{1/2}>|\sigma|.$$

In the first case, the integrand of (158) has no singularities in the range of integration, and one finds that as ψ approaches infinity so does t. Asymptotically, apart from pulsations, one has $\psi\simeq\sigma t+\text{const}$. On insertion of this value in Eqs. (121)–(123) one finds that the frequencies are given by

$$\nu_n\sim\Omega_n+\sigma_n \quad (159)$$

apart from pushing effects and pulsations of phase φ_n, in agreement with the results of Sec. 6 with the approximations made here.

In the second case, $(A^2+B^2)>\sigma^2$, the integral diverges, i.e., $t\to\infty$ when ψ reaches the value $-\sin^{-1}\times(\sigma/(A^2+B^2)^{1/2}$. In other words, $\psi(t)$ approaches this value asymptotically. The disappearance from ψ of any linear dependence on t forces $\nu_3-\nu_2=\nu_2-\nu_1$ and frequency locking ensues, with a definite relative phase angle $2\varphi_2-\varphi_1-\varphi_3$.

Let us suppose that the maser is in normal three-frequency operation with two distinct beat notes $\nu_3-\nu_2$ and $\nu_2-\nu_1$ near to $\Delta\approx 150$ Mc/sec, i.e., $\sigma=(\nu_3-\nu_2)-(\nu_2-\nu_1)$ is somewhat greater than $(A^2+B^2)^{1/2}$. As the middle cavity frequency Ω_2 is tuned closer to the atomic resonance frequency ω, the separation of beat note frequencies $|\sigma|$ decreases. There should be some pulsations in phase which would increase in amplitude as symmetrical tuning is approached. When $|\sigma|$ reaches $(A^2+B^2)^{1/2}$, a quick transition to the locked state should be made, and only one beat note should be observed. Under the additional simplifying assumption $E_2\gg E_1\approx E_3$, and with use of the starting condition (60) for single-frequency oscillation, the separation of the two beat notes which could be attained just before locking occurs should be given by

$$|\sigma|=\tfrac{1}{8}[(\bar{N}+2N_2)/\bar{N}_T](\wp E_2/\hbar\Delta)^2\nu/Q, \quad (160)$$

which is conveniently expressed as a small fraction of the cavity bandwidth.

It might be pointed out that the above phenomenon is very closely related to one discussed by van der Pol[21] in 1924–27. He considered a self-sustained triode oscillator, capable of oscillation at frequency ν_1. If an external signal at ν is injected into the tank circuit, it may be possible to detect a beat note at $|\nu-\nu_1|$ using a square-law detector. If, however, ν is tuned gradually towards ν_1, a very sudden jump occurs, after which oscillations occur only at ν and the beat note disappears. The width of the "quiet" frequency range depends approximately linearly on the amplitude of the injected signal, when this is small. In the case of the optical maser, we can think that an oscillator at ν_1 is being perturbed by an "external" signal at the combination tone frequency $\nu=2\nu_2-\nu_3$ which arises from the third-order polarization $P_1^{(3)}(t)$ induced in the nonlinear active medium.

15. POPULATION CHANGES AND PULSATIONS

In the absence of o.f. oscillations, the density of atoms in one of the two maser states, say a, can be determined by suitable integrations from $\rho_{aa}^{(0)}(a,z_0,t_0,v,t)$ as given by Eq. (24). When oscillations set in, there are contributions of second order which can be calculated from $\rho_{aa}^{(2)}(\alpha,z_0,t_0,v,t)$ using Eq. (31) for $\alpha=a$ and a similar equation for $\alpha=b$. One has

$$\rho_{aa}(z,t)=\int_{-\infty}^{\infty}dv\int_{-\infty}^{t}dt_0\int dz_0\delta(z-z_0-vt+vt_0)\times\sum_{\alpha=a,b}\lambda_\alpha(z_0,t_0,v)\rho_{aa}(\alpha,z_0,t_0,v,t). \quad (161)$$

It will suffice merely to give the result. One finds, with obvious approximations

$$\rho_{aa}(z,t)=[\Lambda_a(z,t)/\gamma_a]+\{[\Lambda_a(z,t)/\gamma_a]-[\Lambda_b(z,t)/\gamma_b]\}\times\tfrac{1}{8}(\wp^2/Ku)\sum_\mu\sum_\rho\{E_\mu E_\rho\mathfrak{D}_a(\nu_\mu-\nu_\rho)iZ(\omega-\nu_\rho)\times\exp i[(\nu_\mu-\nu_\rho)t+(\varphi_\mu-\varphi_\rho)]+\text{c.c.}\}\times\cos[(n_\mu-n_\rho)\pi z/L] \quad (162)$$

apart from terms with rapid spatial oscillations.

For single-frequency operation, one finds

$$\rho_{aa}(z,t)=[\Lambda_a(z,t)/\gamma_a]-\{[\Lambda_a(z,t)/\gamma_a]-[\Lambda_b(z,t)/\gamma_b]\}\times\tfrac{1}{4}(\wp E_1)^2(\gamma_aKu)^{-1}Z_i(\omega-\nu_1), \quad (163)$$

which contains the lowest order effects of o.f. saturation. In some cases, the density could be monitored by observation of the decay radiation emitted from state a (or b) in transition to some lower level. (Of course, if trapping of resonance radiation were involved, the interpretation would be somewhat complicated.) The change produced by o.f. radiation in $\rho_{aa}(z,t)$ might serve to aid in the determination of parameters like

[21] B. van der Pol, Phil. Mag. 3, 65 (1927) and the review article cited in Ref. 17.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

γ_a, E_1^2, etc., which enter into all our equations, but which might not otherwise be known.

For two-frequency operation of the optical maser, ρ_{aa} has a pulsating constituent at a frequency near Δ besides a dc part. If we assume $\gamma_{ab}\sim\gamma_a\gg\Delta\ll Ku$

$$\begin{aligned}\rho_{aa}(z,t)&=[\Lambda_a(z,t)/\gamma_a]-\{[\Lambda_a(z,t)/\gamma_a]-[\Lambda_b(z,t)/\gamma_b]\}\\&\times\tfrac{1}{4}\pi^{1/2}\wp^2(Ku\gamma_a)^{-1}[E_1^2\exp-(\omega-\nu_1)^2/(Ku)^2\\&+E_2^2\exp-(\omega-\nu_2)^2/(Ku)^2]+\{[\Lambda_a/\gamma_a]-[\Lambda_b/\gamma_b]\}\\&\times\tfrac{1}{4}\pi^{1/2}\wp^2(Ku\Delta)^{-1}E_1E_2[\exp-(\omega-\nu_1)^2/(Ku)^2\\&+\exp-(\omega-\nu_2)^2/(Ku)^2]\cos(\pi z/L)\sin(\nu_2-\nu_1)t.\end{aligned}\tag{164}$$

From this expression one sees that the amplitude of the pulsations at frequency near Δ, relative to the dc change in population due to o.f. oscillation, should be

$$2E_1E_2(E_1^2+E_2^2)^{-1}(\gamma_a/\Delta)\cos(\pi z/L),$$

if, for simplicity, we neglect the Gaussian exponentials. Here again, it might be useful to use this phenomenon as a diagnostic tool while undertaking a systematic study of two-frequency operation.

16. CONNECTIONS WITH PREVIOUS CALCULATIONS

The basic paper in this field is, of course, that of Schawlow and Townes[1] who give expressions for threshold equivalent to (62). Townes[22] has also given an equation for linear pulling, as has Javan[23] for nonlinear pulling.

Oscillations of an optical maser involve the propagation of radiation in a nonlinear medium. Several papers have recently appeared which deal with this subject. For various reasons, these do not apply very closely to our particular problem. Thus, Bloembergen *et al.*[24] and Franken and Ward[25] treated harmonic generation which plays a relatively minor role for us. Teng and Statz[26] discussed low-order nonlinearities in a gaseous medium, but, as will be discussed below, their treatment of Doppler broadening is not adequate for our purposes. Also our model for radiation damping is more realistic than theirs which involves just one relaxation time τ, while our equations contain two decay constants γ_a and γ_b. To be sure, the combination $\gamma_{ab}=\frac{1}{2}(\gamma_a+\gamma_b)$ enters most equations, and this might be identified with τ^{-1}.

Among other publications which deal with maser theory are those of Wagner and Birnbaum[27] and of McCumber.[28] These papers consider to some extent the quantum nature of the electromagnetic field. They differ greatly in spirit and content from ours, and we will not attempt to make a comparison here. The work of Haken and Sauermann[29] and of Davis[30] seems much closer to ours, but there are significant differences in the models used, and in the appearance of our equations.

As mentioned in Sec. 4 an earlier calculation[8] applicable to an optical gaseous maser neglected complications arising from the atomic motions and multimode oscillation. It was then possible to work with a density matrix $\rho(\mathbf{r},t)$ characterizing an ensemble[7] of atoms at position $\mathbf{r}$ at time t which were excited at any time $t_0\leqslant t$. This obeyed

$$i\dot{\rho}=[\mathfrak{IC},\rho]-(i/2)(\Gamma\rho+\rho\Gamma)+i\Lambda,\tag{165}$$

which differs from (18) by the term containing a source matrix Λ describing the (slowly varying) rate densities of excitations Λ_a and Λ_b

$$\Lambda=\begin{pmatrix}\Lambda_a & 0\\ 0 & \Lambda_b\end{pmatrix}.\tag{166}$$

(In most applications Λ will be a diagonal matrix.)

It is possible to carry the calculation to higher order in the E_n for multimode oscillation without atomic motion by an iterative procedure in which we begin by neglecting any time dependence in the population difference $\rho_{aa}-\rho_{bb}$. In the rotating wave approximation, one of Eqs. (25) then gives a quasisteady-state solution for $\rho_{ab}(z,t)$

$$\begin{aligned}\rho_{ab}(z,t)=-\tfrac{1}{2}i(\wp/\hbar)\sum_\mu E_\mu U_\mu(z)\mathfrak{D}(\omega-\nu_\mu)\\\times(\rho_{aa}-\rho_{bb})\exp-i(\nu_\mu t+\varphi_\mu).\end{aligned}\tag{167}$$

Inserting this in another one of Eqs. (25) and again making a rotating wave approximation we find rate equations

$$\begin{aligned}\dot{\rho}_{aa}&=-\gamma_a\rho_{aa}+R(\rho_{bb}-\rho_{aa})+\Lambda_a,\\\dot{\rho}_{bb}&=-\gamma_b\rho_{bb}+R(\rho_{aa}-\rho_{bb})+\Lambda_b,\end{aligned}\tag{168}$$

where

$$\begin{aligned}R=\tfrac{1}{4}(\wp/\hbar)^2\sum_\lambda\sum_\mu E_\lambda E_\mu U_\lambda(z)U_\mu(z)\\\times[\mathfrak{D}(\omega-\nu_\mu)(\exp i(\nu_\lambda-\nu_\mu)t+i(\varphi_\lambda-\varphi_\mu))+\text{c.c.}].\end{aligned}\tag{169}$$

The "rate constant" R has pulsations for cases of multifrequency operation, and through Eq. (168) these would lead to pulsations in the populations ρ_{aa} and ρ_{bb} at all beat frequencies $\nu_\lambda-\nu_\mu$. If it were deemed necessary to continue the iteration procedure the pulsating population difference $\rho_{aa}-\rho_{bb}$ could be approximately evalu-

ated from Eq. (168) and put in Eqs. (25) to obtain an improved Eq. (167).

If we neglect the pulsations in R, we obtain

$$R=\tfrac{1}{2}(\wp/\hbar)^2\gamma_{ab}\sum_\mu E_\mu^2[U_\mu(z)]^2\mathfrak{L}(\omega-\nu_\mu), \quad (170)$$

which is a plausible generalization of the rate of transitions previously obtained. In a steady state, the population difference implied by (168), (170) is

$$\rho_{aa}-\rho_{bb}=[(\Lambda_a/\gamma_a)-(\Lambda_b/\gamma_b)] \times[1+(2\gamma_{ab}R/(\gamma_a\gamma_b))]^{-1}, \quad (171)$$

which shows clearly the effect of o.f. saturation.

Since the rate constant (170) depends on position z through normal modes $U_n(z)$, the population difference (171) also depends on position, and may be said to have "holes" burned in it. Consequences of this for mode competition can be discussed along the lines followed in Sec. 10. Under most conditions the behavior will correspond to the weak-coupling case, although if the excitation density were such that $-N_2$ were larger than $\bar{N}$ the strong coupling case might be realized.

Combining Eqs. (165), (167), (171), and (41) we obtain a polarization

$$P(z,t)=\wp(\rho_{ab}+\rho_{ab}^*) \quad (172)$$

and the coefficients S_n and C_n which enter the amplitude and frequency determining Eqs. (13) and (14) are

$$S_n=-\frac{2}{L}(\wp^2/\hbar)\gamma_{ab}\mathfrak{L}(\omega-\nu_n)E_n \times\int_0^L dz[U_n(z)]^2N(z,t)[1+(2\gamma_{ab}R(z))/\gamma_a\gamma_b)]^{-1} \quad (173)$$

and

$$C_n=[(\omega-\nu_n)/\gamma_{ab}]S_n. \quad (174)$$

These expressions depend nonlinearly on the mode amplitudes E_n because of saturation. However, since we have already neglected the beat frequency pulsations of $\rho_{aa}-\rho_{bb}$ which lead to terms with Δ in the denominator, it might not be consistent to keep any terms in R which are off-resonance by more than about $|\omega-\nu_\mu|\sim(\gamma_{ab}\Delta)^{1/2}$.

We will now consider only single-frequency operation, for which our Eqs. (173)–(174) are essentially exact. Then a single summand $\mu=n$ contributes to R and we find

$$S_n=-\frac{2}{L}\wp^2\hbar^{-1}\gamma_{ab}E_n\int_0^L dz[U_n(z)]^2N(z)[\gamma_{ab}^2+(\omega-\nu_n)^2 +\gamma_{ab}^2(\wp E_n)^2[U_n(z)]^2/(\hbar^2\gamma_a\gamma_b)]^{-1}. \quad (175)$$

The integral may be easily calculated if $N(z)$ is a slowly varying function of position, and we find

$$S_n=-\wp^2\hbar^{-1}\gamma_{ab}\bar{N}\mathfrak{L}(\omega-\nu_n)f(w)E_n, \quad (176)$$

where

$$w=[(\wp E_n)^2/(\hbar^2\gamma_a\gamma_b)]\gamma_{ab}^2\mathfrak{L}(\omega-\nu_n) \quad (177)$$

and

$$f(w)=(2/w)[1-(1+w)^{-1/2}]. \quad (178)$$

If Eq. (175) for S_n is expanded to third order in E_n, we obtain a result in agreement with that given by Eqs. (56), (72) for the single-frequency case with no atomic motion. It should be noted that whether (175) is expanded or not, the amplitude of oscillation has a maximum for resonant tuning and falls off monotonically with detuning. There is no indication here that the double maximum of Sec. 8 might be a spurious one which arises from the neglect of fifth or higher order terms.

17. DISCUSSION OF DOPPLER BROADENING

The effect of atomic motion upon our equations is rather curious and warrants discussion which, for simplicity, will be given for single-frequency operation. As we have seen in Sec. 16, the optical properties of the medium may be described by a nonlinear susceptibility

$$\chi(\omega-\nu_n, E_n)=P_n/(\epsilon_0E_n). \quad (179)$$

It would perhaps be plausible to hope that the following simple recipe would take atomic motion into account. Because an atom moving with velocity v sees a Doppler shifted frequency, in the laboratory frame of reference it effectively has its resonance frequency shifted by $\omega v/c$. The effective susceptibility ought then to be

$$\chi_{\text{eff}}=\int_{-\infty}^{\infty}dvW(v)\chi(\omega-\omega(v/c)-\nu_n, E_n), \quad (180)$$

which can easily be expressed in terms of the $Z(\zeta)$ function which is discussed in Sec. 6. The effective damping constant becomes

$$\gamma_{ab}[1+(\wp E_n)^2/(\hbar^2\gamma_a\gamma_b)]^{1/2}$$

instead of γ_{ab}, and when this is much smaller than the Doppler parameter Ku, the line shape should be Gaussian with a normal Doppler width.

The above prescription is incorrect except to the first order in E_n if standing waves rather than running waves are involved in any way. This follows from a study of Eq. (70) contributing to the third-order polarization which involves a threefold integration over times τ', τ'', and τ'''. For single-frequency oscillation, the integrand contains

$$U_n(z-v\tau')U_n(z-v\tau'-v\tau'')U_n(z-v\tau'-v\tau''-v\tau''') \times\exp[-i(\omega-\nu_n)\tau']\exp[\pm i(\omega-\nu_n)\tau'''].$$

Each of the U_n's is a standing wave which can be expressed as the sum of two running waves like $\exp\pm i(Kz-v\tau')$, etc. The physical interpretation is that in order to contribute to $P_n^{(3)}$ at time t an atom

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

has to interact three times with the o.f. field: first at $t'''=t-\tau'-\tau''-\tau'''$, then at $t''=t-\tau'-\tau''$, and finally at $t'=t-\tau'$. At each of these interactions the atom has a "choice" of interacting with one or the other of the two running waves. The τ dependence of a typical term of the integrand of (71) is then

$$\exp-\gamma_{ab}(\tau'+\tau''')-\gamma_a\tau''\exp i(\nu_n-\omega)(\tau'\pm\tau''')\pm iK\nu\tau' \pm iK\nu(\tau'+\tau'')\pm iK\nu(\tau'+\tau''+\tau''').$$

The physical consequence of the appearance of terms involving $\pm K\nu$ in the exponent is that each interaction involves a Doppler shift. Since we are interested in the case of a large Doppler width Ku, such a shift can take a given interaction very far from resonance even if $\omega=\nu_n$. This is expressed by the destructive interference of contributions to the integral at various value of τ', τ'', and τ'''. The interference will be least when the accumulated Doppler phase angle

$$\pm K\nu\tau'\pm K\nu(\tau'+\tau'')\pm K\nu(\tau'+\tau''+\tau''')$$

is zero. In order to obtain a nonvanishing spatial Fourier projection (8) for $P_n{}^{(3)}$, the choices $\pm$ can not be all alike. The six remaining possibilities for the phase angle are

$$\pm K\nu[\tau'+(\tau'+\tau'')-(\tau'+\tau''+\tau''')]=\pm K\nu(\tau'-\tau'''),$$
$$\pm K\nu[\tau'-(\tau'+\tau'')+(\tau'+\tau''+\tau''')]=\pm K\nu(\tau'+\tau'''),$$

and

$$\pm K\nu[-\tau'+(\tau'+\tau'')+(\tau'+\tau''+\tau''')]= \pm K\nu(\tau'+2\tau''+\tau''').$$

As seen in Sec. 7, only the first two possibilities are able to lead to vanishing interference, and then only when $\tau'=\tau'''$.

Physically, one may say that a dominant type of process involves three interactions: first, one with a right (left) running wave at t''', then one with a left (right) running wave at t'', and finally one with a left (right) running wave at t', with the time intervals obeying $t-t'=t''-t'''$ so that the accumulated Doppler phase angle

$$\pm[K\nu(t-t')+K\nu(t-t'')-K\nu(t-t''')]$$

cancels out at time t.

The above cancellation of Doppler interference would not occur if waves running in only one direction were present. The nonlinear terms are much less broadened and weakened by Doppler effect for a standing wave maser oscillator than would be inferred from a study of nonlinear propagation alone. The double peak in the power as a function of tuning met in Sec. 8 can occur only because β_n (saturation) is not as much Doppler broadened as α_n (linear gain profile).

18. HOLE BURNING

In his discussion of maser action Bennett[31] has made use of the notion of "hole burning." Since it aids the physical understanding of the rather complicated equations, we will now show how this phenomenon is described in the present work. As Bennett's treatment does not bring in the population pulsations of Sec. 15, we will base our discussion on the simplified theory of Sec. 16 in which pulsations of population were neglected.

In Sec. 16 the atoms had zero velocity. It is possible to generalize the discussion for the case of atoms having a velocity distribution $W(v)$ at the cost of further fairly plausible assumptions which are no worse than approximations already made. We deal first with those atoms which have a definite velocity v and which were excited at z_0 at time t_0. The perturbation experienced by such an atom is

$$V(t)=-(\wp/\hbar)\sum_\mu E_\mu U_\mu(z_0+v(t-t_0))\cos(\nu_\mu t+\varphi_\mu) \quad (181)$$

so that instead of seeing fields at frequencies ν_μ the moving atom sees fields at twice as many frequencies, i.e., $\nu_\mu\pm Kv$. The rate concept approach of Sec. 16 can not be used since the atoms characterized by different values of z_0 and t_0 experience different perturbations, i.e., the *phases* are not the same for the various members of the ensemble of atoms arriving at z at time t. It is plausible, however, to estimate the effect of saturation on the population difference $\rho_{aa}(v,t)-\rho_{bb}(v,t)$ by using an equation like (171) with a perturbation $V(t)$ given by (181) but with the terms involving z_0 and t_0 omitted. The replacement for the velocity-dependent rate constant $R(v)$ is then plausibly

$$R(v)=\tfrac{1}{8}\gamma_{ab}(\wp/\hbar)^2\sum_\mu E_\mu{}^2[\mathcal{L}(\nu_\mu-\omega+Kv) +\mathcal{L}(\nu_\mu-\omega-Kv)]. \quad (182)$$

If $v=0$, this reduces to the space average of Eq. (170). The corresponding population difference for atoms having velocity v is then

$$\rho_{aa}(v,t)-\rho_{bb}(v,t) =W(v)[(\Lambda_a/\gamma_a)-(\Lambda_b/\gamma_b)] \times[1+2\gamma_{ab}R(v)/(\gamma_a\gamma_b)]^{-1}. \quad (183)$$

A plot of (183) against v would show the assumed velocity distribution with "holes" burned into it due to o.f. saturation effects. These holes would be appreciable whenever $R(v)$ became comparable to $\gamma_a\gamma_b/(\gamma_a+\gamma_b)$ which could occur near $Kv=\pm(\nu_\mu-\omega)$, so that *two* holes could be burned for each cavity mode in oscillation. At a resonance, where $\nu_n=\omega$, the two holes for the nth mode would merge and reinforce one another. The holes in the velocity distribution would have been

[31] W. R. Bennett, Jr., Appl. Opt. Suppl. 1, 24–61 (1962), especially pp. 58–59. It should be noted that the holes are in first instance burned in the curve of population difference versus velocity, and only indirectly in a curve of gain versus frequency.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

seen in Sec. 15 if the integration over velocities had not been carried out so soon.

With the above approximate expression for $\rho_{aa}(v)-\rho_{bb}(v)$ we may use Eqs. (25) to calculate a pseudo-first-order value of $\rho_{ab}(z,v,t)$ and $P(z,v,t)$ in the manner of Sec. 16. The result will be the same as before, but with a velocity dependent reduction factor

$$[1+2\gamma_{ab}R(v)/(\gamma_a\gamma_b)]^{-1}$$

to express the effect of saturation, where $R(v)$ is given by (182). There are similar reductions in the related functions $S_n(v)$ and $C_n(v)$. The coefficients S_n and C_n which enter the equations of self-consistency [(13),(14)] result from integration of these quantities over velocity. Thus

$$S_n=-\wp^2\hbar^{-1}\bar{N}\gamma_{ab}E_n\int_{-\infty}^{\infty}dvW(v)\mathfrak{L}(\omega-\nu_n+Kv)\times[1+2\gamma_{ab}R(v)/(\gamma_a\gamma_b)]^{-1}. \quad (184)$$

For single-mode operation, the rate $R(v)$ in the denominator of (184) contains the two terms given by Eq. (182). If an expansion is made to first order in $R(v)$ the integration over v can be done easily for a Maxwellian velocity distribution in the limit of large Doppler width Ku, and one gets results equivalent to those of Sec. 8. The possible dip in output power as a function of cavity tuning in single-mode operation can be interpreted as a consequence of the merging of the two holes at $Kv=\pm(\nu_n-\omega)\to 0$.

For multimode operation a similar calculation can be made with the complete expression (183) for $R(v)$. This will give the dominant terms of the equations of Sec. 9 for a Maxwellian velocity distribution and large Doppler width. However, the frequency locking terms involving ψ will be missing.

For two-mode oscillation, (184) leads to especially strong mode competition attributable to hole burning when $Kv=\nu_2-\omega=\omega-\nu_1$, i.e., the traveling wave along $+z$ for mode 2 and the traveling wave along $-z$ for mode 1 are both in approximate resonance with the atomic transition frequency for an atom having velocity v. This effect can be correlated with the peak in θ for $\omega=\nu_{12}$ mentioned in Sec. 10.

19. APPROXIMATE HIGHER ORDER THEORY FOR SINGLE MODE OPERATION

It would be possible, but quite tedious, to extend the calculations of the text to fifth and higher order for the single-frequency case. The simpler approximate procedure outlined below may serve in the absence of such calculations. It was mentioned above that an expansion of (184) to first order in $R(v)$ reproduces the equations of single-mode operation correct to third order in E_n. If this expansion is not made one may hope to have equations which are valid for stronger signals. The v integration is complicated, and we will content ourselves here with two special cases (a) $Ku\gg|\nu_n-\omega|\gg\gamma_{ab}$ and (b) $\nu_n=\omega$, $Ku\gg\gamma_{ab}$. In the former case, one finds approximately

$$S_n=-\pi^{1/2}\wp^2\bar{N}E_n/(\hbar Ku)[1+\tfrac{1}{4}(\wp E_n)^2/(\hbar^2\gamma_a\gamma_b)]^{1/2}, \quad (185)$$

while at resonance, when $\nu_n=\omega$,

$$S_n=-\pi^{1/2}\wp^2\bar{N}E_n/(\hbar Ku)[1+\tfrac{1}{2}(\wp E_n)^2/(\hbar^2\gamma_a\gamma_b)]^{1/2}, \quad (186)$$

and the merging of the two holes shows up in a simple manner through the doubling of the term expressing the effects of saturation. It will be remembered that a similar doubling of the coefficient β_n took place in Sec. 8 and was responsible for the possible dip in maser output versus cavity tuning. Although the more general behavior of output versus tuning implied by Eqs. (185)–(186) should be qualitatively correct, it must be remembered that rather uncontrolled approximations have been made in their derivation.

20. EXCITATION OF LOWER MASER LEVEL BY SPONTANEOUS DECAY OF UPPER MASER STATE

It was mentioned in Sec. 6 that the lower maser level could, at least in part, be excited by spontaneous emission from the upper. For the present this complication will be treated only in an approximation in which the rate concept is valid. For simplicity we ignore atomic motion, although the work of Secs. 16 and 19 suggests how this could be allowed for approximately. We write rate equations like (168)

$$\begin{aligned}\dot{\rho}_{aa}&=-\gamma_a\rho_{aa}+R(\rho_{bb}-\rho_{aa})+\Lambda_a,\\ \dot{\rho}_{bb}&=-\gamma_b\rho_{bb}+R(\rho_{aa}-\rho_{bb})+\Lambda_b+f\gamma_a\rho_{aa},\end{aligned} \quad (187)$$

where the extra source term $f\gamma\rho_{aa}$ describes the effects of radiative cascade excitation of b from a assuming that a fraction f of the decays from a are to b. The Λ's describe the uncorrelated excitation of the two levels. In a steady state one finds a population density difference

$$\rho_{aa}-\rho_{bb}=[(\Lambda_a/\gamma_a)(1-f(\gamma_a/\gamma_b))-(\Lambda_b/\gamma_b)]\times[1+R\{\gamma_a(1-f)+\gamma_b\}/(\gamma_a\gamma_b)]^{-1}, \quad (188)$$

which should be compared to Eq. (171). It will be seen that the effect of a nonvanishing branching ratio f is merely to change the unsaturated population difference (obtained for $R=0$), and also to modify the value of R for which a given degree of saturation would be obtained. The saturation parameter of Sec. 8 will be modified in an obvious fashion. Thus if $f=0$, a value of rate $R=\frac{1}{2}\gamma_a\gamma_b/\gamma_{ab}$ would cause 50% saturation, while if $f=1$ the value would be $R=\gamma_a$. It should be recalled that the dominant part of the third-order terms $S_n^{(3)}$ and $C_n^{(3)}$ are direct manifestations of saturation phenomena. At the present state of maser art, the decay constants γ_a and γ_b are not well enough known

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

for the effect of a nonvanishing value of f to be easily seen.

When population pulsations are taking place there will be a correlated time-dependent excitation of the lower level by cascade. It is possible that more interesting consequences than those obtained would result, and it is hoped to explore this possibility in a later paper.

21. OTHER SOURCES OF BROADENING

For some kinds of line broadening, especially in certain solid-state optical masers, one could adopt the recipe proposed in Sec. 17, and rejected for the case of Doppler broadening. If the effect of environment could be described by a distribution function for the atomic resonance frequencies ω, an averaged nonlinear susceptibility could be used. This could also be done for the case of isotopic mixtures of the active atoms in gaseous masers.

Although γ_a and γ_b were introduced into our equations to describe spontaneous radiative decay of the states a and b, it is plausible that such phenomenological decay constants might also describe certain kinds of collision broadening. In that case, the γ's would be functions of the pressure.[32] A more detailed discussion of collision broadening for a gaseous optical maser will be given in another paper.

[32] Evidence for such a dependence has recently been obtained by Javan and Szöke, Ref. 16.

PHYSICAL REVIEW VOLUME 134, NUMBER 6A 15 JUNE 1964

Correlation Effects in Many Fermion Systems. II. Linked Clusters*

HUGH P. KELLY
Department of Physics, University of California at San Diego, La Jolla, California
(Received 31 January 1964)

In a previous paper a set of coupled equations was derived for the ground-state wave function and energy of a finite system of interacting Fermions. The equations are now modified so as to be more applicable to systems in which the number of particles becomes large. The resulting equations are shown to be equivalent to those obtained from many-body perturbation theory.

I. LINKED CLUSTERS

IN a previous paper,[1] a set of coupled equations was derived for the ground-state wave function and energy of a finite system of interacting Fermions. The wave function was expanded in terms of multiple-particle excitations on an uncorrelated zero-order state. The total energy E of the system appeared in the resulting equations and it was pointed out that this restricts the application of these equations to finite systems; in general, the restriction is to systems of small N. In the equations, the amplitudes for one-particle excitations are coupled to those for two-particle and three-particle excitations. The two-particle amplitudes are coupled to those for one-particle, three-particle, and four-particle excitations, and similarly for higher particle excitations. It was mentioned in I that it might be reasonable to approximate four-particle excitation terms, for example, as products of independent two-particle excitations.

It is shown here that four-particle terms involving two independently propagating pairs enter the equations in such a way as to eliminate the dependence of the two-particle excitation equations on the total energy E, and similarly for the other excitations.[2] Explicit inclusion of products of independent excitations yields the equations of the linked cluster expansion. The resulting equations are shown to be the same as those obtained from many-body perturbation theory as formulated by Brueckner[3] and by Goldstone.[4]

In I, the ground-state wave function is expanded as

$$|\psi\rangle = |\Phi_0\rangle + \sum_{\alpha,k} f(k;\alpha)\eta_k^+\eta_\alpha|\Phi_0\rangle + \sum_{\alpha,\beta,k,k'} f(kk';\alpha\beta)\eta_k^+\eta_{k'}^+\eta_\beta\eta_\alpha|\Phi_0\rangle + \cdots . \quad (1)$$

The unperturbed solution $|\Phi_0\rangle$ is a determinant composed of the N single-particle states which are lowest in energy.

Equations are then derived for $f(k;\alpha)$ and $f(kk';\alpha\beta)$ by inserting $|\psi\rangle$ from Eq. (1) into

$$H|\psi\rangle = E|\psi\rangle , \quad (2)$$

where H is written in the usual second-quantized form.[1]

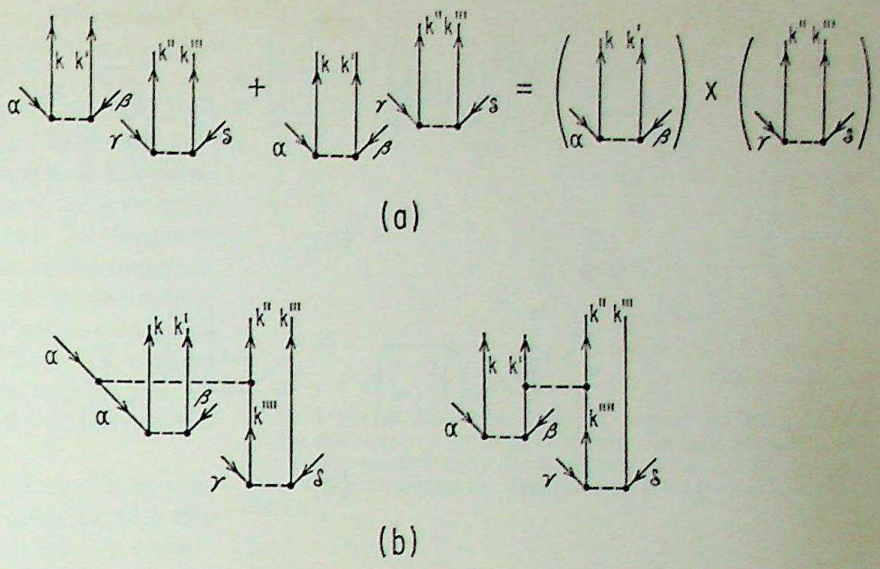

FIG. 1. (a) In perturbation theory two independent pair excitations factor when both time orderings are considered. (b) Typical terms which always link any two excited pairs.

An approximate solution for $f(kk';\alpha\beta)$ is given in Eq. (15) of I, in this paper referred to as Eq. (I.15),

$$f(kk';\alpha\beta)=(\epsilon_\alpha+\epsilon_\beta-\epsilon_k-\epsilon_{k'}-\langle(\alpha\beta)_{ex}|v|\alpha\beta\rangle +E-E_{HF})\langle(kk')_{ex}|v|\alpha\beta\rangle. \quad (3)$$

If we neglect the term $E-E_{HF}$, then this expression is that which is obtained from Rayleigh-Schrödinger perturbation theory when we use a Hartree-Fock basis and include the first-order term and all higher order diagonal hole-hole interaction terms.[5,6] However, for large N the term $E-E_{HF}$ may become so large as to invalidate the equations of I. Such difficulties have been described by Brueckner in his comparison of Rayleigh-Schrödinger and Brillouin-Wigner perturbation theories.[3]

We now show that the term $E-E_{HF}$ may be removed by considering the coupling of four-particle excitations in Eq. (I.11) for $f(kk';\alpha\beta)$. In the equation for $f(kk';\alpha\beta)$, coupling with four-particle excitations adds the term

$$\sum_{\gamma\delta k''k'''}\langle(\gamma\delta)_{ex}|v|k''k'''\rangle f(kk'k''k''';\alpha\beta\gamma\delta) \quad (4)$$

to the left-hand side of Eq. (2) or Eq. (I.11). The coefficients $f(kk'k''k''';\alpha\beta\gamma\delta)$ are composed of parts in which two pairs propagate independently and of remaining parts involving more complicated interactions among the four particles.

The approximation of regarding $f(kk'k''k''';\alpha\beta\gamma\delta)$ solely as a product of two pair excitations has been discussed by Brenig and Sinanoğlu.[7] A justification for this decomposition is found in perturbation theory where the lowest order four-particle excitation is given by the product of two pair excitations when we consider both possible time orderings as in Fig. 1(a). Those parts of $f(kk'k''k''';\alpha\beta\gamma\delta)$ in which two pairs of particles propagate independently should be written as products of $f(kk';\alpha\beta)$. It may be noted that there are always linked terms connecting any two excited pairs, however, as shown in Fig. 1(b).

When product pairs such as $f(kk'';\alpha\gamma)f(k'k''';\beta\delta)$ are inserted into Eq. (4) and used in the equation for $f(kk';\alpha\beta)$, than linked terms result as shown in Fig. 2.

When we consider the products

$$f(kk';\alpha\beta)\sum f(k''k''';\gamma\delta),\quad \gamma\neq\alpha,\beta\quad k''\neq k,k'\quad \delta\neq\alpha,\beta\quad k'''\neq k,k', \quad (5)$$

these give us terms

$$f(kk';\alpha\beta)\sum\langle\gamma\delta|v|(k''k''')_{ex}\rangle f(k''k''';\gamma\delta),\quad \gamma\neq\alpha,\beta\quad k''\neq k,k'\quad \delta\neq\alpha,\beta\quad k'''\neq k,k' \quad (6)$$

on the left-hand side of Eq. (2).

In Eq. (I.8) it is shown that

$$E-E_{HF}=\sum_{\alpha,\beta,k,k'}\langle\alpha\beta|v|(kk')_{ex}\rangle f(kk';\alpha\beta). \quad (7)$$

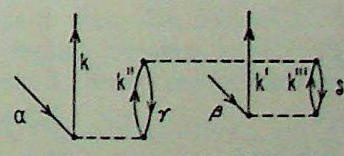

FIG. 2. Diagram illustrating how H may couple two independent pair excitations with a single pair excitation. There is also a diagram in which the time ordering of the first two interactions is reversed. This term enters the equation for $f(kk';\alpha\beta)$.

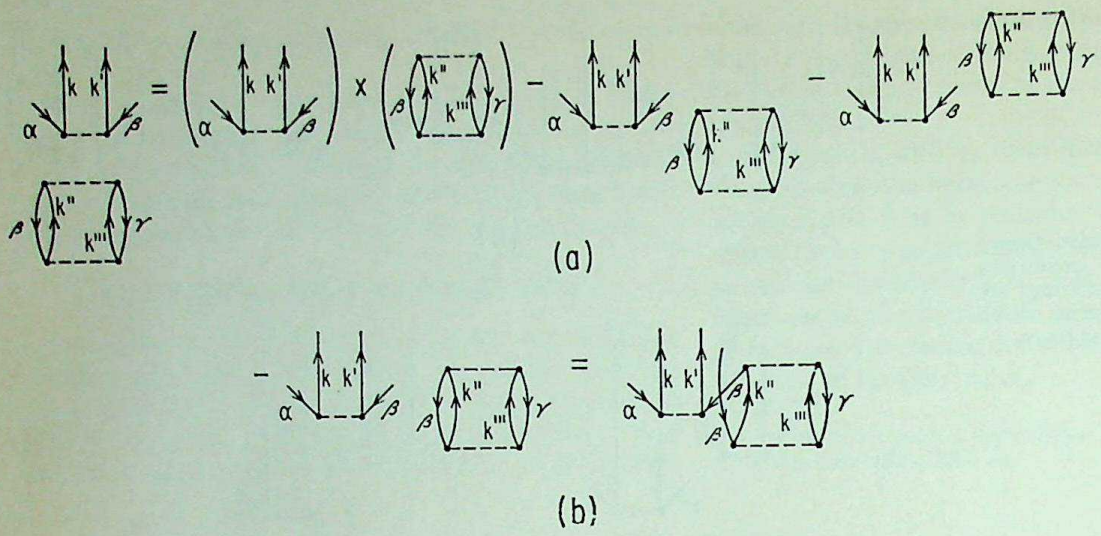

FIG. 3. (a) Diagram factorization when the two disconnected parts have one or more particle or hole lines in common. The two subtracted diagrams are really linked diagrams as shown in (b).

Equation (6) is then rewritten

$$f(kk';\alpha\beta)[E-E_{HF}-\sum_{\delta,k'',k'''}\langle\alpha\delta|v|(k''k''')_{ex}\rangle(k''k''';\alpha\delta)$$
$$-\sum_{\gamma\neq\alpha,k'',k'''}\langle\gamma\beta|v|(k''k''')_{ex}\rangle f(k''k''';\gamma\beta)$$
$$-\sum_{k'''';\ \gamma\neq\alpha,\beta;\ \delta\neq\alpha,\beta}\langle\gamma\delta|v|(kk''')_{ex}\rangle f(kk''';\gamma\delta)$$
$$-\sum_{k''\neq k;\ \gamma\neq\alpha,\beta;\ \delta\neq\alpha,\beta}\langle\gamma\delta|v|(k''k')_{ex}\rangle f(k''k';\gamma\delta)]. \quad (8)$$

When the term of Eq. (8) is added to the left-hand side of Eq. (I.11), $f(kk';\alpha\beta)(E-E_{HF})$ cancels on both sides of Eq. (I.11).

At this point we now have the linked cluster expansion for two-particle excitations.[4] Equation (I.11) is also now nonlinear but in many cases this should not cause any difficulty.[5] The remaining terms are not proportional to N like $E-E_{HF}$; they will be given a simple physical interpretation. The denominators in Eqs. (I.15) and (I.16) are now modified by replacing the terms $E-E_{HF}$ by the summations in Eq. (8) with positive signs. For example, Eq. (I.15), an approximate equation for $f(kk';\alpha\beta)$, becomes

$$f(kk';\alpha\beta)$$
$$=[\epsilon_\alpha+\epsilon_\beta-\epsilon_k-\epsilon_{k'}-\langle(\alpha\beta)_{ex}|v|\alpha\beta\rangle$$
$$+\sum_{\delta,k'',k'''}\langle\alpha\delta|v|(k''k''')_{ex}\rangle f(k''k''';\alpha\delta)$$
$$+\sum_{\gamma\neq\alpha,k'',k'''}\langle\gamma\beta|v|(k''k''')_{ex}\rangle f(k''k''';\gamma\beta)$$
$$+\sum_{k'''';\ \gamma\neq\alpha,\beta;\ \delta\neq\alpha,\beta}\langle\gamma\delta|v|(kk''')_{ex}\rangle f(kk''';\gamma\delta)$$
$$+\sum_{k''\neq k;\ \gamma\neq\alpha,\beta;\ \delta\neq\alpha,\beta}\langle\gamma\delta|v|(k''k')_{ex}\rangle f(k''k';\gamma\delta)]^{-1}$$
$$\times\langle(kk')_{ex}|v|\alpha\beta\rangle. \quad (9)$$

The new terms appearing in the denominator of Eq. (9) which refer to states $|\alpha\rangle$ and $|\beta\rangle$ combine with the single-particle energies ϵ_α and ϵ_β and with the diagonal hole-hole interaction term $\langle(\alpha\beta)_{ex}|v|\alpha\beta\rangle)$ to give an effective two-body energy for $|\alpha\beta\rangle$. When the denominator also includes the particle-particle and exclusion principle violating (EPV) hole-particle terms of Eq. (I.17), then the denominator becomes approximately the difference between the two-body energies of the states $|\alpha\beta\rangle$ and $|kk'\rangle$. However, the two-body energy of $|kk'\rangle$ is not given so accurately as that of $|\alpha\beta\rangle$ because the interaction of the excited particles with unexcited particles is accounted for only in the Hartree-Fock approximation. However, pair-correlation energy terms of a ground-state particle with the other ground-state particles are now included. The last two terms in the denominator of Eq. (9) which refer to states $|\gamma\delta\rangle$ account for the fact that correlation terms for ground-state particles which involve excited states $|k\rangle$ or $|k'\rangle$ will be eliminated by the Pauli principle when there are other particles excited into $|k\rangle$ or $|k'\rangle$.

As a simple example of this result we consider the beryllium atom and let α, β, γ, δ refer to the $2s^+$, $2s^-$, $1s^+$, and $1s^-$ single-particle states, respectively. In Ref. 5 it was shown that the $1s-2s$ interactions are small compared to $1s-1s$ and $2s-2s$ interactions and so $f(kk';1s2s)$ is omitted in the denominators. Also the excited single-particle states used in Ref. 5 were all in the continuum and so the sums in Eq. (9) which do not run over both continuum states vanish because, as shown in Ref. 5, $\Sigma=(R_0/\pi)\int dk$ and continuum states have normalization $(2/R_0)^{1/2}$. Equation (9) becomes

$$f(kk';\alpha\beta)$$
$$=(\epsilon_\alpha+\epsilon_\beta-\langle(\alpha\beta)_{ex}|v|\alpha\beta\rangle+\sum_{k'',k'''}\langle\alpha\beta|v|(k''k''')_{ex}\rangle$$
$$\times f(k''k''';\alpha\beta)-\epsilon_k-\epsilon_{k'})^{-1}\times\langle(kk')_{ex}|v|\alpha\beta\rangle. \quad (10)$$

In the denominator of Eq. (10) we have the effective two-particle energy for the state $|\alpha\beta\rangle$. The term

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$-\langle(\alpha\beta)_{ex}|v|\alpha\beta\rangle$ corrects for the inclusion of the Coulomb interaction of $|\alpha\rangle$ and $|\beta\rangle$ in both single-particle energies ϵ_α and ϵ_β. The term $\sum_{k''k'''}\langle\alpha\beta|v|(k''k''')_{ex}\rangle f(k''k''';\alpha\beta)$ accounts for second and higher order interactions among the particles in states $|\alpha\rangle$ and $|\beta\rangle$. In the calculations of Ref. 5 it was found that omission of this term would have resulted in approximately a 10% error in the correlation energy among the two $2s$ electrons When there are bound "excited" states in the complete set of single-particle states then the energy denominators will also include terms from the last two summations in the denominator of Eq. (9). These correlation terms which we have been considering may be related to a type of "rearrangement diagram" considered by Brueckner and Goldman.[8]

The equation for one-particle excitations $f(k;\alpha)$ also has the term $E-E_{HF}$ removed when coupling with the three-particle excitation term is considered. We write

$$f(kk'k'';\alpha\beta\gamma)=f(k;\alpha)\sum_{k',k''\neq k,\beta,\gamma\neq\alpha}f(k'k'';\beta\gamma)+\cdots. \quad (11)$$

The result is that we replace $(E-E_{HF})$ in Eq. (I.10) by

$$\sum_{\gamma,k',k''}\langle\alpha\gamma|v|(k'k'')_{ex}\rangle f(k'k'';\alpha\gamma)+\sum_{\beta,\gamma\neq\alpha,k''}\langle\beta\gamma|v|(kk'')_{ex}\rangle f(kk'';\beta\gamma). \quad (12)$$

II. CONNECTION WITH PERTURBATION THEORY

The results which we have just obtained may also be derived by a consideration of the perturbation expansion.[3,4] We begin by examining the factorization of unlinked diagrams as shown in Fig. 3(a). The two apparently disconnected parts of each diagram are assumed to have one or more hole or particle lines in common and the two diagrams on the right of Fig. 3(a) must not be considered as "unlinked." They are really "linked" as is shown in Fig. 3(b). The first term on the right-hand side of Fig. 3(a) is eliminated by the usual cancellation of unlinked clusters.[3,4] Similar factorizations were considered in Ref. 5 where the two diagrams on the right of Fig. 3(a) were called third-class EPV diagrams. These diagrams were summed in an approximate way, although with sufficient accuracy for the numerical calculations of that paper. However, these two diagrams on the right of Fig. 3(a) may be summed exactly by noticing that both possible time orderings appear[9] or by merely writing down the algebraic expressions and adding.[8] For example, in the first subtracted

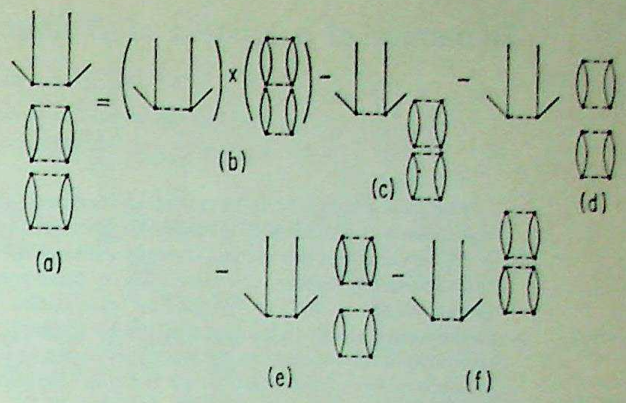

FIG. 4. Factorization of an unlinked diagram. It is assumed that all the disconnected parts have at least one hole or particle line in common so that there are correction terms (c), (d), (e), and (f) to the factorization (b). Diagrams (c) and (d) must be factored further.

diagram of Fig. 3(a), shown in Fig. 3(b), the product of the energy denominators is $(B(A+B)A)^{-1}$, where B is the denominator of the closed part considered separately and A is the denominator of the other part. The second subtracted diagram of Fig. 3(a) has the same matrix elements and a contribution $(A(A+B)A)^{-1}$ from the denominators. The sum of these expressions is $(A^2B)^{-1}$, so the two subtracted expressions add to give a result which is the first correction term obtained in an expansion of the linked part with a shifted denominator. In other words, it is the second term obtained in an expansion of the denominator of the following expression:

$$(\epsilon_\alpha+\epsilon_b-\epsilon_k-\epsilon_{k'}+\langle bc|v|(k''k''')_{ex}\rangle(\epsilon_b+\epsilon_c-\epsilon_{k''}-\epsilon_{k'''})^{-1}\times\langle k''k'''|v|bc\rangle)^{-1}\langle(kk')_{ex}|v|ab\rangle. \quad (13)$$

The higher order terms are obtained from a consideration of the factorizations of diagrams of Fig. 4. Such factorizations were shown in more detail in Ref. 5. Correction terms resulting from the factorization of the diagrams in Figs. 4(c) and 4(d) and from the diagrams of 4(e) and 4(f) add to give the second correction term in an expansion of the denominator of Eq. (13) and the first correction term which would result from using the appropriately shifted denominator in the correction term of the denominator of Eq. (13). The result of such factorizations then gives the summation terms in the denominator of Eq. (9) or, in a more simple case, it produces the shift in energy denominators as shown in Eq. (10).

ACKNOWLEDGMENTS

I would like to thank Dr. Andrew M. Sessler for his encouragement and for very helpful suggestions and Professor Keith A. Brueckner for his support and for a helpful discussion.

PHYSICAL REVIEW VOLUME 134, NUMBER 6A 15 JUNE 1964

Dynamics of a System of N Atoms Interacting With a Radiation Field

E. R. Buley and F. W. Cummings*
Aeronutronic Division, Philco Corporation, Newport Beach, California
(Received 4 December 1963)

The time-dependent behavior of an idealized laser is analyzed. The analysis avoids the use of the rate equations and includes N-particle "superradiant" effects. Perturbation theory is not used; the dynamics of N two-level atoms interacting strongly with a single-radiation field mode yields four coupled nonlinear equations which are integrated numerically for some special cases appropriate to lasers operating under ordinary power output as well as "Q-spoiling" conditions. Loss effects are grafted onto the dynamical equations phenomenologically. It is seen that under appropriate conditions, the laser is expected to emit one or more appreciable subsequent output bursts following an initial giant pulse, and that the subsequent emissions may be emitted by a population which is below inversion.

I. INTRODUCTION

THE continuing refinement of experimental techniques as well as of crystal growing techniques allows the mechanism underlying the production of coherent bursts of radiation, such as produced in lasers, to be probed in more detail. In the past, the analysis of the time dependence of a system of atoms coupled to a radiation field has most frequently been based on a rate equation, or energy balance approach.[1,2] While this approach is satisfactory in many situations, the rate equations ignore phase effects between the dipole moment of the radiators and the radiation field. As will be pointed out below, a more complete analysis can lead to interesting effects in lasers under certain conditions; in particular, to the extraction of coherent radiation from a population which is below inversion.

The model is essentially semiclassical, since the expectation values of products of field and atomic operators are factored into a product of field and atom expectation values. The results of this factorization do not differ significantly from the electrodynamic treatment for these purposes, and it is of some interest to note that "superradiant" spontaneous emission,[3] including the correct Einstein B coefficient, follows naturally from the resulting equations.

Phonomenological terms are added to the basic set of equations, in a way familiar from the field of magnetic resonance, to describe the loss of radiation from the resonant structure, the "dephasing" of the total dipole moment and the effect of pumping radiation. The equations are cast into a form amenable to numerical solution and a three-level, ruby prototype laser is discussed under various conditions such as Q spoiling[4] and variation of the material parameters.

II. MATHEMATICAL FORMULATION

Consider an N-atom system in which only two levels of each atom interact appreciably with the resonant modes of the electromagnetic (e.m.) field. In the dipole approximation, the Hamiltonian for the system, with zero-point energy of the e.m. field subtracted, is taken as

$$\mathcal{H}=\sum_i \hbar\Omega^i R_3{}^i+\sum_\lambda \hbar\omega_\lambda a_\lambda{}^+ a_\lambda + \sum_{\lambda,i}\hbar K_\lambda{}^i(a_\lambda{}^+ R_-{}^i+a_\lambda R_+{}^i)\,. \quad \text{(II.1)}$$

The operators $R_3{}^i$, $R_\pm{}^i$, following Dicke's notation,[3] in the space of the jth atom satisfy the commutation rules

$$[R_3{}^i, R_\pm{}^{i'}]=\pm R_\pm{}^i\delta_{ii'}\,, \quad \text{(II.2a)}$$

$$[R_\pm{}^i, R_\mp{}^{i'}]=2R_3{}^i\delta_{ii'}\,, \quad \text{(II.2b)}$$

respectively, and the field creation and destruction operators $a_\lambda{}^+$ and a_λ of the λth mode satisfy the commutation rules

$$[a_\lambda, a_{\lambda'}{}^+]=\delta_{\lambda\lambda'}\,, \quad \text{(II.3a)}$$

$$[a_\lambda, a_{\lambda'}]=0\,. \quad \text{(II.3b)}$$

The electric and magnetic fields are assumed to have the normal mode expansions

$$\mathbf{E}(\mathbf{x},t)=-\sum_\lambda(2\pi\hbar\omega_\lambda)^{1/2}E_\lambda(\mathbf{x})\,\boldsymbol{\varepsilon}_\lambda(a_\lambda{}^+ + a_\lambda)\,, \quad \text{(II.4a)}$$

$$\mathbf{H}(\mathbf{x},t)=-i\sum_\lambda(2\pi\hbar\omega_\lambda)^{1/2}H_\lambda(\mathbf{x})\mathbf{h}_\lambda(a_\lambda{}^+ - a_\lambda)\,. \quad \text{(II.4b)}$$

The $E_\lambda(\mathbf{x})$ and $H_\lambda(\mathbf{x})$ are normalized so that

$$(\boldsymbol{\varepsilon}_\lambda\cdot\boldsymbol{\varepsilon}_{\lambda'})\int E_\lambda(\mathbf{x})E_{\lambda'}(\mathbf{x})\,d(\mathrm{vol})=\delta_{\lambda\lambda'}\,, \quad \text{(II.5a)}$$

$$(\mathbf{h}_\lambda\cdot\mathbf{h}_{\lambda'})\int H_\lambda(\mathbf{x})H_{\lambda'}(\mathbf{x})\,d(\mathrm{vol})=\delta_{\lambda\lambda'}\,. \quad \text{(II.5b)}$$

The electric dipole moment operator for the jth atom is taken as the odd operator

$$\boldsymbol{\mu}_{\mathrm{op}}{}^j=\boldsymbol{\mu}^j(R_+{}^j+R_-{}^j)\delta(\mathbf{x}-\mathbf{x}^j)\,. \quad \text{(II.6)}$$

We have defined the coupling constant

$$K_\lambda{}^j=(2\pi\omega_\lambda/\hbar)^{1/2}\mu^j\cdot\varepsilon_\lambda E_\lambda(\mathbf{x}), \tag{II.7}$$

and have also defined the zero of energy as midway between the two levels of each atom so that $E_2{}^j-E_1{}^j=\hbar\Omega^j$ and $E_2{}^j+E_1{}^j=0$, where $E_2{}^j$ and $E_1{}^j$ are the energies of the upper and lower state of the jth atom, respectively.

The operator identity valid for any time-independent operator O

$$i\hbar\dot{O}=[O,\mathfrak{H}] \tag{II.8}$$

is easily worked out and gives the set

$$i\dot{R}_+{}^j=-\Omega^jR_+{}^j+2\sum_\lambda K_\lambda{}^j a_\lambda{}^+R_3{}^j, \tag{II.9a}$$

$$i\dot{R}_-{}^j=+\Omega^jR_-{}^j-2\sum_\lambda K_\lambda{}^j a_\lambda R_3{}^j, \tag{II.9b}$$

$$i\dot{R}_3{}^j=-\sum_\lambda K_\lambda{}^j(a_\lambda{}^+R_-{}^j-a_\lambda R_+{}^j), \tag{II.9c}$$

$$i\dot{a}_\lambda=\omega_\lambda a_\lambda+\sum_j K_\lambda{}^jR_-{}^j, \tag{II.9d}$$

$$i\dot{a}_\lambda{}^+=-\omega_\lambda a_\lambda{}^+-\sum_j K_\lambda{}^jR_+{}^j. \tag{II.9e}$$

Normally, expectation values of these operator identities are taken over the complete density matrix of the system (atoms+field). Taking expectation values on the right-hand side of (II.9a), (II.9b), and (II.9c) gives expectation values of products of atom and field operators, e.g., $\langle a_\lambda R_3{}^j\rangle$, etc. The problem is then essentially intractable, except in perturbation theory, for systems more complicated than a single atom interacting with a single mode. However, if we now assume that the density matrix of the system can be factored into the direct product

$$\rho=\rho_f\otimes\rho_a{}^1\otimes\rho_a{}^2\otimes\cdots\rho_a{}^N \tag{II.10}$$

of atom and field density matrices, terms such as $\langle a_\lambda R_3{}^j\rangle$ factor to the product of expectation values $\langle a_\lambda\rangle\langle R_3{}^j\rangle$. This is equivalent to phenomenological semiclassical theory, or the "S.C.F.A." (self-consistent field approximation) of Willis.[5]

It is convenient to define the slowly varying complex quantities A_λ, r^j by

$$\langle a_\lambda\rangle=A_\lambda e^{-i\omega_\lambda t}, \tag{II.11a}$$

$$\langle a_\lambda{}^+\rangle=A_\lambda{}^*e^{+i\omega_\lambda t}, \tag{II.11b}$$

$$\langle R_+{}^j\rangle=r^je^{i\Omega^jt}, \tag{II.11c}$$

$$\langle R_-{}^j\rangle=r^{j*}e^{-i\Omega^jt}. \tag{II.11d}$$

In terms of these new variables, we obtain from (II.9), after taking expectation values with respect to the factored density matrix (II.10), the set of five coupled equations

$$iA_\lambda=\sum_j K_\lambda{}^jr^{j*}e^{i(\omega_\lambda-\Omega^j)t}, \tag{II.12a}$$

$$i\dot{r}^j=2\sum_\lambda K_\lambda{}^jA_\lambda{}^*e^{i(\omega_\lambda-\Omega^j)t}R_3{}^j, \tag{II.12b}$$

$$i\dot{R}_3{}^j=-\sum_\lambda K_\lambda{}^j(A_\lambda{}^*r^{j*}e^{i(\omega_\lambda-\Omega^j)t}-A_\lambda r^je^{-i(\omega_\lambda-\Omega^j)t}), \tag{II.12c}$$

as well as their complex conjugates (where $\langle R_3{}^j\rangle$ is written simply as $R_3{}^j$).

We digress somewhat now and consider a special case of (II.12) to point out some of Dicke's results using these equations. Suppose for the moment that $\Omega^j=\Omega$ and $K_\lambda{}^j=K_\lambda$, independent of j. That is, all atoms are identical, as well as being confined in a volume whose dimensions are small compared to a wavelength $\lambda\simeq 2\pi c/\Omega$. We can then define

$$r=\sum_j r^j \tag{II.13a}$$

and

$$n=\sum_j R_3{}^j, \tag{II.13b}$$

in which special case we find the first integrals of (II.12).

$$\sum_\lambda |A_\lambda|^2+n=\text{const} \tag{II.14a}$$

and

$$|r|^2+n^2=\text{const}=R^2. \tag{II.14b}$$

(II.14a) is, of course, an expression of the conservation of energy. In analogy to Dicke's terminology, we would call (II.14b) the conservation of "cooperation." In a discussion of permanent dipole moments (spins) (II.14b) would be an expression of the conservation of total angular momentum. Here, however, we explicitly have in mind induced electric dipole moments. It is convenient to represent a radiation process geometrically in a 3-dimensional space labeling the coordinates (1,2,3) following Feynman.[6,7] According to (II.14) we can picture this simple radiation process as the motion of a vector $\mathbf{R}$ on the surface of a sphere in this space, (which, incidentally, is real space when considering permanent dipoles). The projection of $\mathbf{R}$ onto the (3) axis is the value of n, the population difference divided by two, and the projection of $\mathbf{R}$ onto the (1) axis gives $\mathrm{Re}(r)$ which is proportional to the expectation value of the induced dipole moment. The value of the induced dipole moment is zero when all atoms are exactly in their upper or lower states $n=\pm(N/2)$ and so we see that the maximum possible value of $|\mathbf{R}|=N/2$ (N is the total number of radiators), and it can have the (constant) values $(N/2)$, $(N/2)-1$, $\cdots 0$, depending on initial conditions of the problem.

To obtain spontaneous emission (using the same restrictive assumptions $\Omega^j=\Omega$, $K_\lambda{}^j=K_\lambda$), we simply perform a power-series expansion in powers of the coupling constant K_λ

$$A_\lambda(t)=A_\lambda{}^0(t)+K_\lambda A_\lambda{}^{(1)}(t)+\cdots,$$
$$r(t)=r^0(t)+K_\lambda r^{(1)}(t)+\cdots.$$

Inserting these into (II.12) and equating like powers of K_λ gives

$$i\dot{A}_\lambda{}^{(1)}(t)=K_\lambda r^*(0)e^{i(\omega_\lambda-\Omega)t}, \tag{II.15a}$$

$$r^0(t)=r^0(0)=r(0). \tag{II.15b}$$

$A_\lambda{}^0(t)=A_\lambda(0)=0$ for spontaneous emission. Integration of (II.9a) and insertion into (II.9c) leads to

$$\dot{n}=-|r(0)|^2\frac{d}{dt}\sum_\lambda K_\lambda{}^2\frac{\sin^2(\omega_\lambda-\Omega)t/2}{[(\omega_\lambda-\Omega)/2]^2}. \tag{II.16}$$

For spontaneous emission from the small volume into a large box of volume V, we find, in the usual way[8] (replacing the summation by an integral)

$$\dot{n}\simeq-2|r(0)|^2\rho(\Omega)K_\Omega{}^2. \tag{II.17}$$

Using

$$\rho(\Omega)=V\Omega^2/c^3 \quad\text{and}\quad \langle K_\Omega{}^2\rangle_{\text{sphere}}=2\pi\Omega\mu^2/3\hbar V \tag{II.18}$$

gives

$$\dot{n}=-|r(0)|^2/\tau=-(R^2-n^2(0))/\tau, \tag{II.19}$$

which is the desired result. Here τ^{-1} is the usual Einstein B coefficient

$$\tau^{-1}=\tfrac{4}{3}(\Omega^3\mu^2/\hbar c^3).$$

Suppose the system is started off with all atoms exactly in the upper state, $R^2=(N/2)^2$. Then, according to (II.19), nothing happens. This is a point of unstable equilibrium in the semiclassical theory. However, if $R^2=(N/2)^2$, but $N-1$ atoms are excited and one atom is in its ground state, then $n=(N/2)-1$, $\dot{n}=-(N-1)/\tau$, and the system emits "normally," that is, proportional to the number of excited atoms. But if we start off with $R^2=(N/2)^2$ and with half the atoms excited and half in their lower states, then $n(0)=0$ and $\dot{n}=-[(N/2)^2/\tau]$. The population then starts to decrease at a rate proportional to the square of the total number of atoms, and it is this situation that Dicke calls "superradiant" or "coherent" spontaneous emission. The situation is analogous to a physical pendulum which "radiates" at a very slow rate initially when aligned closely along the (3) axis but rather much more rapidly when in the (1–2) plane (when the electric field then sees a large dipole moment).

We now return to consideration of the more general set of Eqs. (II.12). Interest is in casting these into a form describing an idealized laser operating in one mode; the resulting set of 4 nonlinear coupled equation will be cast in a form which will readily yield to numerical integration.

Define the new variables m_λ, ψ_λ so that

$$m_\lambda e^{i\psi_\lambda}=\sum_j K_\lambda{}^j r^j{}^* e^{i(\omega_\lambda-\Omega^j)t}, \tag{II.20}$$

which is the (complex) dipole moment which couples into the λth mode; also define the e.m. field amplitude and phase e_λ and ϕ_λ of mode λ by

$$A_\lambda=e_\lambda e^{i\phi_\lambda}. \tag{II.21}$$

In terms of the new variables we have from (II.12)

$$\dot{e}_\lambda=-m_\lambda\sin(\phi_\lambda-\psi_\lambda), \tag{II.22a}$$

$$e_\lambda\dot{\phi}_\lambda=-m_\lambda\cos(\phi_\lambda-\psi_\lambda), \tag{II.22b}$$

$$\dot{m}_\lambda e^{i\psi_\lambda}+im_\lambda e^{i\psi_\lambda}\dot{\psi}_\lambda=\sum_{\lambda',j}2iK_\lambda{}^jK_{\lambda'}{}^j e_{\lambda'}e^{i\phi_{\lambda'}}e^{i(\omega_\lambda-\omega_{\lambda'})t}R_3{}^j+i\sum_j K_\lambda{}^j r^j{}^*(\omega_\lambda-\Omega^j)e^{i(\omega_\lambda-\Omega^j)t}. \tag{II.22c}$$

We now make the reasonable assumption that if we take an average of these equations assuming a random distribution of atomic sites $\mathbf{x}^j$, the modes will decouple due to the orthogonality condition (II.5a). That is, we now assume that

$$\langle K_\lambda{}^jK_{\lambda'}{}^j\rangle_{\text{av}}=(2\pi\omega_\lambda/\hbar V)\langle(\boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}_\lambda)^2\rangle_{\text{av}}\delta_{\lambda\lambda'}\cong(2\pi\omega_\lambda/\hbar V)\mu_\lambda{}^2\delta_{\lambda\lambda'}, \tag{II.22d}$$

taking $\boldsymbol{\mu}^j\simeq\boldsymbol{\mu}$, for all j. μ_λ is the component of the dipole moment which couples into mode λ.

The second term on the right of (II.22c) would vanish if $\Omega^j=\Omega=\omega_\lambda$. It represents a dephasing of the total dipole moment due to different local environments giving rise to a spread in natural frequencies about Ω. We wish to take this term into account in a way familiar from nuclear resonance theory by saying that when $e_\lambda=0$, its effect is to cause the magnitude m_λ to decay exponentially to zero at a rate γ_λ. Then we write

$$\dot{m}_\lambda+\gamma_\lambda m_\lambda=-2\Gamma e_\lambda n\sin(\phi_\lambda-\psi_\lambda), \tag{II.23}$$

$$\dot{\psi}_\lambda m_\lambda=2\Gamma e_\lambda n\cos(\phi_\lambda-\psi_\lambda), \tag{II.24}$$

with

$$n=\sum_j R_3{}^j \tag{II.25}$$

and

$$\Gamma=2\pi\omega_\lambda\mu_\lambda{}^2/\hbar V. \tag{II.26}$$

From (II.12c), (II.20), and (II.21), we have that

$$\dot{n}=e_\lambda m_\lambda\sin(\phi_\lambda-\psi_\lambda)+\sum_{\lambda'\neq\lambda}e_{\lambda'}m_{\lambda'}\sin(\phi_{\lambda'}-\psi_{\lambda'}). \tag{II.27}$$

The sum $\sum_{\lambda'}$ runs over all those modes, except mode λ, which are at approximately frequency ω_λ but which are appreciably more lossy than the mode designated by λ. For instance, this term represents the losses of

[8] L. I. Schiff, *Quantum Mechanics* (McGraw-Hill Book Company, Inc., New York, 1955).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

radiation from the sides of a lasing crystal due to spontaneous emission. The usually small stimulated emission into these modes which are characterized by high loss (free-space-like modes) will be neglected.

If we add a phenomenological mode loss rate term to (II.22a), and collect equations, we have finally the set

$$(d/dt)(e_\lambda^2)+2\beta e_\lambda^2=-m_\lambda e_\lambda \sin\theta_\lambda, \tag{II.28a}$$

$$(d/dt)m_\lambda+\gamma_\lambda m_\lambda=-2\Gamma e_\lambda n \sin\theta_\lambda, \tag{II.28b}$$

$$(d/dt)n=e_\lambda m_\lambda \sin\theta_\lambda+\sum_{\lambda'} e_{\lambda'} m_{\lambda'} \sin\theta_{\lambda'}, \tag{II.28c}$$

$$m_\lambda(d/dt)\psi_\lambda=2\Gamma e_\lambda n \cos\theta_\lambda, \tag{II.28d}$$

$$e_\lambda(d/dt)\phi_\lambda=-m_\lambda \cos\theta_\lambda, \tag{II.28e}$$

$$\theta_\lambda\equiv\phi_\lambda-\psi_\lambda. \tag{II.29}$$

From (II.28a), (II.28d), and (II.28e) we note the first integral

$$e_\lambda m_\lambda \cos\theta_\lambda=(e_\lambda m_\lambda \cos\theta_\lambda)_0 e^{-(\beta_\lambda+\gamma_\lambda)t}, \tag{II.30}$$

which states that if m_λ, e_λ, or $\cos\theta_\lambda$ were ever zero, then $\cos\theta_\lambda=0$ for all time for a nontrivial solution to exist. Otherwise, $\cos\theta_\lambda$ will approach zero at a rate $\beta_\lambda+\gamma_\lambda$. $\cos\theta_\lambda=0$ implies $\sin\theta_\lambda=\pm 1$. It must be noticed, however, that $\sin\theta_\lambda$ as a function of time takes on the two values $+1$ or -1, since by inspection of (II.28a), (II.28c) the sign of $\sin\theta_\lambda$ determines whether the atomic system is emitting or absorbing radiation.

If in (II.28b) we assume that $\dot{m}_\lambda \ll K_\lambda m_\lambda$, then we may neglect $\dot{m}_\lambda$, solve for m_λ, and insert its value into (II.28a) and (II.28c). This gives, by use of (II.30) with $\cos\theta_\lambda=0$,

$$(d/dt)e_\lambda^2+2\beta_\lambda e_\lambda^2=(2\Gamma/\gamma_\lambda)e_\lambda^2 n, \tag{II.31a}$$

$$(d/dt)n=-(2\Gamma/\gamma_\lambda)e_\lambda^2 n-(n+N/2)/\tau. \tag{II.31b}$$

The term $(n+N/2)/\tau$ has been used as an approximation for the last term of (II.28c); $n+(N/2)$ is simply the population of the excited state and τ^{-1} is the spontaneous rate. The two coupled equations constitute the well-known rate equation approach to radiation dynamics.[1] The absorption rate (per atom) for mode λ is given by $\alpha_\lambda=\Gamma/2\gamma_\lambda=\pi\omega_\lambda\mu_\lambda^2/\hbar V\gamma_\lambda$.

At the other extreme from the rate equation approximation (II.31), the completely "coherent" description of radiation into a single mode is afforded by dropping all terms in (II.19) which describe losses, that is by setting $\gamma_\lambda=\beta_\lambda=\sum e_{\lambda'} m_{\lambda'} \sin\theta_{\lambda'}=0$. In this case, by defining the angle variable Θ in the $m_\lambda/(2\Gamma)^{1/2}$, n plane as $\Theta=\tan^{-1}[(2\Gamma^{1/2})m_\lambda/n]$ we find the equation of motion for Θ

$$(d^2\Theta/dt^2)+(2\Gamma)\sin\Theta=0, \tag{II.32}$$

which is simply the equation of motion of a spherical pendulum. The initial conditions are determined from $d\Theta/dt=-(2\Gamma)^{1/2}e_{\lambda'}$. The solutions are elliptic functions and become sinusoids when $e_\lambda(0)$ gets large ($\gtrsim 10$). The case $e_\lambda(0)=0$ appropriate to spontaneous emission leads to the same general results as in Eq. (II.19) concerning the rate of spontaneouse mission as a function of N. Keeping only the mode loss rate in (II.28) results in the equation

$$(d^2\Theta/dt^2)+\beta_\lambda(d\Theta/dt)+2\Gamma \sin\Theta=0, \tag{II.33}$$

easily recognized as the equation for a damped physical pendulum.

The "perfectly coherent" process is one which describes a circle in the n, $m_\lambda/(2\Gamma)^{1/2}$ plane. The solutions to the rate equation, on the other hand, are restricted to one quadrant in this plane. Since $m_\lambda \simeq \Gamma e_\lambda n/\gamma_\lambda$, $n=0$ implies that $m_\lambda=0$, and thus the only crossing point of the axis $n=0$ is the improbable point $n=0$, $m_\lambda=0$, in the rate equation approximation.

In order to facilitate numerical integration of this set of equations, we define the new variables

$$I=e_\lambda^2/2N, \tag{II.34a}$$

$$m=m_\lambda/N(2\Gamma)^{1/2}, \tag{II.34b}$$

$$\zeta=-me_\lambda \sin\theta_\lambda/(2N)^{1/2}, \tag{II.34c}$$

$$\Delta=n/N, \tag{II.34d}$$

$$\alpha=(N\Gamma)^{1/2}. \tag{II.34e}$$

The equations (II.28) then take the form

$$\dot{I}+2\beta I=\alpha\zeta, \tag{II.35a}$$

$$dm^2/dt+2\gamma m^2=2\alpha\zeta\Delta, \tag{II.35b}$$

$$d\zeta/dt+(\beta+\gamma)\zeta=\alpha(m^2+2I\Delta), \tag{II.35c}$$

$$\dot{\Delta}=-\alpha\zeta-[(\Delta+\tfrac{1}{2})/\tau]-P(\Delta-\tfrac{1}{2}), \tag{II.35d}$$

where we have suppressed the subscript λ, written the term $\sum_{\lambda'} e_{\lambda'} m_{\lambda'} \sin\theta_{\lambda'}$ as $(\Delta+\frac{1}{2})/\tau$, and added a term to the equation for the rate of change of the population difference Δ (normalized to $2N$) to describe the effect of a "pump" which takes atoms from the ground state and puts them into the upper state. We are thus assuming an infinitely fast transition from the pumping band to the upper laser level, as well as an optically thin material so that the pumping is uniform throughout the volume V. We can allow P (the pumping rate) as well as β, the cavity mode loss rate, to be functions of time; the numerical solutions below, however, only include the case of a time varying β.

III. RESULTS OF NUMERICAL INTEGRATION

The set of Eqs. (II.35) were integrated on a high-speed digital computer for several values of a (constant) pump rate P, and the coupling parameter α, and the dipole moment dephasing rate γ. The function β is taken to be a "Fermi function" of time

$$\beta(t)=[(\beta_i-\beta_f)/(1+e^{(t-t_0)/\Delta t})]+\beta_f, \tag{III.1}$$

and will represent approximately the "Q switching" by a Kerr cell or similar apparatus. t_0 will be chosen as a

time somewhere just before the populations Δ reach a threshold determined by β_i.

Figure 1 shows the "relaxation oscillations" for a laser operating under conditions of ordinary power output.[9] Both the intensity I as a function of time as well as the corresponding phase diagram of $(m\cos\psi)$ versus Δ is shown for each case. The dots in the phase diagrams correspond in time to the peaks in the intensity diagram. In Fig. 1(b), the entire phase diagram is seen to lie in the first quadrant and the solution is very well predicted by the rate equations, since the rate γ is much greater than the fractional rate of change of m. The intensity I is shown in units of photons/N, where N is the effective number of atoms participating. By changing the cavity loss rate to a larger value we see in Fig. 2, as expected, that the

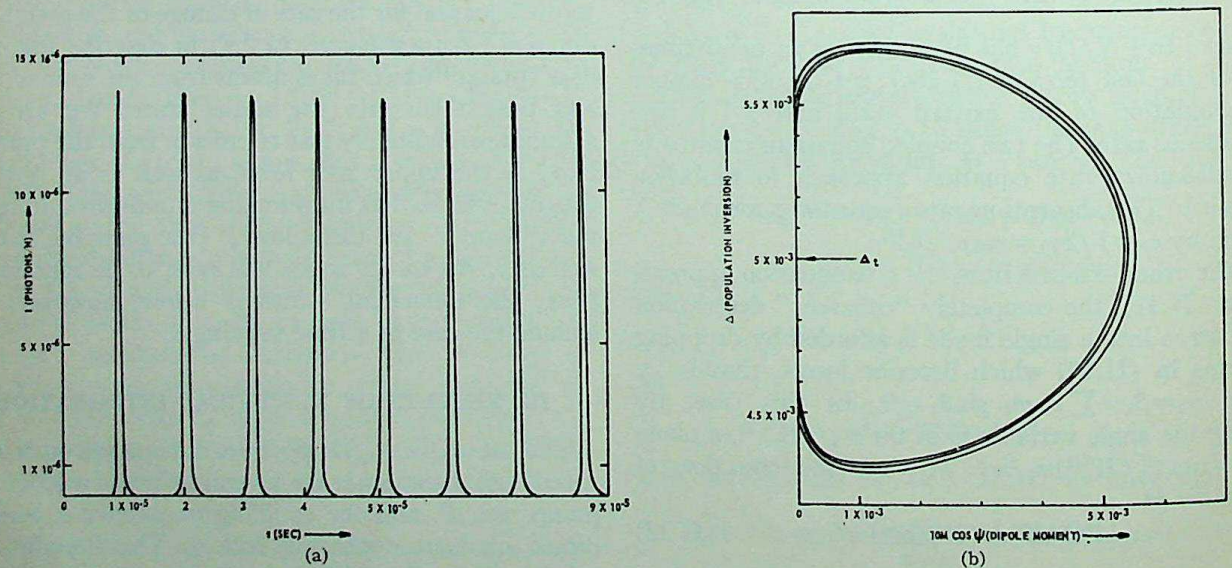

FIG. 2. Same as Fig. 1, except for higher cavity loss rate, $\beta=10^8$ $\sec^{-1}$.

[9] For all the following figures, the quantity $(e_\lambda m_\lambda \cos\theta_\lambda)_0$ was taken as zero. [See Eq. (II.30).] Moreover, for convenience in graphing, the same discontinuous properties are attributed to ψ and ϕ as are exhibited by $\theta=\phi-\psi$. That is, $\sin\phi$ and $\sin\psi$ as functions of time are made to alternate between the values $+1$ and -1 in such a manner that $\sin\theta(t)$ takes on the correct values and the functions $m\cos\psi$ and $e\sin\phi$ are continuous.

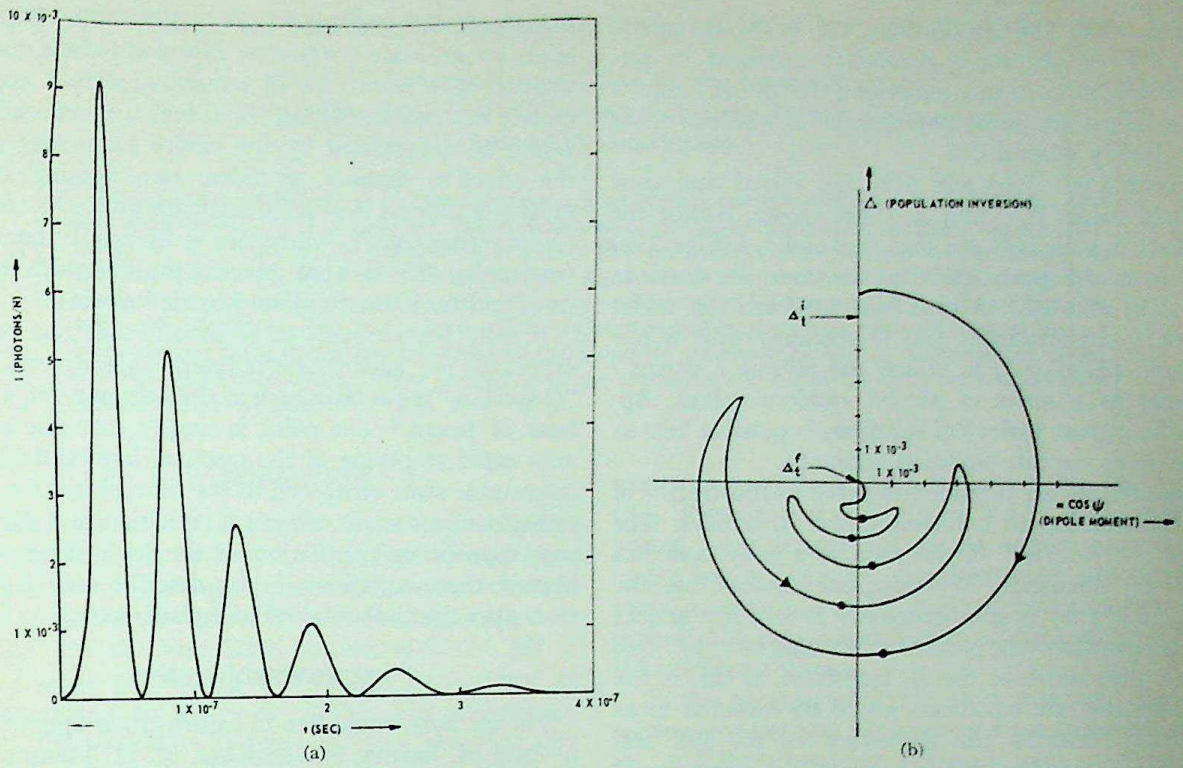

FIG. 3. Same as Fig. 1, except for a larger pump $P=10^4$ sec^{-1}, a smaller dephasing rate $\gamma=10^7$ sec^{-1}, and the addition of Q spoiling with cavity loss rate initially $\beta_i=10^9$ sec^{-1} changing to a final cavity loss rate of $\beta_f=10^7$ sec^{-1} in a time $\Delta t=2.5.10^{-8}$ sec.

spiking is almost continuous; clearly the radiation almost completely escapes from the cavity before the pump can again bring the population over threshold, $\Delta_t=\beta\gamma/2\alpha^2$, and the process simply repeats itself. (The parameter τ, the spontaneous emission time has been taken as 3×10^{-3} sec in all computations.) Figure 3 shows a case of "Q switching" [Eq. (III.1)], where parameters are chosen to exhibit a rather extreme situation (in present day practice) of very low γ and β.

The second, third, etc., spikes in Fig. 3(a) are seen

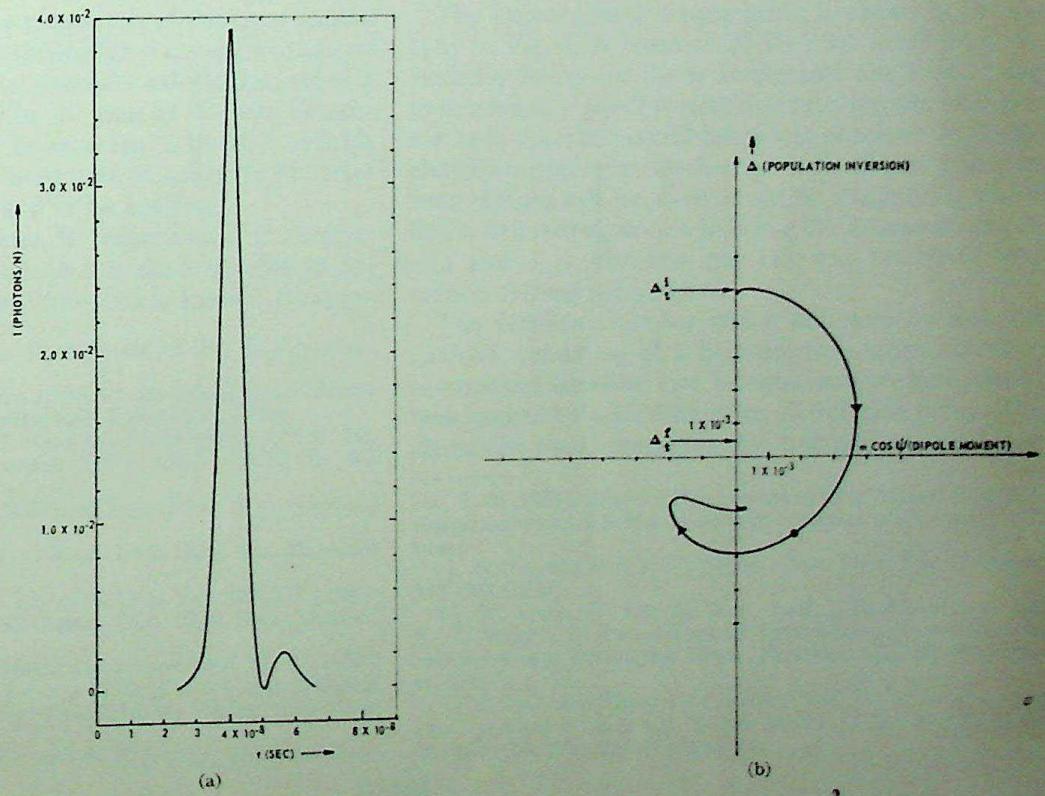

FIG. 4. Same as Fig. 3, except that final cavity loss rate $\beta_f=10^8$ sec^{-1} and Q spoiling occurs over time $\Delta t=5.10^{-9}$ sec.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

to occur when the populations are below inversion, $\Delta<0$. This is strictly a possibility inherent in this analysis and not in a rate equation description. Figure 4 again exhibits the same phenomena; the second spike occurs totally when $\Delta<0$.

In both Figs. 3(b) and 4(b) the initial and final threshold values $\Delta_t^{(i)}$ and $\Delta_t^{(f)}$ are shown. Notice the difference in scale between Figs. 1, 2 and 3, 4. Figs. 1(b) and 2(b) would appear as diffuse dots near the Δ axis in Figs. 3(b) and 4(b). A case has also been run under "normal" circumstances (no Q spoiling) with a low threshold ($\Delta_t\approx 0.001$) in which the output I versus t appeared as a series of almost random spikes. Apparently, a great variety of solutions is possible here as compared to the rate equation approach.

These results are intended to serve as illustrative of some possibilities in coherent device dynamics. The case of a "two-level" device akin to a ruby laser has guided the discussion. However, one expects that the laser line in ruby is homogeneously broadened, and at room temperatures the parameter γ would be $\approx 10^{11}$ cps, the full time width of the R_1 transition. If this is the case then the rate equations would be expected to as adequately describe the dynamics as the full set, (II.35) and secondary pulses as described above would not be possible unless one operated as a much lower temperature, $\lesssim 70°$K. However, if the laser line is inhomogeneously broadened even at room temperature, (which appears unlikely in ruby), then such "hopping" might occur, since γ would be expected to be a good bit smaller. The above set of equations should approximately describe the dynamics of such a system where γ would be determined by the cavity parameter β and the effective number of atoms participating in the radiation process into a single mode would be roughly $(N)\text{eff}\approx(\Delta\omega_c/\Delta\omega)N$, where $\Delta\omega_c$ is the cavity linewidth (presuming this is what governs the linewidth in this case) and $\Delta\omega$ is the full laser atomic linewidth.

It may be pertinent to point out that one cannot expect to see such "superradiant" hopping effects by "Q spoiling" a gas laser such as the helium-neon, 4-level laser of Javan.[10] The point is simply that due to the very rapid emptying of the terminal laser state into a metastable state compared to the time width of a giant pulse, one can never achieve a condition of $\Delta<0$ with any appreciable population in the lower laser state; that is, these equations do not describe such a device even over the time interval of a giant pulse.

Collisional Electron Detachment from 20-MeV D^0 and D^- Ions*

KLAUS H. BERKNER, SELIG N. KAPLAN, AND ROBERT V. PYLE
Lawrence Radiation Laboratory, University of California, Berkeley, California
(Received 27 January 1964)

Cross sections for collisional electron detachment from 20-MeV deuterium atoms and negative ions have been measured in H_2, He, N_2, and Ar. The cross sections σ_{01} per target molecule for the ionization of neutral atoms are 2.2, 1.6, 20, and 36, respectively, in units of 10^{-18} cm^2. Results for single-electron detachment from D^- ions, σ_{-10}, are 7.5, 4.7, 58, and 75, respectively. All values have an uncertainty of $\pm 10\%$, chiefly from absolute-pressure calibration uncertainties. The experimental values for atoms in H_2 and He are in agreement with calculations that use the Born and free-collision approximations. The measured cross sections for single-electron detachment from negative ions in H_2 and He are about one-half of the calculated values. The two-electron detachment cross sections, σ_{-11}, are approximately 4% of the single-detachment cross sections, σ_{-10}, in all gases.

I. INTRODUCTION

THE cross sections for electron loss from fast hydrogen atoms in hydrogen and helium targets have been calculated by using three models: the semiclassical model of Bohr,[1] the "free-collision" (impulse) approximation,[2] and the first Born approximation.[3,4] All of these models predict an E^{-1} energy dependence at high energies (i.e., where $Ze^2/\hbar v \ll 1$). For a hydrogen target, this condition implies energies above a few hundred kilovolts. In this asymptotic region, the Born and free-collision approximations give numerical values that agree with each other and with experiment[5] to within 15%.

For single-electron detachment from fast H^- ions, the evaluation of the cross section by the Born approximation has been considered too cumbersome to carry out with the best available H^- wave function, and the result is so sensitive to the choice of other approximate wave functions that the magnitude of the cross section is very uncertain.[6] The free-collision approximation, on the other hand, permits a simpler calculation; since it has given good results in the case of electron detachment from H^0 it might be expected to be fairly reliable in the H^- case. It has been used to calculate H^- cross sections in H and He[2] and in N_2 and O_2.[7]

We know of only three H^- experiments at energies that are sufficiently high to test the free-collision approximation. Rose *et al.*[8] have made gas-cell measurements at energies up to 1.8 MeV in H_2, O_2, Ar, and CO_2. Fremlin and Spiers[9] and Verba *et al.*[10] have reported measurements in air at higher energies (but under less well-known conditions) by observing the radial attenuation of H^- internal cyclotron beams. In general, the experimental cross sections are well below the calculated values.

In the present work we have measured the cross sections for electron detachment from hydrogen atoms, σ_{01}, and from negative hydrogen ions, σ_{-10} and σ_{-11}, in a single high-energy experiment under well-controlled conditions.

We note that the magnitudes of these cross sections and the way they extrapolate to higher energies are of interest in certain high-energy-accelerator design considerations.[7,9]

II. EXPERIMENTAL ARRANGEMENT

The experimental arrangement is shown schematically in Fig. 1. A beam of 20-MeV D^- ions[11] from the Berkeley heavy-ion linear accelerator was bent 15 deg to remove any possible contaminants. For the measurements of σ_{01}, the neutral beam was obtained by single-electron stripping in the first gas cell; all ions emerging from the gas cell were swept out by magnet $S1$, which had a field strength of 4 kG. For the measurements of σ_{-10} and σ_{-11}, the first gas cell was evacuated and magnet $S1$ was set at 0 kG.

The collision chamber was a differentially pumped gas cell, consisting of a high-pressure target chamber sandwiched between two intermediate-pressure chambers backed by a 1500-liter/sec oil diffusion pump. The chambers were connected by 6-mm-diam 5-cm-long

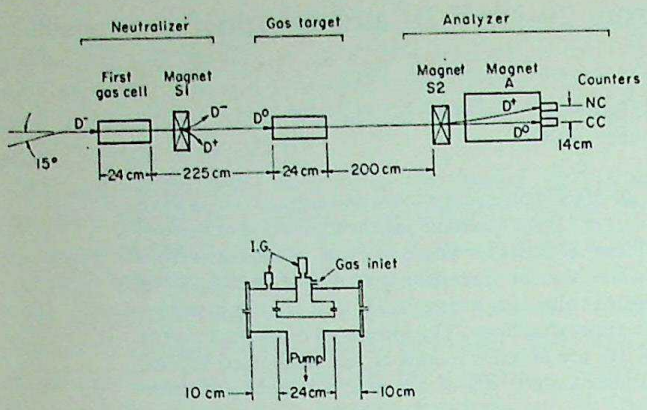

FIG. 1. The experimental arrangement.

tubes (inset Fig. 1). With this cell a base pressure of 5×10^{-6} Torr could be maintained in the drift sections when the pressure in the target chamber was 5×10^{-2} Torr. The effective length of the target chamber was $L=24\pm1$ cm. Integrated target densities ranged from $NL=0.5$ to 30×10^{15} atoms/cm^2 for Ar and N_2, and $NL=2$ to 200×10^{15} atoms/cm^2 for He and H_2. The pressure in the target chamber was monitored by a Westinghouse type-7676 high-pressure ionization gauge (Schulz-Phelps gauge) which was cross calibrated with three liquid-nitrogen-trapped McLeod gauges. Fluctuations of the calibration from day to day and uncertainty of the absolute accuracy of the McLeod gauges indicate an uncertainty of $\pm10\%$ in the pressure.

The ions in the beam emerging from the gas target were deflected by magnet $S2$ (3 kG) and steered into the detector CC by magnet A($\approx$8 kG), the neutrals were detected by NC. The detectors NC and CC each consisted of a 5-cm-diam plastic scintillator and photomultiplier. By means of collimating slits it was determined that the ions reaching the detector were well localized in a 5-mm-diam beam spot, which was small compared to the size of the detector. If two species of ions were to be detected, magnet A was used to steer first one and then the other into the detector CC, while the neutral counter was used as a monitor.

III. RESULTS AND ANALYSIS

Cross sections were calculated at a number of pressures for each target gas according to the following formulas. (We neglect cross sections for electron capture by the fast ions; these are at least three orders of magnitude smaller than the electron loss values considered here.[12])

If n_0 is the number of hydrogen atoms at a depth π in the target, σ_{01} is the cross section for electron detachment, $\Pi\equiv NL$ is the target thickness (atoms/cm^2), and n_+ is the number of positive ions produced in the thickness π, then we have

$$dn_0/d\pi=-n_0\sigma_{01}=-dn_+/d\pi, \tag{1}$$

with the solution

$$\sigma_{01}=\frac{1}{\Pi}\ln\left[1+\frac{n_+(\Pi)}{n_0(\Pi)}\right]. \tag{2}$$

Similarly, the disappearance rate for negative hydrogen ions due to loss of one electron (σ_{-10}) and two electrons (σ_{-11}) in a single collision is given by

$$dn_-/d\pi=-n_-(\sigma_{-10}+\sigma_{-11}), \tag{3}$$

with the solution

$$\sigma_{-10}+\sigma_{-11}=\frac{1}{\Pi}\ln\left[1+\frac{n_+(\Pi)+n_0(\Pi)}{n_-(\Pi)}\right]. \tag{4}$$

Using the additional relation

$$dn_0/d\pi=n_-\sigma_{-10}-n_0\sigma_{01}, \tag{5}$$

we obtain

$$\sigma_{-10}=\frac{n_0(\Pi)}{n_-(\Pi)}\left[\frac{\sigma_{01}-(\sigma_{-10}+\sigma_{-11})}{1-\exp\Pi(\sigma_{-10}+\sigma_{-11}-\sigma_{01})}\right]. \tag{6}$$

Equations (4) and (6) were solved for σ_{-10} and σ_{-11}, and Eq. (2) was solved for σ_{01}. Uncertainties in the pressure, cell length, background correction, and counting statistics were propagated through the above equations to obtain the uncertainties in the cross sections.

At sufficiently low pressures, the above equations and the uncertainties in the results can be approximated by relatively simple expressions that demonstrate the correct limiting behavior.

The σ_{01} calculations quoted in the text have been carried out for fast hydrogen atoms in the ground state. If an appreciable fraction of the atoms of our beam were in excited states, and if the variation of σ_{01} with quantum level, n, were sufficiently large, then the experimental values could be considerably greater than the ground-state cross sections. This situation would show up as a decrease in the measured cross sections with increasing gas-cell pressure, closely approaching the ground-state value at the higher pressures. Unfortunately, we did not have time to take σ_{01} over a large pressure range (the maximum was a factor of 10 in H_2), but no variation of the kind mentioned above occurred in any of the gases.

It is known[13,14] that perhaps 15% of the neutral atoms produced by charge exchange or H_2^+ breakup are excited to $n\gtrsim3$; the fraction in each state is $f\approx(2-3)n^{-3}$. (The $n=2$ states completely decay in our geometry.) Preliminary measurements by us indi-

Digitized by Arya Samaj Foundation Chennai and eGangotri

cate that the excited-state populations are an order of magnitude smaller when the atoms are produced by electron detachment from negative hydrogen ions, as in this experiment. There is also evidence[14,15] that the detachment cross section varies more slowly than n. We therefore conclude that the measured cross section is appropriate to the ground state. This question does not arise for the negative-hydrogen-detachment cross sections.

Results for nitrogen are shown in Fig. 2 in order to illustrate the degree of internal consistency. Results for other targets are of similar quality.

The weighted averages of the various cross-section measurements are given in Table I. To aid in the discussion, they are also plotted in Fig. 3 together with lower energy data from other experiments and theoretical estimates. In this figure, and in the following discussion, the ions are treated as if they were 10-MeV hydrogen rather than 20-MeV deuterium particles.

IV. DISCUSSION AND CONCLUSIONS

A. Electron Detachment from Neutral Atoms, σ_{01}

Our measured cross sections for electron detachment from neutral hydrogen in H_2 and He are in excellent agreement with the theoretical predictions of the free-collision[2] and Born approximations[3,4] and are consistent with an E^{-1} extrapolation of the lower energy results of Barnett and Reynolds[5] (Fig. 3). For the heavier targets, N_2 and Ar, such cross-section calculations have not been reported. A linear extrapolation to the results of Barnett and Reynolds indicates that certainly in Ar, and probably also in N_2, the cross section falls off less rapidly than the E^{-1} predicted for and observed in the lighter targets. The semiclassical theory of Bohr,[1] which also predicts the E^{-1} energy dependence in light elements (although it considerably overestimates the magnitudes of the cross sections), predicts a weaker energy dependence, approximately proportional to $E^{-1/2}$ for medium-Z elements. For reference, lines corresponding to E^{-1}, $E^{-2/3}$, and $E^{-1/2}$ variations are drawn through our σ_{01} point in Ar, but these are not intended to suggest that the asymptotic energy region has been reached.

TABLE I. Measured cross sections per target molecule for 20-MeV deuterium (in units of 10^{-18} cm^2).

	σ_{01} ±10%	$\sigma_{-11}+\sigma_{-10}$ ±10%	σ_{-10} ±10%	σ_{-11} ±25%	$\frac{\sigma_{-11}}{\sigma_{-10}}$	$\frac{\sigma_{01}}{\sigma_{-10}}$
H_2	2.2	7.8	7.5	0.29	0.038	0.31
He	1.6	4.9	4.7	0.14	0.029	0.34
N_2	20	61	58	2.7	0.046	0.34

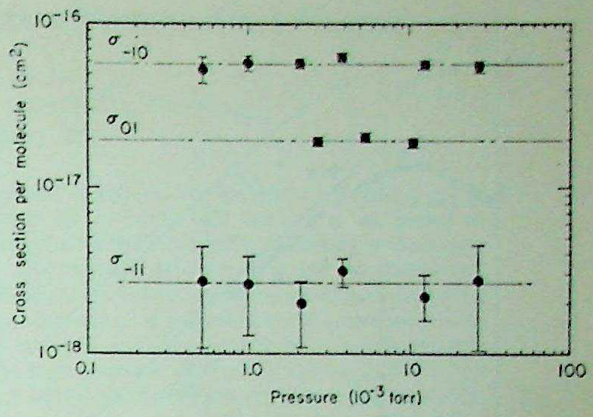

FIG. 2. Cross-section measurements in N_2 versus pressure.

B. Single-Electron Detachment from Negative Hydrogen Ions, σ_{-10}

The results for single-electron loss from negative hydrogen ions, σ_{-10}, seem to show the same energy dependence as the σ_{01} cross sections at high energies (Fig. 3). The Born-approximation calculation of McDowell and Peach[6] for a hydrogen target predicts a cross section that is $2\frac{1}{2}$ times our experimental value. Moreover, in the 1–10-MeV energy range their calculated cross section has not yet reached the asymptotic dependence and thus varies much more slowly than E^{-1}. (The line marked M-P in Fig. 3 is their asymptotic solution.) As mentioned in the introduction, this calculation is extremely sensitive to the choice of the approximation to the H^- wave function. Because of this, they state that their results should not be in error by more than a factor of 5 at high energies.

The free-collision approximation, which requires only a knowledge of the ionization potential, also gives results that are higher than the experimental values for H_2,[2] He,[2] and N_2.[7]

C. The Two-Electron Detachment Cross Sections, σ_{-11}

The cross section for the loss of both electrons from an H^- ion, σ_{-11}, is approximately 4% of the one-electron detachment cross section, σ_{-10}, at 10 MeV in all of the target gases. This proportion is similar to that observed by Fogel *et al.* at energies of 40 keV or less.[16] We know of no theoretical predictions for the σ_{-11} cross sections; the problem is currently under consideration by McDowell.[17]

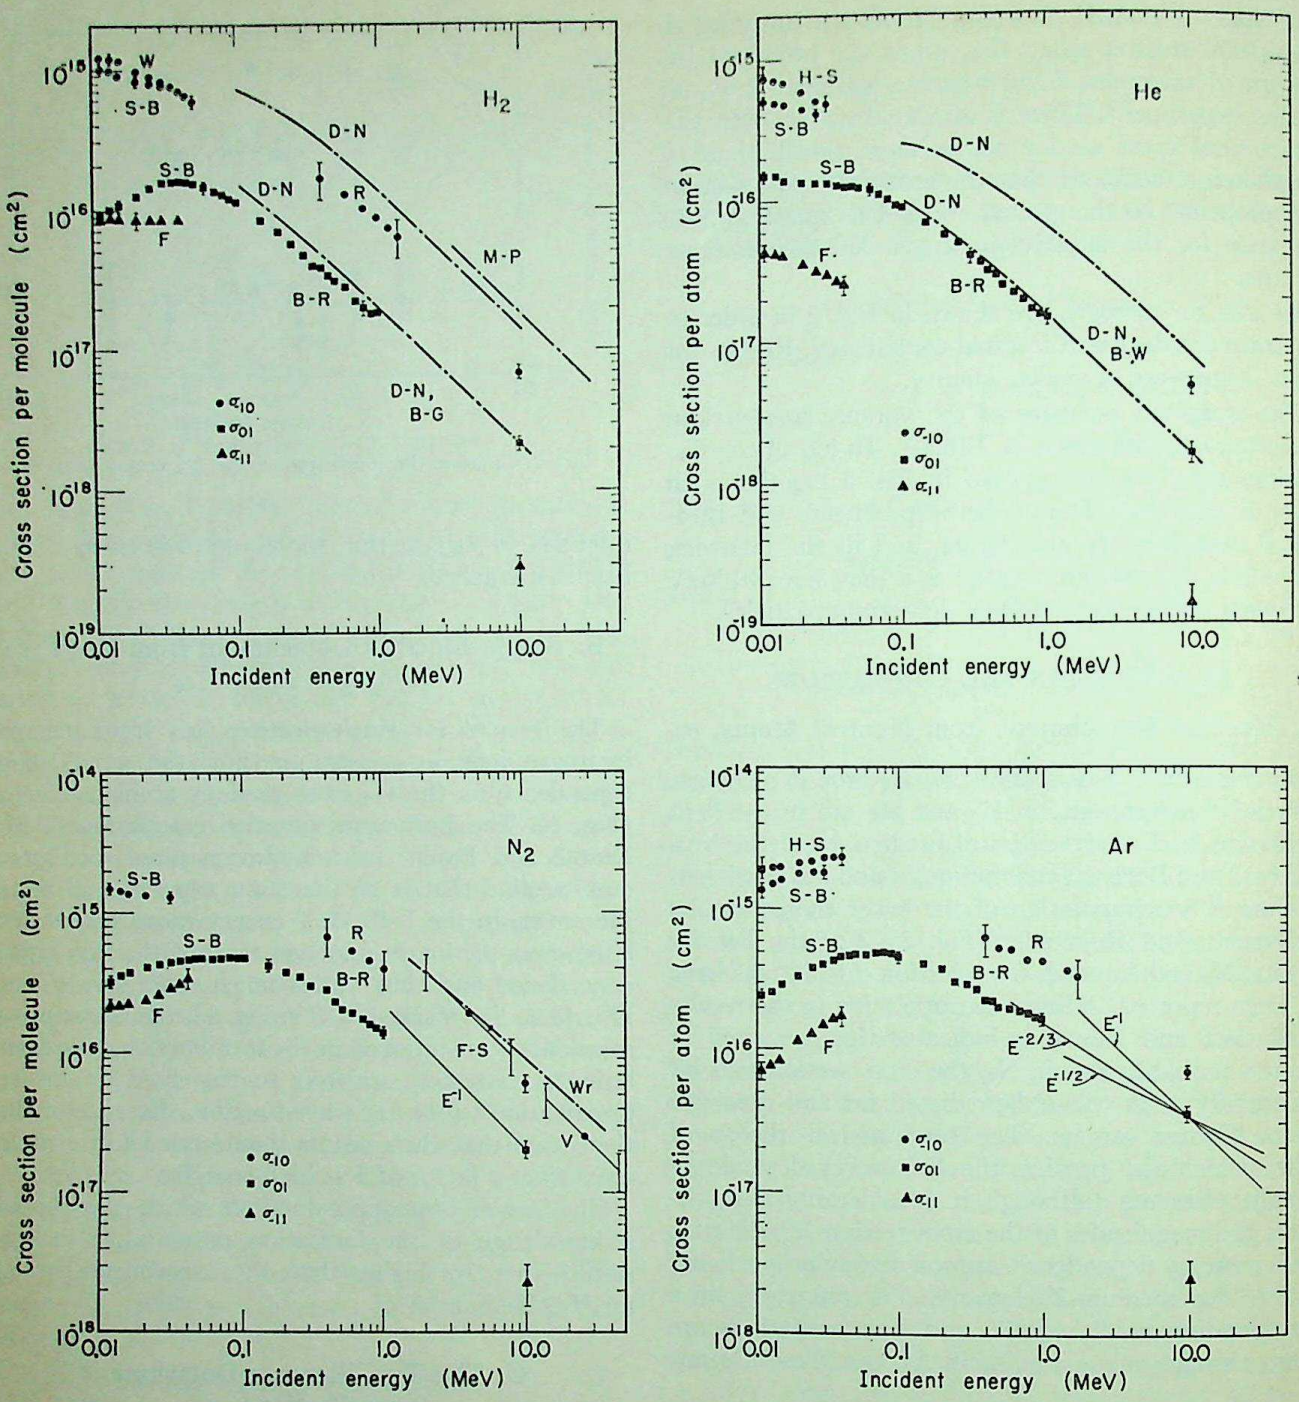

FIG. 3. Energy dependence of the hydrogen cross sections. ●:σ_{-10}; ■:σ_{01}; ▲:σ_{-11}. The "10-MeV" points are the 20-MeV deuterium data of this paper, and the others are from Allison's review article (Ref. 12), which includes measurements by Barnett and Reynolds (B-R), Fogel *et al.* (F), Hasted and Stedeford (H-S), Rose *et al.* (R), Stier and Barnett (S-B), and Whittier (W). The solid lines are internal cyclotron-beam measurements by Fremlin and Spiers (F-S) (Ref. 9) and Verba *et al.* (V) (Ref. 10). The broken lines give Born-approximation calculations by Bates and Williams (B-W) (Ref. 3), Bates and Griffing (B-G) (Ref. 4), and McDowell and Peach (M-P) (Ref. 6), and free-collision-approximation calculations by Dmitriev and Nikolaev (D-N) (Ref. 2) and Wright (Wr) (Ref. 7).

D. Summary

The measured σ_{01} cross sections are in good agreement with theory for H_2 and He target gases; calculations are not available in higher Z materials. The σ_{-10} cross sections are not in good agreement with theory. As yet, no calculations of σ_{-11} have been reported.

Measurements at considerably higher energies are necessary before the asymptotic nature of many of the cross sections can be established.

PHYSICAL REVIEW VOLUME 134, NUMBER 6A 15 JUNE 1964

Hysteresis in Stability Conditions of Electron-Hole Plasma

BETSY ANCKER-JOHNSON
Boeing Scientific Research Laboratories, Seattle, Washington
(Received 13 January 1964)

The investigation of the hysteresis occurring in the threshold conditions for the helical instability oscillations in electron-hole plasma has been extended. The hysteresis in electric field strength E can exceed 45 V/cm and 50% of the applied E at threshold. By determining the stability-instability boundary in the p-type InSb as a function of the parallel (or antiparallel) electric and magnetic field strengths and also the plasma density, the magnetic field induced by the formation of the helical density perturbation is deduced. Resulting displaced loop B-H curves are presented. The magnitude of the induction enhancement B_{hys} can be as large as 165 Oe and 55% of the applied B at threshold. The extent of applied magnetic field (or electric field strength) over which the loops can occur is limited at the high magnetic field end (typically $\lesssim$600 G) by vanishingly small plasma density and at the other end ($\gtrsim$280 G) by the occurrence of magnetic pinching. The loops are largest at the low magnetic field end. The range of loop energy, defined as the product of E_{hys} and B_{hys}, increases with decreasing plasma cross-sectional area until saturation occurs at a plasma radius of $\sim 3\times10^{-2}$ cm. The full range from largest to smallest loop in any one sample is achieved by a relatively small variation in the "input energies," i.e., the product of the magnetic and electric field strengths at threshold.

I. INTRODUCTION

IT is well known that the stability of a plasma may be enhanced by the application of a longitudinal magnetic field.[1] Early stability and confinement experiments also showed the existence of a definite limit to the improvement so obtainable. Indeed, too large a magnetic field causes the onset of oscillations in the plasma and its rapid radial diffusion to the container boundaries. The helical instability theory first proposed by Kadomtsev and Nedospasov[2] accounts for these occurrences and describes the boundary between stability and instability in terms of the applied, parallel electric and magnetic field strengths. Johnson and Jerde[3] supplied a firm mathematical base for the theory and improved its predictions.

Almost concurrently with these electron-ion plasma experiments,[1] Ivanov and Ryvkin[4] reported the occurrence of current oscillations in germanium immersed in a longitudinal magnetic field. Larrabee and Steele[5] made a detailed study of this phenomenon and named it the oscillistor. They demonstrated that the oscillations occur only if excess carriers, i.e., an electron-hole plasma, is present in the semiconductor. Glicksman[6] recognized the applicability of Kadomtsev and Nedospasov's theory to this phenomenon and adapted it to electron-hole plasmas in an insulator. Holter[7] used Johnson and Jerde's[3] approach to derive again explicit expressions for the threshold frequency and electric field strength as functions of magnetic field strength, some parameters of the plasma and its container (the semiconductor), this time applicable also to both extrinsic and intrinsic semiconductors as well as to insulators. His comparison with Ancker-Johnson's[8] measurements of the threshold conditions showed good agreement. Other data[9,10] on the threshold conditions which do not include the densities of the plasmas, a parameter of the theory, are compatible with theory.

Recently, hysteresis in the conditions necessary for the production of the helical instability oscillations in electron-hole plasmas was reported along with the suggestion of its practical application to memory devices.[11] This hysteresis differs from the familiar type possessed, for example, by ferrites, in that it exhibits two loops which are displaced from the origin of the B–H curve, as illustrated by Fig. 1(a). A plasma is

[a] Obtained by extrapolation of the I–V characteristic after the onset of current pinching.

normally diamagnetic but at the onset of the helical instability it becomes paramagnetic as experimentally demonstrated in an electron-ion plasma by Johnson.[12] This paramagnetism occurs because the formation of the helical density perturbation produces an enhanced induction. The hysteresis follows from the fact that as the applied magnetic field is reduced, the threshold induction is not reached until the applied field has a smaller magnitude than it had at the onset of instability. Drummond[13] first deduced that Johnson's results implied the existence of such a new hysteresis effect. The hysteresis observed[11] in an electron-hole plasma is an hysteresis in the parameter which defines the boundary between a stable and unstable plasma, namely the magnitude of the produce of the electric and magnetic fields, as illustrated in Fig. 1(b). The present paper extends these hysteresis measurements to the determination of the induction enhancement caused by the helical instability and, hence, B–H curves of the type illustrated in Fig. 1(a) are presented.

II. EXPERIMENT

The circuit is the same as that employed previously.[11] It consists simply of a triangular waveform delivered to a single crystal parallelepiped of p-type InSb at 77°K in the presence of a magnetic field which is applied essentially parallel to the direction of current flow. The plasma is produced by injection[14] from indium solder contacts of various cross-sectional area. The electric field strength is determined by measuring the potential difference between two very small contacts spaced a known distance apart. The series of measurements reported here involves four samples of similar bulk properties but different dimensions and contact arrangements as recorded in Table I. The waveform of the

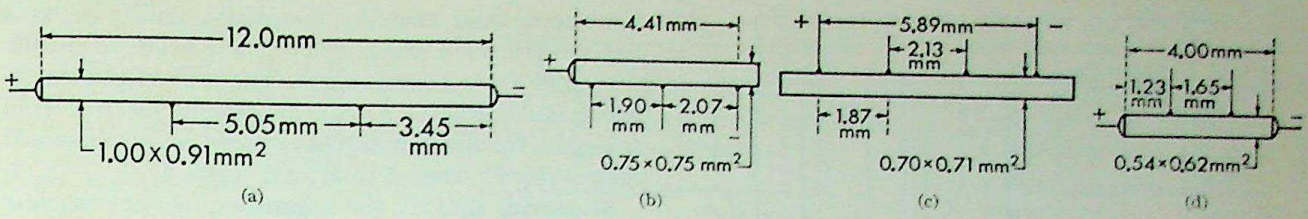

FIG. 3. Dimensions of samples. (a) 2D-2, (b) 2D2-7, (c) 2D2-8, (d) 2D2-2.

helical instability oscillations is markedly affected by the degree of parallelism (as also noted previously[5]) between the applied magnetic field and the direction of current flow, particularly in the cases of nonsymmetric current contacts (samples 2D2-7 and 2D2-8). By careful adjustment it was always possible to obtain essentially sinusoidal oscillations as illustrated by Fig. 3(d) of Ref. 11.[15]

The use of a triangular input waveform enables the simultaneous determination of the following pertinent parameters: the electric field strength threshold E_{th} at a given magnetic field strength B_{th}, and the difference in electric field strength at the onset and cessation of oscillations E_{hys}, as Fig. 2 illustrates. A separate measurement of the current-voltage characteristics (see Figs. 1 and 4 of Ref. 8 and Fig. 5 of Ref. 14, for examples) relates E_{th} to the total current and, by subtraction of the extrapolated Ohmic current, to the plasma current. Hence the boundary between stability and instability may be delineated by plotting B_{th} as a function of E_{th} with the ratio of the injected plasma density to the initial density of carriers (or background plasma density) ξ as a parameter. (See Part IV for method of calculating ξ.)

Two examples of boundary diagrams are shown in Figs. 4 and 5. The correpsonding ξ parameters for each measured point on the boundary are listed in Table I. As the electric field strength is increased with the plasma immersed in a constant magnetic field, oscillations commence at the conditions corresponding to the circles. A line connecting these points defines the boundary, a line which has no characteristic locus since the third controlling parameter ξ is arbitrarily fixed by the injection properties of the particular contacts. In practice, however, each boundary is of such a shape that the product of the threshold electric and magnetic fields is very approximately a constant. The conditions marked by the triangles on Figs. 4 and 5 indicate the observed hysteresis in electric field strength, i.e., the lower than E_{th} values at which oscillations are observed to cease.

A square-wave input was also employed whose rise and fall times (<13 nsec) are less than the period of these helical instability oscillations. With a circuit identical to that in which the triangular-waveform input is used, except for the absence of the capacitance to ground which makes the square-wave triangular, oscillations do not persist after cutoff of the square wave from an electric field strength greater than E_{th} to one less than that at which oscillations cease when a slowly falling E is applied, i.e., $E<(E_{th}-E_{hys})$. Thus, E_{hys} cannot be attributed to a slowly damping oscillation.

E_{th} is constant to within $\pm 5\%$ when the magnitude of the peak value of the applied field strength is varied from E_{th} to $2E_{th}$. The magnitude of the field strength at which the oscillations cease is constant to within $\pm 3\%$ for the same excursion into the supercritical region and, in fact, deviations can only be observed when the maximum field strengths are close to E_{th}. Variations in the time-rate-of-change of the applied field strength by as much as a factor of 4 also do not affect E_{th} and E_{hys} beyond the above-stated limits.

By completing the loops as drawn in Figs. 4 and 5 the enhancement in the magnetic induction caused by the formation of the helical instability may be deduced. The influence of the parameter ξ in deducing this enhancement is discussed in Sec. IV. Figure 4 records more typical results than Fig. 5 which shows the occurrence of some very large induction enhancements.

The larger magnitudes of the hysteresis electric field strengths, E_{hys} and larger induction increases, B_{hys},

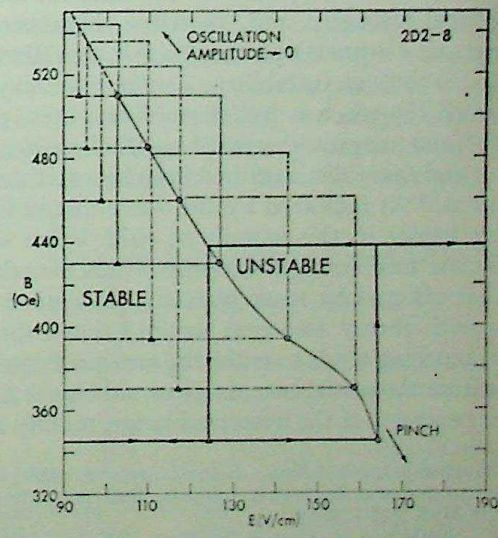

FIG. 4. A typical B–E threshold diagram showing the boundary between a quiescent and a rotating plasma. The circles which define this boundary correspond to the measured E_{th} at the onset of oscillations and the triangles indicate the measured electric field strengths at cessation, $(E_{th}-E_{hys})$. Simplified hysteresis loops corresponding to these thresholds are drawn.

[15] Small deviations (e.g., $\sim 1°$) from the alignment between the direction of current flow and the magnetic field yielding the most nearly sinusoidal oscillations do not noticeably affect E_{th} and E_{hys}.

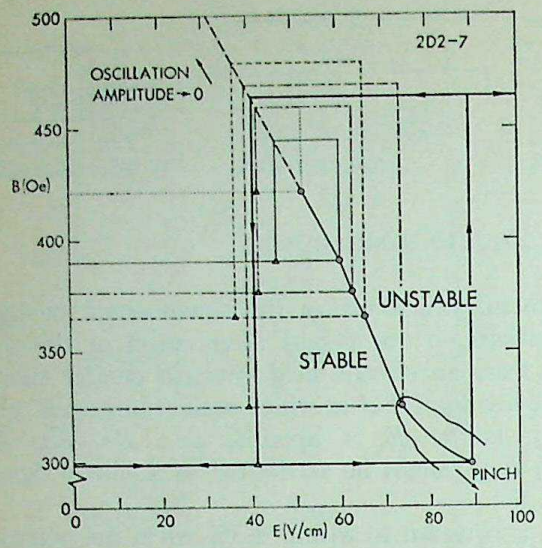

FIG. 5. A B–E threshold diagram exhibiting very large hysteresis loops.

and, therefore, the larger hysteresis loops, accompany the smaller applied magnetic fields as Figs. 4 and 5 and Table I show. The E_{hys} decreases steadily with increasing applied magnetic field but the magnitude of B_{hys} (Table I) depends on the shape of the instability boundary. If the boundary is steep at the high B end, i.e., $|dB/dE|$ is large, the B_{hys} values do not steadily decrease with increasing applied magnetic field, as in the case of samples 2D-2 and 2D2-2 whose $|dB/dE|$ at the high B end of the instability boundary are 6.5 and 7.0, respectively, compared with 3.8 and 4.2 for 2D2-8 and 2D2-7. Independent of $|dB/dE|$, however, is the fact that the hysteresis magnetic fields are smallest at the highest applied magnetic fields.

The extent of the B–E boundary over which hysteresis loops can occur is limited by two factors: At high electric field strengths and, therefore, high currents, the magnetic (Bennett) pinch effect[8,14] prevails which inhibits the helical instability. Oscillations may still occur when the pinch is well formed but these pinch-unpinch[8] and magnetothermal[16] oscillations are very different and easily distinguished from helical instability oscillations.[17] As indicated by the wavy line in Fig. 5, pinching begins in this sample at ~73 V/cm so the high electric field strength extreme of this boundary is somewhat affected by weak pinching. A detailed comparison with theory (see next section) shows that the onset of pinching tends to make the measured threshold deviate from the actual boundary toward higher E_{th}. At the other extreme of the hysteresis range, namely at the low electric field strengths, the plasma density becomes vanishingly small along with the amplitude of oscillations and the hysteresis effect. The ratio of plasma-to-background-density ξ at the lowest electric field strengths for which hysteresis can be readily observed range typically from 1 to 3% (cf. Table I).

Measuring directly the magnitudes of the magnetic fields produced by the helical paths of plasma current is difficult, principally because of the relatively small sample sizes and large currents. Inadequate electrostatic shielding plus the unavailability of a sufficiently high current source which could be appropriately modulated prevents the use of pickup coils, a highly satisfactory method for such magnetic field measurements in electron-ion plasmas.[12] Hall probes, however,

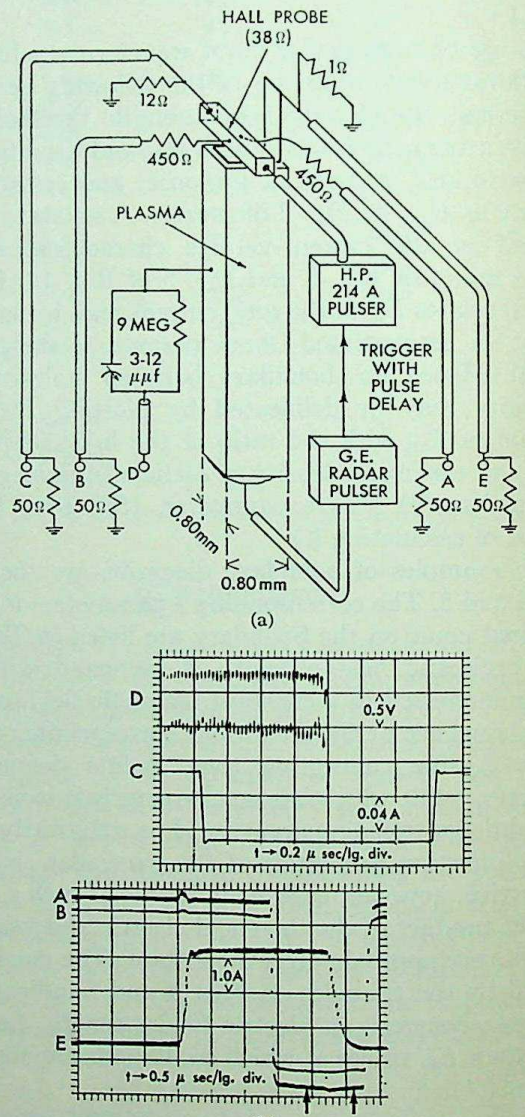

FIG. 6. (a) Experimental arrangement used to measure B_{hys} with a Hall probe. The plasma-injecting contact at the probe end is made with a gold strip. The spacing between this strip and the probe is 0.27 mm. (b) Oscilloscope traces: D shows the helical instability oscillations and their cutoff while the current in the Hall probe C remains on. The lower oscillogram has a faster sweep time and shows both the beginning and end of the current pulse in the plasma E. Traces A and B correspond to the voltages on the Hall probe side contacts.

[17] M. C. Steele and T. Hattori [J. Phys. Soc. Japan 17, 1661 (1962)] offer an explanation of some very small amplitude oscillations observed during pinching by M. Glicksman and R. A. Powlus [Phys. Rev. 121, 1659 (1961)] in impact-ionization plasmas in n-type InSb which is related to the generation of sound waves. Impact ionization is not occurring in the present experiments.

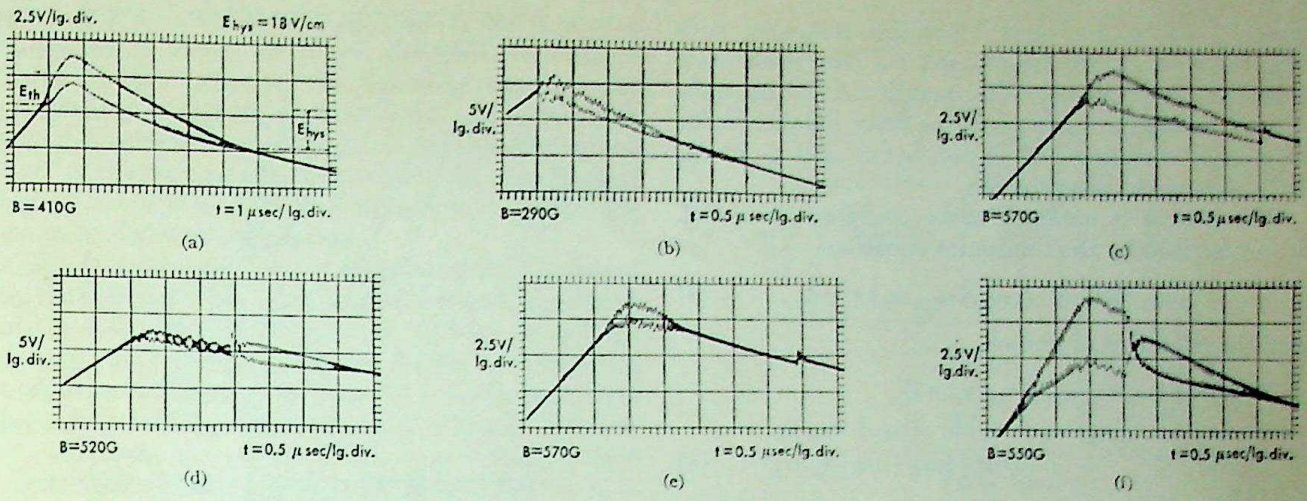

FIG. 7. Oscilloscope diagrams illustrating some of the startling properties of the oscillatory behavior.

do yield a direct estimate when the arrangement shown in Fig. 6 is employed. A small parallelepiped of n-type InSb is located orthogonally to a plasma-containing sample, so that the former senses the applied longitudinal magnetic field as well as the helix field, but not azimuthal fields produced by current flow.

The Hall probe circuit is supplied with resistances such that the transmission line is everywhere matched and the voltage contacts A and B are effectively isolated from the current path. The outputs of A and B are fed into a storage oscilloscope (Tektronics No. 564) equipped with a sampling dual-trace plug-in unit (No. 3S76). These voltages, at a time selected with the manual scan of a sampling sweep plug-in unit (No. 3T77) and indicated by the arrows at the bottom of Fig. 6(b), are taken from the output jacks of the dual-trace unit through two bucking voltages supplies and a pair of dc amplifiers. The difference between these signals is then read on a voltmeter which is directly calibrated in gauss by varying the applied longitudinal magnetic field. The bucking voltages are adjusted to maximize the sensitivity: No signal is detected when the applied magnetic field is on but no oscillations are present [right-hand arrow in Fig. 6(b)], so that only the field added by the helix is measured when the manual scan is located at the left-hand arrow. Although the sensitivity of this system is $\sim$1 G, drifting of the zero makes the measurements tedious. The results are summarized in Table II.

Certain observed aspects of the hysteresis effect are quite startling. Some are illustrated by the oscillograms of Fig. 7. The first, 7(a), shows how rapidly the amplitude of oscillations can grow to surprisingly large amplitudes in an otherwise perfectly typical hysteresis oscillogram. Oscillations can apparently cease as the electric field strength decreases to some magnitude and then with further decrease commence again, 7(b).[18] Unusually large amplitude oscillations occasionally cease suddenly with decreasing electric field strength, producing a discontinuity in the average E, 7(c). A sudden switch from moderate to larger amplitude oscillations can also occur during decreasing E, 7(d). No hysteresis or a "reverse hysteresis," an anomaly in itself, can be followed by a sudden discontinuity in the measured E at some E well below $(E_{th}-E_{hys})$, 7(e). Rare but reproducible is the oscillatory pattern displayed in 7(f). The input waveform was monitored before each of these oscillograms was made and found to be smooth as usual.

Detailed observations regarding threshold frequency (i.e., frequency at the instability boundary) cannot be made from this type of data since the frequency is a function of electric field strength in the supercritical region.[2,3,6-10]

III. THEORY

The helical instability[2,3,6,7] is a growing helical density perturbation superimposed on an unperturbed, steady-state plasma density and electric potential in a plasma column immersed in parallel (or antiparallel) electric and magnetic fields.[19] The perturbed density and potential are assumed to have the following forms, respectively,

$$n_i = n_{i,0} + f(r,z)\exp[ikz + im\theta + i\omega t], \quad (1)$$

$$U = U_0 + g(r)\exp(ikz + im\theta + i\omega t], \quad (2)$$

TABLE II. Hall probe measurements on sample 2D2-13.

Bulk properties	$B_{II}(G)$	$I_p(A)$	when $B_{helix}(G)$ at end is:	$I_p(A)$ at threshold
$p_0=3.5\times10^{14}$ cm^{-3}	340	1.9	10±2	0.4
$\mu_p=8000$ cm^2/V-sec	320	2.3	13±2	0.5

[18] A possibly related and also as yet not understood effect was noted in Ref. 8: As the magnetic field strength was increased above threshold while the total current was held constant, the oscillations became noisy and then another "mode" at a higher frequency emerged before noise ultimately resulted.

[19] F. C. Hoh and B. Lehnert, Phys. Rev. Letters 7, 75 (1961) give one simple, physical interpretation of the theory.

where f and g are small quantities compared with $n_{i,0}$, the steady-state density and U_0, the steady-state potential, respectively. The quantity k is the wave number along the z axis, m is the wave number in the azimutual direction ($m=1$ for helix) and ω is the frequency of the perturbation.

The plasma is assumed to be collision dominated. It is described by the continuity equations

$$(\partial n_{i\pm}/\partial t)\pm\nabla\cdot\{(n_{0\pm}+n_{i\pm})v_\pm\}=\gamma n_{i\pm}, \tag{3}$$

and the equations of motion

$$D_\pm\nabla n_{i\pm}=\pm(\mu_\pm/c)(n_{0\pm}+n_{i\pm})\mathbf{v}_\pm\times\mathbf{B} \pm\mu_\pm(n_{0\pm}+n_{i\pm})\mathbf{E}-(n_{0\pm}+n_{i\pm})\mathbf{v}_\pm -(\partial/\partial t)[(n_{0\pm}+n_{i\pm})\mathbf{v}_\pm]\nu_\pm^{-1}. \tag{4}$$

The last term in (4) is negligible because the collision frequencies $\nu_\pm$ are so large. The subscripts $\pm$ refer to holes and electrons, respectively; γ is the recombination and generation coefficient; n_0 is the density of initial carriers, D is the diffusion constant, μ the mobility and v the velocity. An essentially neutral injected plasma $|n_{i+}-n_{i-}|\ll|n_{i\pm}|$ with equal electron and hole temperatures is assumed. Even at relatively elevated electric field strengths ($\sim$200 V/cm) equal temperatures seems to be the most reasonable assumption.[20]

A dispersion relation for the frequency is derived from Eqs. (1) and (2) and the boundary between stability and instability occurs when $\mathrm{Im}(\omega)=0$. Using the additional condition[3,7] that the derivatives of Im (ω) with respect to k must equal 0 at the onset of instability, the electric field strength (also the wavelength and frequency of oscillation) is expressed in terms of the threshold magnetic field strength.

Holter[7] has taken into account that the flow of current causes plasma heating above the semiconductor lattice temperature, here $V_0=6.6\times10^{-3}$ eV. Hence the mobilities are expressed as

$$\mu_\pm=\mu_{0\pm}(V_0/V)^\alpha, \tag{5}$$

where $\mu_{0\pm}$ are the hole and electron mobilities, respectively, at V_0 which is less than the plasma temperature V. For InSb in the temperature range of interest $\alpha\approx0.5$. Then dimensionless threshold magnetic and electric field parameters may be expressed, respectively, as

$$y=y_0(V_0/V) \tag{6}$$

and

$$\mathcal{E}=\mathcal{E}_0(y/y_0). \tag{7}$$

With the use of these definitions

$$y_0=\mu_{0-}\mu_{0+}B_{\mathrm{th}}{}^2, \tag{8}$$

$$\mathcal{E}_0=E_{\mathrm{th}}R/V_0. \tag{9}$$

R is the radius of the plasma. Equation (7) is obtained by eliminating the temperature V when Eqs. (6) and (9) are combined. In the limit of small threshold magnetic fields, i.e., $y\ll1$, which is the case in these experiments, $\mathcal{E}$ has an asymptotic solution which may be expressed as

$$\mathcal{E}=K_0y^{-1/2}. \tag{10}$$

K_0 is dependent on the injected-plasma-to-background-density ratio ξ but not on magnetic field, hence, it may be evaluated for a particular $y\ll1$, e.g., $y_1=10^{-3}$. Then the corresponding values of $\mathcal{E}_1$ are known as a function of ξ and the plasma temperature is found by equating Eqs. (7) and (6) and using (9) and (10):

$$V=\left[\frac{y_0V_0}{y_1}\left(\frac{E_{\mathrm{th}}R}{\mathcal{E}_1}\right)^2\right]^{1/3}. \tag{11}$$

A nonlinear theory treating the hysteresis effect itself in electron-ion plasmas has been worked out by Holter and Johnson.[21] Such a theory applicable to electron-hole plasmas is as yet lacking.

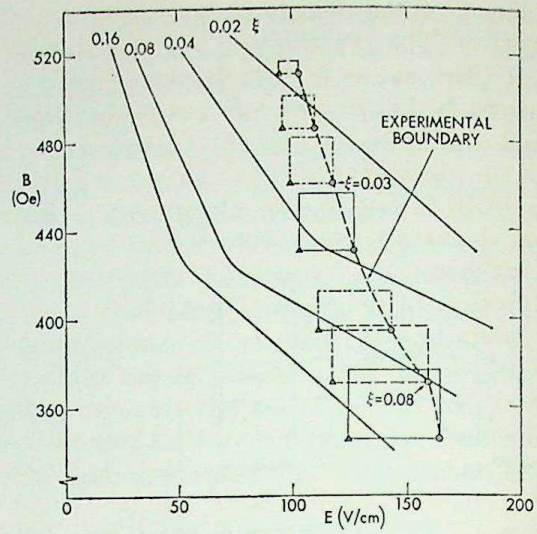

FIG. 8. B–E threshold diagrams for plasmas of constant densities in the same sample as used to obtain the data in Fig. 4. Simplified hysteresis loops corresponding to constant ξ values are shown. The experimentally determined threshold boundary (nonconstant ξ) is also indicated. The ξ values for two experimental points are identified for an illustration (see text).

IV. DISCUSSION

The parameter ξ is estimated from the readily obtainable Ohmic and total current magnitudes, respectively,

$$I_\Omega=ep_0\mu_{0+}EA, \tag{12}$$

$$I_T=I_\Omega[1+((\mu_{0-}/\mu_{0+})+1)n/p_0], \tag{13}$$

as

$$\xi\approx\frac{n}{p_0}=\frac{I_T-I_\Omega}{I_\Omega((\mu_{0-}/\mu_{0+})+1)}, \tag{14}$$

when A is the cross-sectional area of a semiconductor

containing an intial density of holes p_0 and a plasma of density n. The experimental ξ values are listed in Table I. (The radius of the plasma assumed for the calculations is that of the inscribed circle within each semiconductor cross section.) The calculated temperatures of the plasmas at the instability threshold ranged from 5.9×10^{-2} to 1.1×10^{-2} eV while the lattice remains at the bath temperature.

The influences of ξ on the enhancement in B caused by the presence of an helical current path are considered in the following: As E increases so does the plasma density which is injected by the current contacts, and as E exceeds E_{th} more and more of the plasma current goes into a helical path producing an enhanced B. When E decreases, the total $B=B_{applied}+B_{helix}$ remains greater than B_{th} even though the plasma current I_p is decreasing. Thus, a cessation of oscillation occurs at an $I_p<I_p$ at threshold and, therefore, at a ξ value $<\xi_{th}$. This fact and its influence on the magnitude of the deduced B_{hys} is illustrated by Figs. 8 and 9. The lines labeled with numbers represent the threshold conditions for constant ξ values. The experimental threshold points are represented by circles and the triangles refer to conditions at cessation of the oscillations, consistent with the symbols in Figs. 4 and 5. At both threshold and cessation the amplitude of the oscillations is vanishingly small (cf. Fig. 2) and, hence, the perturbation theory[7] is applicable.

Hysteresis loops are drawn in Figs. 8 and 9 corresponding to constant ξ-value boundaries. The resulting B_{hys} are smaller than those deduced for nonconstant ξ boundaries, Table I. In general, the magnitude of I_p at some operating point in the supercritical region determines the B produced by the helix. If ξ were made independent of E and constant, e.g., by supplying the plasma optically when noninjecting contacts carry the current, the smaller set of B_{hys} magnitudes would

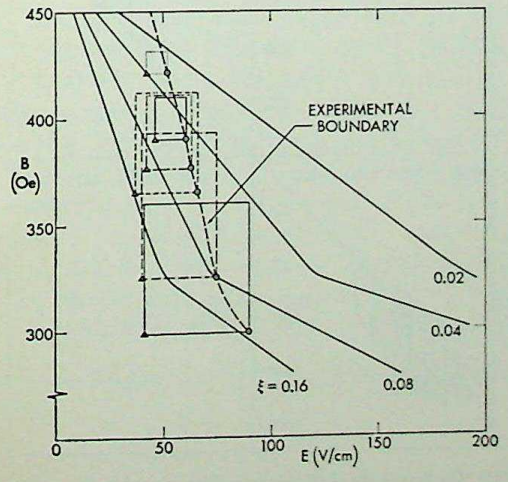

FIG. 9. B–E threshold diagrams for plasmas of constant density in the same sample as used to obtain the data in Fig. 5. Simplified hysteresis loops corresponding to ξ values are shown. The experimentally determined threshold boundary (nonconstant ξ) is also indicated.

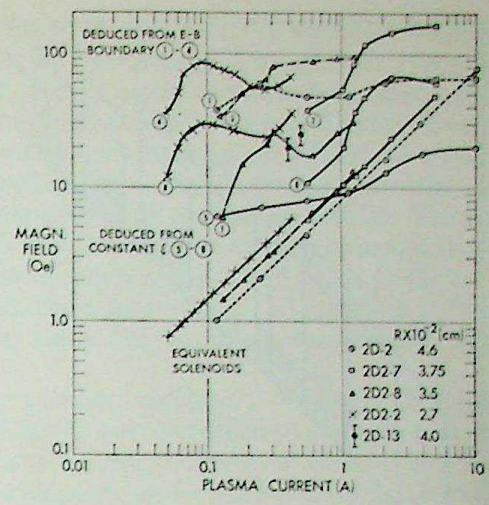

FIG. 10. Magnetic field is plotted as a function of plasma current using: (1–4) the experimentally deduced B_{hys} values (nonconstant ξ); (5–8) B_{hys} values derived from constant ξ conditions; and calculated B values produced by solenoids of equivalent turns ratio. The two points with error brackets represent the results of Hall probe measurements.

result. Conversely, the steeper the I–V characteristic and, therefore, the more rapid the increase of plasma density with E, the steeper the B–E boundary and the larger resulting B_{hys}. Sample 2D2-7 compared with 2D2-8 is an example of the latter case (Figs. 5 and 4).

Reference to a particular set of operating conditions (see Figs. 4 and 8) clarifies these statements: A threshold for the helical instability in sample 2D2-8 is at $B=370$ G, $E=159$ V/cm and $\xi=0.08$. The plasma becomes quiescent again at $E=E_{th}-E_{hys}=117$ V/cm and: (a) for a constant plasma density and therefore $\xi=0.08$ at $B=B_{th}+B_{hys}=370+26=396$ G; (b) for a plasma density dictated by the properties of the current injecting contacts $\xi=0.03$ at $B=370+91=461$ G.

The magnitude of the fields produced by the helices are plotted in Fig. 10 as a function of the plasma current at the threshold. Curves 1 through 4 refer to the experimentally determined threshold boundaries and 5 to 8 to boundaries of constant plasma density. The shape of each of these curves is controlled, as stated earlier in connection with Figs. 4 and 5, by the arbitrary properties of the injection contacts. The two points with error brackets represent the results of the Hall probe measurements. These two points are plotted at the threshold plasma current, consistent with the rest of the data points, although the measurements were made at higher currents, Table II. Also graphed in this figure are the magnetic fields that solenoids would produce which possess the same radius and number of turns per cm as the helical instability in the four samples. The turns ratios of the equivalent solenoids are derived from Holter's calculation of the wavelength of the helix at threshold (Fig. 1, Ref. 7). The dimensionless wavelength λ/R is nearly constant for all the present measurements; it varies only between 3.2 and 3.6. The radius R (Table I) has a range of less than a factor of 2, hence

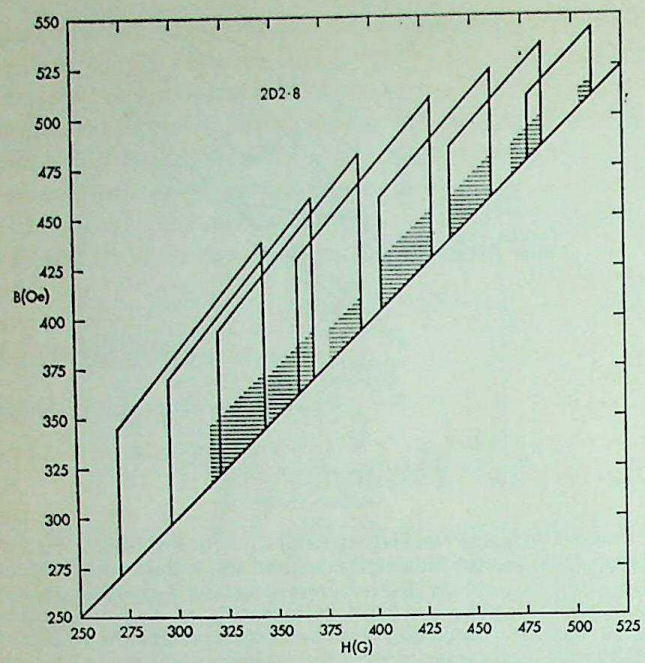

FIG. 11. The first quadrant of deduced B–H curves. The larger loops correspond to Fig. 4 and the smaller (hatched) to Fig. 8.

the fields produced by the equivalent solenoids are essentially determined by the magnitude of the current they carry. The equivalent solenoid results in Fig. 10 are obtained with the assumption that all the plasma current goes into the helix at threshold which, of course, is not compatible with the perturbation theory.

Figure 10 indicates that the equivalent solenoids produce far less B than their counterparts in the plasma at low I_p even though it was assumed that they carry all the plasma current. The fields deduced from the boundary measurements, however, result from excursions into the supercritical region, hence curves 1 to 8 should be shifted toward higher currents for comparison with the solenoid curves. The fields sensed by the Hall probes, when plotted against the I_p they carried during the measurements (Table II), agree well with the fields produced by equivalent solenoids conducting the same current. The agreement may be so good fortuitously since the λ of the helix in the supercritical region may not be constant in the range of these threshold magnetic fields. There is experimental evidence to suggest it is not constant[8,22] but a nonlinear theory for electron-hole plasmas, as stated earlier, is not available.

The Hall probe measurements were made on a sample with radius somwhat larger than 2D2–7. At $I_p = 0.5$ A the B_{hys} deduced from the experimentally determined threshold boundary is $\sim$35 G whereas that deduced from the constant-plasma-density boundary is $\sim$10 G. Since the Hall-probe value of $\sim$26 G is likely to be too small because the measurements were made a finite distance from the end of the plasma helix [Fig. 6(a)], agreement with the experimentally determined B_{hys} value is indicated.

The magnitude of B_{hys} is very large compared with the part of it associated with the diamagnetism normally exhibited by a plasma. Recently Moore and Kessler[23] have measured the magnetic moment of an optically injected plasma in Ge. For a plasma density equal to 10^{15} cm^{-3} and an essentially infinite surface recombination velocity, a condition corresponding to the highest magnetic moment, they find a diamagnetic moment density of $\sim 2\times 10^{-5}$ cgs units at 1 kG. The plasmas utilized in the present experiments can be expected to exhibit an even smaller moment since the plasma densities are 1 to $2\frac{1}{2}$ orders of magnitude smaller and the surface recombination velocity is finite. Hence essentially all of the deduced B_{hys} is associated with the paramagnetism produced by the helical instability. The first quadrant of the resulting B–H curves corresponding to Figs. 4 and 8 (the more typical set of hysteresis loops) is shown in Fig. 11. The larger loops correspond to the experimentally determined threshold boundary and the smaller loops (hatched) to the constant ξ boundary. The full B–H diagrams for sample 2D2-7, which exhibited the largest loops, are shown in Fig. 12. The loops are again drawn with straight sides for simplicity but their shapes cannot be ascertained by the present experiments.

The sign of the enhanced induction associated with the helical instability is positive as stated in the introduction, according to Johnson's measurements in electron-ion plasmas[12] and as verified by the described Hall probe measurements. This switch from diamagnetism to paramagnetism is completely compatible with

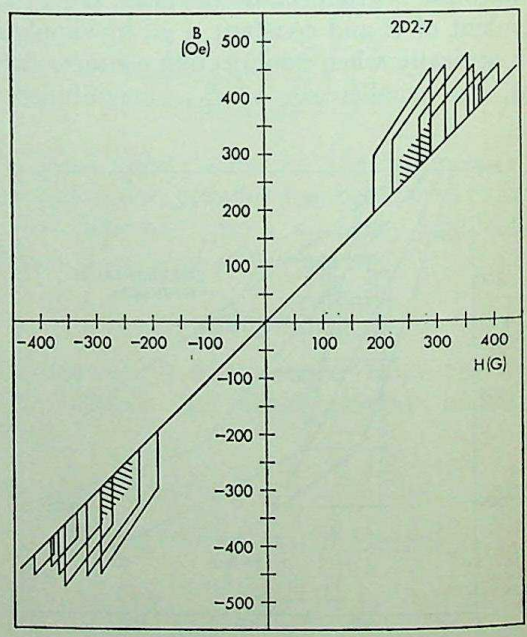

FIG. 12. Deduced B–H diagrams. The larger loops correspond to Fig. 5 and the smaller (hatched) to Fig. 9.

[22] The only published wavelength measurements known to the author are in Ref. 9. These results yield a λ/R 4 to 5 times Holter's calculated values. This makes the equivalent solenoid fields even smaller.

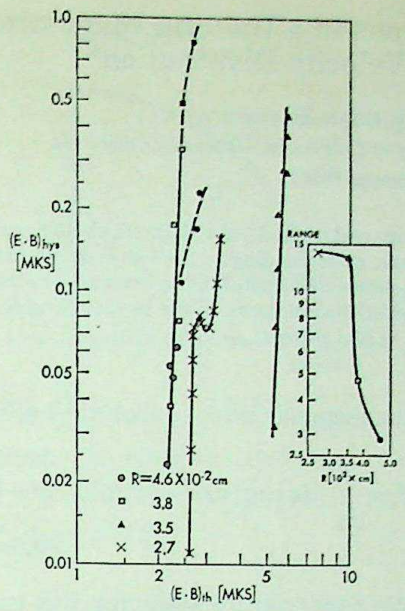

FIG. 13. The hysteresis loop energy as a function of the input energy at threshold for the experimentally determined boundaries, i.e., ξ nonconstant. The solid points represent hysteresis energy in a weakly pinched plasma. The insert shows the range of hysteresis loop energy as a function of plasma radius.

the helical instability theory[9b] which states that the the helical instability theory which states that the sense of the helix is positive (negative) with respect to the applied magnetic field when the applied E is parallel (antiparallel), and is independent of the drift direction of the helical density perturbation. Enhancement of the magnetic field results and, therefore, paramagnetism. That paramagnetism results is also evident from simple physical reasoning: Since the application of a B, large compared to B_{th}, causes a shift in the equilibrium position of the plasma toward its container walls, the magnetic pressure inside the helix must be greater than that outside, thus the magnetic field produced by the helix must *add* to the applied B.[24]

The effect of the plasma radius on the hysteresis is illustrated by Fig. 13 in which a measurement of the "hysteresis loop energy" is plotted against the "input energy" required to achieve oscillations for the four different plasma radii. The input energy necessary to produce hysteresis is quite constant as expected from both theory and the experimental results shown in Figs. 4 and 5. The theoretical curves of E_{th} as a function of B_{th}^2 have a slope of -0.5, hence for any one value of ξ the product $E_{th}\times B_{th}$ is a constant as illustrated by the hyperbolic boundaries for constant ξ values drawn in Figs. 8 and 9. Since ξ varies in the experiments (Table I), this product is only approximately constant. Of considerable practical interest is the fact that very little change in input energy is necessary for very large changes in loop energy. The greatest range in loop energy, defined as the ratio of the loop energy at the lowest $(E\times B)$ at which observable hysteresis occurs to the loop energy at the highest $(E\times B)$ at which noise-free oscillations occur, is produced by the smallest diameter plasma, if pinching is avoided. The insert in Fig. 13 indicates that the range saturates with decreasing plasma radius at $\sim 3\times 10^{-2}$ cm. If weak pinching is allowed, there appears to be an optimum intermediate plasma radius for obtaining the greatest hysteresis range.

The startling oscillatory behavior illustrated by Figs. 7(b)–(f) may be related to a complicated relationship between the direction of current flow and the applied magnetic field direction, since such behavior has not been observed in the two samples investigated which possess symmetrically located plasma injectors, namely samples 2D-2 and 2D2-2.

V. CONCLUSION

The hysteresis in electric field strength E accompanying the onset and cessation of the helical instability can exceed 45 V/cm and 50% of the applied E at threshold. The attendant hysteresis in magnetic field intensity B, deduced from measurements of the boundary conditions between a quiescent and a rotating plasma which agree well with theory, can exceed 160 G and 55% of the applied B at threshold. Hall probe measurements of the B produced by the helical path of plasma current tend to verify the deduced B_{hys} values both in magnitude and sign (paramagnetic). The resulting, novel B–H curves consist of loops which are displaced from the origin. An infinite number of hysteresis loops can be generated by a small variation in input energy $(E_{th}\times B_{th})$. The extent in E (or B) over which loops can occur is limited at the high E (low B) end by the onset of current pinching and at the low E (high B) end by vanishing plasma current and, hence, vanishing hysteresis. The existence of the largest loops at low magnetic fields is in agreement with Holter and Johnson's nonlinear theory[21] of the helical instability in electron-ion plasmas.

These loops are easily and reproducibly obtained in p-type InSb at 77°K.

PHYSICAL REVIEW VOLUME 134, NUMBER 6A 15 JUNE 1964

Stability of Longitudinal Oscillations in a Uniform Magnetized Plasma with Anisotropic Velocity Distribution*

LAURENCE S. HALL AND WARREN HECKROTTE
Lawrence Radiation Laboratory, University of California, Livermore, California

(Received 13 January 1964)

We consider the longitudinal oscillations of a uniform magnetized plasma in which the particles are allowed to have anisotropic distributions in velocity space, corresponding to the two temperatures $T_\perp$ and $T_\parallel$ perpendicular and parallel to the magnetic field. It is shown that no instabilities can exist unless $T_\perp > T_\parallel$ for at least one of the species of plasma particles. An additional theorem, of use in surveying for possible unstable roots to the dispersion equation when $T_\perp > T_\parallel$, is also proved.

THE stability of longitudinal oscillations of a uniform plasma with anisotropic velocity distribution in the presence of a uniform magnetic field has been studied by a number of authors[1–3] in various approximations. We consider here a multicomponent nonrelativistic plasma in which the zeroth-order distribution function may be written as a bi-Maxwellian, viz.,

$$f_{0j}=(2\pi\kappa T_{\perp j}/m_j)^{-1}(2\pi\kappa T_{\parallel j}/m_j)^{-1/2} \times\exp\left[-\frac{m_j v_\perp^2}{2\kappa T_{\perp j}}-\frac{m_j v_\parallel^2}{2\kappa T_{\parallel j}}\right], \quad (1)$$

and show that no instability exists unless $T_{\perp j}>T_{\parallel j}$ for at least one species. (Here $\parallel$ and $\perp$, respectively, denote directions parallel and perpendicular to the magnetic field B_0; j denotes the species of particle; and m, T, and κ are, respectively, mass, temperature, and Boltzmann's constant.) An additional theorem of use in locating possible instabilities when $T_{\perp j}>T_{\parallel j}$ is also proved.

Assuming that all perturbations vary in space and time according to the form $\exp[i(\mathbf{k}\cdot\mathbf{r}-\omega t)]$, where $\mathbf{k}$ is real and ω complex, and $\mathrm{Im}(\omega)>0$, one can follow step by step the prescription of Bernstein[4] in obtaining the dispersion relation for longitudinal oscillations. After a straightforward but laborious computation, one may write

$$1+\textstyle\sum_j \omega_{pj}^2\Omega_j^{-2}F_j=0, \quad (2)$$

where $\omega_{pj}=(4\pi Z_j^2e^2n_j/m_j)^{1/2}$=plasma frequency, $\Omega_j=|Z_je|B_0/m_jc$=cyclotron frequency, and the sum is over particle species. If we write $\omega_j=\omega/\Omega_j$; $\gamma_j=k(2\kappa T_{\perp j}/m_j\Omega_j^2)^{1/2}=k\cdot$(radius of gyration); $t_j^2=T_{\parallel j}/T_{\perp j}$; and take $n_\parallel$ and $n_\perp$, respectively, to be the direction cosines of the propagation vector parallel and perpendicular to the magnetic field, so that $n_\parallel^2+n_\perp^2=1$, we have

$$F_j=\int_0^\infty dx\,\exp\{i\omega_j x-\tfrac{1}{4}\gamma_j^2t_j^2n_\parallel^2x^2-\tfrac{1}{2}\gamma_j^2n_\perp^2(1-\cos x)\} \times[n_\parallel^2x+n_\perp^2\sin x]. \quad (3)$$

We now drop the subscript j as understood, and consider the integral in (3) noting that it may be rewritten after an integration by parts of the first term to read

$$F=2\gamma^{-2}t^{-2}+2\gamma^{-2}t^{-2}F_A+(1-t^{-2})n_\perp^2F_B, \quad (4)$$

where

$$F_A=i\omega\int_0^\infty dx\,\exp\{i\omega x-\mu x^2-\lambda(1-\cos x)\}, \quad F_B=\int_0^\infty dx\,\exp\{i\omega x-\mu x^2-\lambda(1-\cos x)\}\sin x, \quad (5)$$

and we have set $\mu=\frac{1}{4}\gamma^2t^2n_\parallel^2$ and $\lambda=\frac{1}{2}\gamma^2n_\perp^2$. All of the parameters are real except ω which is complex and which, for an instability, has positive imaginary part. We propose to show that, when $\mathrm{Im}(\omega)>0$,

$$\mathrm{Re}(\omega)\cdot\mathrm{Im}(F_A)\geq 0, \quad \mathrm{Re}(\omega)\cdot\mathrm{Im}(F_B)\geq 0. \quad (6)$$

Since both $\mathrm{Im}(F_A)$ and $\mathrm{Im}(F_B)$ are antisymmetric in $\mathrm{Re}(\omega)$, it is only necessary to prove (6) for ω in the first quadrant of its complex plane. We then use the fact that if $f(\omega)$ is an analytic function of ω in the region of consideration, the map of any closed contour C in the ω plane onto the f plane encircles all values of f attained by letting ω assume values within C. We choose C as in Fig. 1, and note that F_A and F_B both vanish on the infinite quarter circle. Further, for ω on the imaginary axis both $\mathrm{Im}(F_A)$ and $\mathrm{Im}(F_B)$ vanish. Thus, we need only show that $\mathrm{Im}(F_A)$ and $\mathrm{Im}(F_B)$ are sign-definite for ω real and positive in order to show they are sign-definite for ω anywhere in the first quadrant.

First, consider $\mathrm{Im}(F_A)$ and use the identity

$$e^{\lambda\cos x}=\sum_{l=-\infty}^{\infty} I_l(\lambda)e^{ilx}, \quad (7)$$

where the $I_l(\lambda)$ are Bessel functions of the first kind

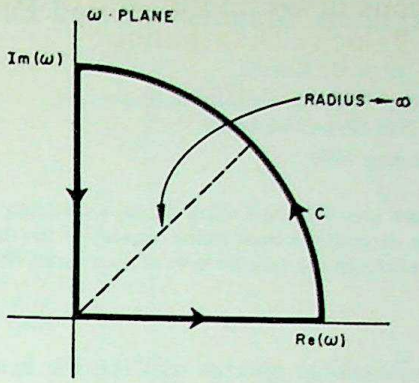

FIG. 1. Contour for the examination of various integrals.

and imaginary argument, obtaining for $\omega>0$

$$\mathrm{Im}(F_A)=\omega(\pi/4\mu)^{1/2}\sum_{l=-\infty}^{\infty}e^{-\lambda}I_l(\lambda)\times\exp\{-(\omega+l)^2/4\mu\}>0. \quad (8)$$

Similarly, with the use of (7) together with the fundamental relation $I_{l-1}(\lambda)-I_{l+1}(\lambda)=2lI_l(\lambda)/\lambda$, one can also write that for $\omega>0$

$$\mathrm{Im}(F_B)=\lambda^{-1}(\pi/\mu)^{1/2}\sum_{l=1}^{\infty}e^{-\lambda}I_l(\lambda)\times\exp\{-(\omega^2+l^2)/4\mu\}l\sinh(l\omega/2\mu)>0. \quad (9)$$

According to our previous discussion, (8) and (9) establish (6). Now consider the dispersion relation (2) which can be satisfied only if either (a) $\mathrm{Im}(F)$ vanishes for all species or (b) $\mathrm{Re}(\omega)\cdot\mathrm{Im}(F)<0$ for at least one species.[5] Condition (a) can be satisfied in general only when $\mathrm{Re}(\omega)=0$, which, if unstable, corresponds to purely growing waves. However, as pointed out by Kammash and Heckrotte,[3] $\mathrm{Re}(F)$ is positive definite in this limit and no purely growing modes can exist. Hence, an instability can only occur if $\mathrm{Re}(\omega)\cdot\mathrm{Im}(F)<0$ for at least one species. From (4) and (6), then, we have the result that no instability exists unless $t^2=T_{\parallel}/T_{\perp}<1$ for at least one species in the plasma.

It is also of interest to be able to determine whether or not roots to the dispersion relation occur when $t^2<1$, and if they exist, where they lie. In this connection, the labor involved in exploring the ω plane can often be reduced by utilization of the theorem, which we refer to as (10):

If $Re(\omega)\cdot Im[F(\omega)]$ is non-negative for ω real and lying in the interval $l\leq\omega\leq l+1$, where l is an integer, it is also non-negative in the entire strip $l\leq Re(\omega)\leq l+1$, $Im(\omega)\geq 0$. (10)

Hence, if one can show that $\mathrm{Re}(\omega)\cdot\mathrm{Im}(F)\geq 0$ for some integral range of ω on the real axis, one also can eliminate the possibility of unstable roots appearing anywhere in the strip above that range.

In order to prove (10), we rewrite (3) in the form[6]

$$F=n_{\parallel}^2F_C+n_{\perp}^2F_B, \quad (11)$$

where

$$F_C=\int_0^{\infty}xdx\exp\{i\omega x-\mu x^2-\lambda(1-\cos x)\}, \quad (12)$$

and investigate F along the contours $\mathrm{Re}(\omega)=l$. We have already proved $\mathrm{Re}(\omega)\cdot\mathrm{Im}(F_B)>0$, and so we need only prove $l\cdot\mathrm{Im}(F_C)>0$ when $\mathrm{Re}(\omega)=l$ to establish (10). Setting $\omega=l+i\sigma$ and again using the expansion (7), we can rewrite (12) after a little manipulation to read

$$\mathrm{Im}(F_C)=\sum_{k=1}^{\infty}e^{-\lambda}[I_{k-l}(\lambda)-I_{k+l}(\lambda)]\times\int_0^{\infty}xdxe^{-\sigma x-\mu x^2}\sin kx. \quad (13)$$

Consider the integral $K(\omega')=\int_0^{\infty}xdx\exp\{i\omega' x-\mu x^2\}$, $\mathrm{Im}(\omega')>0$, whose imaginary part is antisymmetric in $\mathrm{Re}(\omega')$. Evaluating K along the contour C in Fig. 1, again we find $\mathrm{Im}(K)=0$ along the imaginary axis and the infinite quarter circle. Along the real axis $k\cdot\mathrm{Im}[K(k)]=\frac{1}{4}\pi^{1/2}k^2\mu^{-3/2}\exp(-k^2/4\mu)\geq 0$. Hence k times the integral in (13), which is just $\mathrm{Im}[K(k+i\sigma)]$, is non-negative. Moreover, the Bessel function $I_k(\lambda)$ is a monotonically decreasing function of the absolute value of its order, so that $[I_{k-l}(\lambda)-I_{k+l}(\lambda)]\geq 0$. Hence $\mathrm{Re}(\omega)\cdot\mathrm{Im}(F_C)>0$ and (10) is proved.

In conclusion, we have shown that in a uniform magnetized plasma whose particles are distributed anisotropically in velocity space in zero order according to the bi-Maxwellian form (1), no unstable longitudinal oscillations exist unless $T_{\perp}>T_{\parallel}$ for at least one species. In addition, instabilities can exist when $T_{\perp}>T_{\parallel}$ only for complex frequencies lying in the strip $\mathrm{Im}(\omega)>0$, $l<\mathrm{Re}(\omega)<l+1$, where l is an integer, and where $\omega\,\mathrm{Im}(F)<0$ for some real ω lying in the range $l<\omega<l+1$.

[5] We consider that the plasma has at least two species of particles. If one species only is principally responsible for the motion, we always consider here that the small but vanishing contribution from the neglected particles is in the stabilizing sense, as will almost always correspond to the physical situation. This means that any instability arising as a limiting case of (b) must be such that $\mathrm{Im}(F)\rightarrow 0^-$ for the active species.

[6] We may note in passing that since F may be written in either of the forms (4) and (11), the inequalities (6) show that there can be no instabilities whenever either $n_{\parallel}=0$ or $n_{\perp}=0$. This is an extension of the result noted by Harris (Ref. 1) for the special case $T_{\parallel}=0$.

Lattice Vibrational Spectra of Beryllium, Magnesium, and Zinc

JAMES A. YOUNG AND JUAN U. KOPPEL
General Atomic Division of General Dynamics, John Jay Hopkins Laboratory for Pure and Applied Science, San Diego, California

(Received 27 January 1964)

The lattice vibrational spectra of Be, Mg, and Zn have been obtained using the root sampling method. The force constants used in the calculations were those determined from measurements of the dispersion relations by slow neutron-scattering techniques. Calculations of the specific heat of each metal show good agreement with measured values.

I. INTRODUCTION

IN recent years the scattering of slow neutrons in solids has proved valuable as a tool for investigating the dispersion relations of lattice waves in crystals. In particular, measurements have been made on beryllium, magnesium, and zinc, all having the hexagonal close-packed lattice structure. In the first case (Be), Schmunk *et al.*[1] have determined the force constants for a central force model with interactions out to fifth nearest neighbors. For Mg, Collins[2] determined the force constants for both a tensor force model and a central force model with interactions out to fourth nearest neighbors. A similar experiment by Borgonovi *et al.*[3] has given the force constants of zinc for the tensor force model used for Mg.[2] Using these experimentally determined force constants, we have computed the lattice vibrational spectra and specific heat for each of the above metals.

II. RESULTS

The vibrational spectrum of a crystal $\rho(\omega)$ is defined such that $\rho(\omega)d\omega$ is the fraction of frequencies ω between ω and $\omega+d\omega$. The method used here to approximate $\rho(\omega)$ is to sample the frequencies $\omega(\mathbf{k})$ for a large number of values of the wave vector $\mathbf{k}$ in the first Brillouin zone of the crystal. The frequencies obtained must be weighted according to their degeneracy in the zone, and a histogram constructed of the number of frequencies falling in a given frequency interval.

In the Born-von Kármán[4] theory of lattice dynamics the frequencies ω are determined by the following secular equation:

$$|D(\mathbf{k})-M\omega^2 I|=0, \tag{1}$$

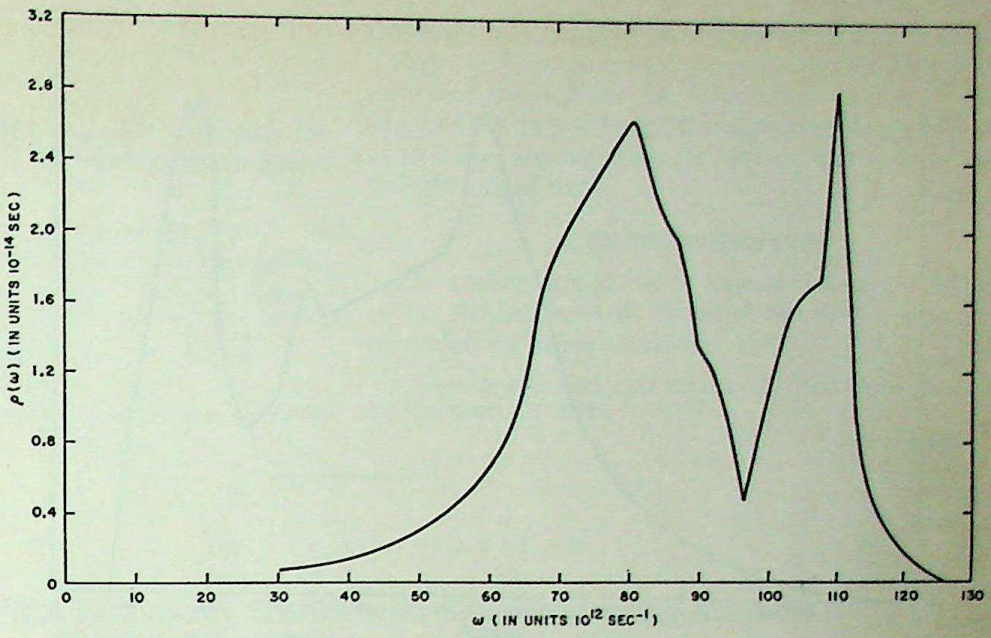

FIG. 2. Lattice vibrational spectrum of beryllium for a sampling of 2413 points in the reduced Brillouin zone.

where M is the atomic mass and I the unit matrix. The matrix $D(\mathbf{k})$ is 6×6 for hexagonal close-packed crystals and depends upon the force constants of the lattice. Equation (1) has been solved for equally spaced points in that region which is one twenty-fourth of the first Brillouin zone, and irreducible under the symmetry operations that leave the roots of the secular equation invariant. The points are then weighted as to whether or not they are on the faces, edges, etc., of this reduced zone. For beryllium, the calculation was performed for 10 261 equally spaced points ($\mathbf{k}$ values) in the reduced zone, and the spectrum shown in Fig. 1. Figure 2 shows, for comparison, the same calculation for 2413 equally spaced points. We see that greatly increasing the number of points does not significantly change the vibrational spectrum.

In the case of magnesium, the calculation was performed for a sampling of 2413 equally spaced points in the reduced zone, for both the central and tensor force models. Figures 3 and 4 show the vibrational spectra for central and tensor forces, respectively.

The vibrational spectrum of zinc was also obtained

Electron Spin Resonance Studies with Superconducting Magnets: The Spectrum of Dy^{3+} and Sm^{3+} in CaF_2

W. Low*

Department of Physics† and National Magnet Laboratory,‡ Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received 28 January 1964)

An electron spin resonance spectrometer has been constructed using strong magnetic fields up to 46 000 G generated by a superconducting magnet. It is being used for the measurement of the magnetic properties of transition elements in ionic crystals such as (a) small g factors, (b) energy level separations up to 20 cm^{-1}, (c) isotropic and anisotropic exchange terms in spectra of pairs of paramagnetic ions, (d) spin-lattice relaxation times at high magnetic fields. The method is illustrated in the measurements of (1) the energy level separation of $\Gamma_8-\Gamma_7$ levels of Dy^{3+} in CaF_2 which is found to be $7.3_5\pm0.2$ cm^{-1}; (2) the g factors of the tetragonal spectrum of Sm^{3+} in CaF_2 which are found as $g_\parallel=0.907\pm0.01$, $g_\perp=0.544\pm0.015$.

INTRODUCTION

ELECTRON spin resonance methods have been widely used in determining the magnetic properties of transition elements in ionic and semiconducting crystals.[1] Most of these experiments have been performed with magnetic fields of less than 20 000 G.[2] The availability of superconducting magnets with fields of the order of 50 000 G permit a number of additional experiments of interest. These experiments are of the kind: (a) Measurements of energy level separations of the order of 3–20 cm^{-1}. (b) Measurement of small g factors, i.e., $g\ll1$. (c) Measurement of some isotropic or anisotropic exchange splittings of neighboring paramagnetic ions. (d) Spin-lattice relaxation phenomena in high magnetic fields.

Many iron group and rare-earth elements have an energy level scheme in which a few levels are closely bunched together. Examples of such ions are V^{3+}, Cr^{4+} (d^2) in trigonal fields which have a singlet as a ground state and a doublet at 7–10 cm^{-1} above the singlet. A similar case is Fe^{2+} (d^6) in noncubic fields. In some crystal hosts, transitions between the two levels of the non-Kramers doublet can be induced. However, transitions between the singlet and the doublet cannot be seen with conventional resonance spectrometers and magnetic fields. With very strong magnetic fields one of the doublet levels can be brought close enough to the singlet so that transitions between these levels can be effected. One usually can find a suitable magnetic-field orientation with respect to the crystal axis which will permit transitions of the type $\Delta S_z=\pm1$ of sufficient intensity. The appropriate spin Hamiltonian is

$$\mathcal{H}=g_{\parallel}\beta HS_z+g_{\perp}\beta(H_xS_x+H_yS_y)+D(S_z^2-\tfrac{1}{3}S(S+1))+E(S_x^2-S_y^2), \qquad (1)$$

[1] See, for example, W. Low, *Paramagnetic Resonance in Solids* (Academic Press Inc., New York, 1960).

[2] S. Foner and W. Low, Phys. Rev. **120**, 1585 (1960), have performed ESR experiments using pulsed magnetic fields of the order of 2 000 000 G. However, this method has the disadvantage of poor accuracy in the field measurements. Relaxation effects due to fast variation of the magnetic field as a function of time effect the intensity of the spectrum. It can be used, however, to some advantage in the measurement of relaxation times at high magnetic fields [L. Rimai (private communications)].

with $S=1$. When $E=0$ the initial separation of $|\pm1\rangle$ levels from the $|0\rangle$ level can be determined. When $E\neq0$ then the separation of one of the nearly degenerate levels from the $|0\rangle$ level can be measured.

Of greater interest are the rare-earth and uranium group elements. Here the various J levels are split into a number of Stark levels through the crystal field. In many cases, the total amount of the splitting of 5–10 Stark levels may be only of the order of a 100 cm^{-1}. There are levels separated by less than 20 cm^{-1}. The position of these levels can be estimated by diverse methods such as by measuring (1) the magnetic susceptibility or specific heat as a function of temperature, (2) the spin-lattice relaxation time as a function of the temperature and evaluation of the Orbach process,[3,4] (3) the fluorescence in the optical spectra, (4) the Faraday rotation, and (5) the intensity of the spin resonance of the excited state as a function of the temperature, provided this resonance can be observed in the temperature range where this level is still sufficiently populated. Most of these methods are not very accurate and permit the evaluation of the level only to an accuracy of about 1 cm^{-1}. Others do not work well in dilute salts which are used in spin resonance methods.

Since many of the g factors of rare-earth ions are large, one can bring levels, which in the absence of a magnetic field are far apart, close together and even cause them to cross.[5] Assuming a magnetic field of about 50 000 G and g factors of about 6 for the two levels, and operating K-band frequencies, one can determine energy levels separated by about 15 cm^{-1}.

The g factors in the rare-earth ions depend on the crystal-field parameters $A_n{}^m\langle r^n\rangle$. In general there are many more crystal-field parameters than the measured three or less g factors. Paramagnetic resonance measurements of these g factors on one single Kramers doublet does not permit the evaluation of these crystal-field parameters. These can be determined from the optical spectra which give the average value of the $A_n{}^m\langle r^n\rangle$ over all the optical levels. There are reasons to believe that the crystal-field parameters may depend to some extent on the various $J\Gamma$ levels because of the shielding and antishielding factors,[6,7] i.e., that $A_n{}^m\langle r^n\rangle_{\text{true}}(1-p_n{}^m(J,\Gamma))$, where $p_n{}^m$ is a shielding factor. It is, therefore, of interest to measure sufficient g factors and a separation of Stark levels of a given J level in order to determine the $A_n{}^m\langle r^n\rangle$ for this particular level and to compare it with the weighted average over all optical levels.

Separation of energy levels in the range of 1–20 cm^{-1} are also found in exchange coupled pairs of paramagnetic ions. For example the spectrum of exchange couplet Ir^{4+} in $K_2IrPtCl^6$ can be explained by the interaction spin Hamiltonian[8]

$$\mathcal{H}_{ij}=J_1\mathbf{S}^i\cdot\mathbf{S}^j+D(2S_z{}^iS_z{}^j-S_x{}^iS_x{}^j-S_y{}^iS_y{}^j)+E(S_x{}^iS_x{}^j-S_y{}^iS_y{}^j),$$
$$\text{with } S^i=S^j=\tfrac{1}{2}, \quad \text{and } J_1=8\ cm^{-1}. \quad (2)$$

The isotropic exchange parameter can be determined by one or more of the methods described above. Strong magnetic fields would permit a more accurate determination of these parameters.

Some of the g factors in paramagnetic resonance are smaller than one. An example of this is Sm^{3+}. A magnetic field of about 50 000 G and at K_μ band frequency would permit the determination of g factors as small as 0.2.

Finally, it would be very interesting to determine the spin-lattice relaxation in high magnetic fields, in particular, the magnetic-field dependence of the direct process, the Orbach process, and the Raman process both for Kramers and non-Kramers doublets.

We report here the techniques of using superconducting magnets for spin resonance experiments. We illustrate this by two types of experiments (a) the determination of the $\Gamma_8-\Gamma_7$ separation of Dy^{3+} in CaF_2 and (b) the determination of the small g factors of Sm^{3+} in CaF_2. Experiments as outlined in (c) and (d) are in progress.

EXPERIMENTAL DETAILS

We briefly describe here the experimental setup. A fuller description of the apparatus will be given elsewhere.

The experiments were made with a stabilized K_μ spectrometer operating between 15 000–18 000 Mc/sec and at liquid-helium temperature. The cavity and the stainless-steel waveguide section were enclosed in a 1-in. i.d. thin stainless-steel tubing. This tubing was inserted into the bore of the superconducting magnet. The modulation coils were wound around the stainless-steel tubing concentric with the cylindrical cavity. Fifty to 100 turns of thin pure copper wire were sufficient for a modulation depth of about 80 G. The heat dissipation at such modualtion depth was not excessive. About 8 liters of liquid helium were required to cool the superconducting magnet and waveguide section to fill the Dewar for a 3–4-h experiment.

The superconducting magnet was about 4 in. long

[5] An interesting experiment is to measure the fluorescence or absorption of light when the energy levels cross. The polarization of the light or the angular distribution of the light would be expected to change. This experiment is very similar to the optical atomic level crossing experiments except that in the case of a crystal you have the advantage of the symmetry planes and axes. Such an experiment should permit the accurate determination of g factors and splittings of both of the ground state as well as optically excited states of transition group elements in crystals.

and i.d. slightly larger than 1 in.[9] The power supply was a standard stabilized supply. The magnetic field could be swept by putting a small dc error signal in the sensing elements of the power supply. The rate of sweep could be controlled by varying the magnitude of the error voltage. Sweeps of several minutes to several hours over the range of 46 000 G could be achieved without difficulty. A superconducting switch permitted the magnet to be operated in the persistent mode.

The measurement of the magnetic field presents a little difficulty. The inhomogeneity of this particular magnet over a sample volume of 0.02 cm^3 and a sample height of about 2 mm was of the order of 10–15 G at the center field of about 20 000 G. This inhomogeneity was estimated by putting small crystals with paramagnetic impurities of known linewidth and g factors. Calibrating the sweep, one could estimate the broadened linewidth in the superconducting magnet. The linewidth would probably be even larger for a proton resonance sample which has a larger volume and would not permit an accurate or easy determination of the magnetic field. (Since our spectrometer was inserted in the liquid-helium bath, a solid-state proton sample would have to be used. However, one could use also a liquid sample by using an inner Dewar so that the spectrometer and proton resonance could be operated at any temperature.) We have used a more primitive method. By placing various paramagnetic samples of known g factors in the magnetic field, we have made an experimental plot of the magnetic field H against the current I. It was found that the magnetic field was not quite linear with the current, particularly at high magnetic fields. There is also a noticeable hysteresis. At center band, near 20 000 G, and sweeping rapidly over the whole range back forth the hysteresis amounts to 100–150 G. In all measurements reported here were made with slow sweep rates and always in the same direction. The maximum error in the determination of the magnetic field is estimated to be about 0.2%.

Once a line was observed on the scope or by phase-sensitive detection the superconducting solenoid was switched to the persistent mode. In this case the line stayed at a constant magnetic field with only a very small drift.

Such a system, with a more homogenous magnet, could be used for magnet of frequency stabilization. It also permits the use of the continuous averaging technique[10] to greater advantage. In this technique the signal and the noise are fed into a multichannel analyzer. The signal is additive, i.e., proportional to the number n of sweeps across the line, whereas the noise is proportional to $n^{1/2}$, so that the signal to noise is proportional to $n^{1/2}$. This is also true for phase-sensitive detection. However, in practice it is found that low-frequency noise components are difficult to filter out, even with large time constants in the R.C. filter of lock-in detector. A system, such as a superconducting magnet, in which the magnetic field is constant and ripple is nearly absent, lends itself admirably to such a technique.

THE SPECTRUM OF Dy^{3+} IN THE CUBIC FIELD OF CaF_2

The cubic field of CaF_2 splits the $J=15/2$ of the $^6H_{15/2}$ level into three Γ_8, one Γ_7 and one Γ_6. The ground state is a $\Gamma_8^{(1)}$ and the g factors within the Γ_8 quartet have recently been determined by Bierig and Weber[11] as 2.63 ± 0.05, 5.48 ± 0.15, and 14 ± 1. The next excited state Γ_7 has been measured by Low[12] as $g=7.47\pm0.03$ and by the above authors at 7.52 ± 0.05. These authors estimate from the temperature dependence of the intensity of the Γ_7 level to be at 8.5 ± 1.0 cm^{-1} above the Γ_8 level. All other levels are far removed. In addition Bierig and Weber observed many lines associated with tetragonal or trigonal symmetries and with g factors varying from 1.50 to 16.

This spectrum, therefore, has a wealth of lines which can be used for field calibration. We have confirmed many of the g factors determined by these authors (the high g factor is found to be 13.7 ± 0.3). In addition we observe lines at near 29 000 and 34 000 G when $H\|$ to the 100 axis. These two lines are identified to belong to the cubic transition before and after crossover from the

$$\Gamma_8:\ a_1|\pm15/2\rangle+a_2|\pm7/2\rangle+a_3|\mp1/2\rangle a_4|\mp9/2\rangle \text{ to the}$$

$$\Gamma_7:\ c_1|\pm13/2\rangle+c_2|\pm5/2\rangle+c_3|\mp3/2\rangle+d_4|\mp11/2\rangle \text{ levels.}$$

From these measurements and the known g factors of the Γ_8 and Γ_7 levels we evaluate the $\Gamma_8-\Gamma_7$ separation as $7.3_5\pm0.2$ cm^{-1}. The main errors arise from the additive errors of the g factors and the field calibration.

These data permit the evaluation of the crystal-field parameters. Writing in the notation of Lea *et al.*,[13]

$$\frac{A_4\langle r^4\rangle}{A_6\langle r^6\rangle}=\frac{x}{1-|x|}\frac{F(6)}{F(4)},$$

where $A_m\langle r^n\rangle$ are the crystal-field parameter, $F(4)$ and $F(6)$ multiplication factors, and we find $x=0.59\pm0.01$. From this we find

$$A_4\langle r^4\rangle=-242\pm20 \text{ cm}^{-1},$$

$$A_6\langle r^6\rangle=41\pm5 \text{ cm}^{-1}.$$

In these calculations we have not taken into account the admixtures from the $J=13/2$ level at about 3500 cm^{-1}.

THE SPECTRUM OF Sm^{3+} IN THE TEGRAGONAL FIELD OF CaF_2

The Landé g factor of the ${}^6H_{5/2}$ level is small, only 2/7, and one would expect that the spectroscopic splitting factor of the Sm^{3+} in crystals would be small as well.

In the cubic field the $J=5/2$ levels is split into a Γ_8 and Γ_7. The Γ_8 level in the absence of admixture of higher excited states gives rise to transitions at $g=22/21$, 2/3, and 2/7 with relative intensity of 25/36, 2/3, and 9/8, respectively, when $H\|$ (100). With the magnetic field parallel to the (111) direction the calculated g factors are 16/21, 2/3, and 2/12 with relative intensities of 16/9, 4/9, 25/18. However, the $J=7/2$ is only at about 1000 cm^{-1} followed by $J=9/2$ near 2000 cm^{-1} and one expects that the various levels would be admixed considerably, reducing in general the g factors from the values given above. In the presence of an axial field the Γ_8 level splits into two doublets. Rabbiner[14] has observed the fluorescence spectrum of Sm^{3+} supposedly in an axial field and has analyzed the spectrum. The interpretation, however, should be treated with caution because of the complexity of this spectrum.

We have looked for the resonance spectrum of two CaF_2 with nominal concentration of 0.05 and 0.1%. One set of crystals was nearly colourless supposedly contained mainly trivalent Sm^{3+}, and the other set of deep green color and containing a mixture of Sm^{3+} and Sm^{2+}. The spectrum of the green crystal was very rich in lines whereas the other showed only a few lines. The lines common to both samples could be shown to have tetragonal point symmetry with

$$g_{\|}=0.907\pm0.01,$$
$$g_{\perp}=0.544\pm0.15.$$

[14] N. Rabbiner, Phys. Rev. **130**, 507 (1963).

[*Note added in proof.* M. J. Weber and R. W. Bierig have observed a similar spectrum with

$$g_{\|}=0.93\pm0.04$$
$$g_{\perp}=0.57\pm0.05$$

(private communication).]

In addition there were many other lines (apart of hyperfine structure from the Sm^{147} and Sm^{149}, both with spins $I=\frac{7}{2}$). These lines have not been yet interpreted, some of which no doubt are of cubic and trigonal symmetry. The presence of the rich hyperfine structure complicated the identification of the spectra. For example along the (111) direction, lines were found with $g=0.893$, 0.87, 0.70, 0.67 (tetragonal), 0.62 and 0.415. (It is likely that line at 0.415 belongs to the cubic set. Possibly the line at $g=0.89$ or 0.87 may also belong to the cubic set. However, this needs further confirmation.) It is of interest to note that there are so many more lines in the mixed $Sm^{2+}-Sm^{3+}$ crystal. Possibly some of the Sm^{2+} which presumably is in the cubic site oxidizes later to Sm^{3+}.

The above g factor can be interpreted to arise from a wave function of the $a|\pm5/2\rangle+b|\mp3/2\rangle$ with a ~0.86. This is indicative of considerable tetragonal admixture and is consistent with similar results found for[15,16] Nd^{3+} and for Ce^{3+}.[17]

Paramagnetic Resonance of Yb^{3+} in $CaWO_4$†

U. RANON
Israel Atomic Energy Commission, Soreq Research Establishment, Yavne, Israel
AND
V. VOLTERRA
Department of Physics, The Hebrew University, Jerusalem, Israel
(Received 31 January 1964)

Paramagnetic resonance of Yb^{3+} has been observed in single crystals of $CaWO_4$ at 20°K and 3 cm. A tetragonal as well as two rhombic spectra were found. The tetragonal spectrum is fitted to an axial spin Hamiltonian with $g_{\parallel}=1.058\pm0.002$, $g_{\perp}=3.920\pm0.005$, $|^{173}A|=(77\pm1)10^{-4}$ cm^{-1}, $|^{173}B|=(285\pm1)10^{-4}$ cm^{-1}, $|^{173}P|<2.10^{-3}$ cm^{-1}, $|^{171}A|=(279\pm3)10^{-4}$ cm^{-1}, $|^{171}B|=(1034\pm3)10^{-4}$ cm^{-1}. The rhombic spectra have the y and z axes in the {110} planes. One has the z axis at $6°\pm1°$ to the crystallographic c axis and $g_x=3.012\pm0.005$, $g_y=4.788\pm0.005$, $g_z=0.975\pm0.003$. The other has the z axis at $7°\pm1°$ to the c axis and $g_x=4.155\pm0.005$, $g_y=3.704\pm0.005$, $g_z=1.155\pm0.003$. The spectra arise from Yb^{3+} ions at Ca^{2+} sites and the rhombic symmetry is caused by charge compensation at next-nearest-neighbor Ca^{2+} sites. The possibility of W^{6+} substitution is discussed.

I. INTRODUCTION

CRYSTALS of the $CaWO_4$ structure (sheelite), doped with rare-earth ions have been used extensively in the past few years as solid-state lasers. This fact stimulated the optical as well as paramagnetic resonance studies of these crystals.[1,2]

Paramagnetic resonance in $CaWO_4$ has been reported on the trivalent ions gadolinium,[3] terbium,[4] and neodymium.[5,6] In all these cases the symmetry of the crystalline field at the sites of the paramagnetic ions was found to be tetragonal. Recently, orthorhombic spectra of Fe^{3+} and Nd^{3+} have been reported.[6] These spectra were attributed to substitutional sites of W^{6+} ions in the WO_4^{2-} complex.

The purpose of this paper is to report on the investigation of Yb^{3+} in $CaWO_4$. A tetragonal as well as two rhombic spectra have been found and the results cast some doubt on the attribution of rhombic spectra to the W^{6+} sites.

II. THE STRUCTURE OF $CaWO_4$

$CaWO_4$ (sheelite) is a tetragonal body-centered crystal which belongs to the C_{4h} point group. The point symmetry at the sites of the Ca^{2+} ions is S_4. The structure is shown in Fig. 1. The distorted oxygen tetrahedra which surround the W^{6+} ions, are represented schematically.

III. THEORY

The ion Yb^{3+} has $4f^{13}$ electrons and the ground term of the free ion is $^2F_{7/2}$. In the rare earths, the interaction with the crystal field is usually much weaker than the spin-orbit coupling and therefore J is a good quantum number. In crystal fields of lower than cubic symmetry the J manifold of the ground state of the free Yb^{3+} ion, splits into four Kramers doublets. Paramagnetic resonance is observable at liquid-hydrogen temperature where only the lowest Kramers doublet is populated.

IV. RESULTS

Two crystals of $CaWO_4$, doped with Yb^{3+}, were investigated by paramagnetic resonance at 3 cm and 20°K. They were obtained from Isomet Corporation and Semi-Elements Inc. The concentration of Yb^{3+} in the former was nominally 0.01% and higher in the latter. An intense tetragonal spectrum was observed in the two crystals and the hyperfine structure of the

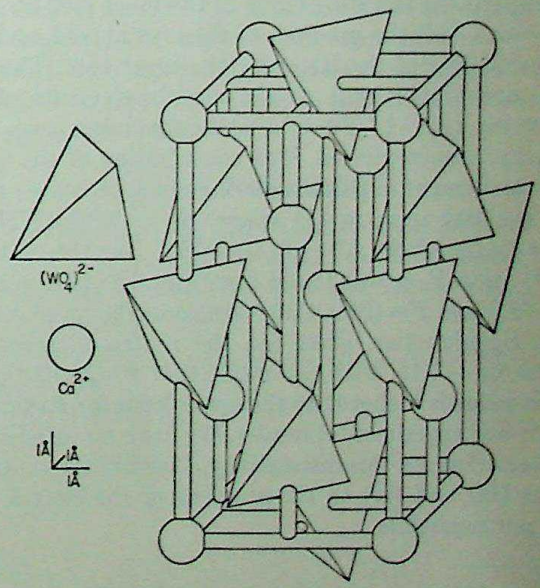

FIG. 1. Unit cell of $CaWO_4$. For clarity the oxygen tetrahedra are presented schematically.

isotopes Yb 171($I=\frac{1}{2}$) and Yb 173($I=\frac{5}{2}$) was clearly resolved. Two spectra of rhombic symmetry which were much weaker, were also shown by each of the two crystals.

The Tetragonal Spectrum

The tetragonal spectrum fits the spin Hamiltonian,

$$\mathcal{H}=g_{11}\beta H_z S_z+g_1\beta(H_x S_x+H_y S_y)+AS_zI_z+B(S_xI_x+S_yI_y)+P(I_z^2-1/3I(I+1)), \quad (1)$$

where the z axis is parallel to the crystallographic c axis and the parameters are

$$g_{11}=1.058\pm0.002,$$
$$|^{173}A|=(77\pm1)10^{-4}\ \text{cm}^{-1},$$
$$|^{173}B|=(285\pm1)10^{-4}\ \text{cm}^{-1},$$
$$|^{173}P|<2.10^{-3}\ \text{cm}^{-1},$$
$$g_1=3.920\pm0.005,$$
$$|^{171}A|=(279\pm3)10^{-4}\ \text{cm}^{-1},$$
$$|^{171}B|=(1034\pm3)10^{-4}\ \text{cm}^{-1}.$$

These results give $|g_{11}A/g_1B|=1$ within the experimental error, and therefore the admixture of $J=\frac{5}{2}$ into the ground state is negligible.[7] Accordingly, the Kramers doublet can be described by an eigenfunction within the $J=\frac{7}{2}$ manifold. In a tetragonal field this eigenfunction may be of the form $a|\pm\frac{7}{2}\rangle+b|\mp\frac{1}{2}\rangle$ or $c|\pm\frac{5}{2}\rangle+d|\mp\frac{3}{2}\rangle$. Only the latter expression is compatible with the measured g factors, giving $g_{11}=1.052$ and $g_1=3.957$ when $c=0.700$ and $d=0.714$.

The gradient of the electric field at the nucleus is determined by four contributions: (i) that of the $4f$ electrons, (ii) the shielding effect of the inner core on these electrons, (iii) the gradient of the crystal field, and (iv) the shielding of the latter by the inner core. The first two are proportional to the matrix elements of the operator $(J_z^2-\frac{1}{3}J(J+1))$, while the other two have usually been neglected. The contribution of the quadrupole moment in paramagnetic resonance is then given by the last term in (1) where[7] $P=-9e^2Q/4I(2I+1)\times\langle r^{-3}\rangle\langle J\|\alpha\|J\rangle\langle\Psi|J_z^2-\frac{1}{3}J(J+1)|\Psi\rangle$. In the case of Yb^{3+} in CaF_2 it was found that[8] $\langle\Psi|J_z^2-\frac{1}{3}J(J+1)|\Psi\rangle=-3.9$ and $P=(86\pm4)10^{-4}\ \text{cm}^{-1}$. In the present case, the eigenfunction gives for the matrix element the value of -1.16, with the result that $P=25.10^{-4}\ \text{cm}^{-1}$. This value is higher than the upper limit for P obtained from our experimental results. We have no satisfactory explanation for this discrepancy. Possibly the contributions (iii) and (iv) to the gradient of the electric field are not negligible.

[8] W. Low and U. Rosenberger, Compt. Rend. 254, 1771 (1962).

The Rhombic Spectra

The rhombic spectra can be fitted to the spin Hamiltonian

$$\mathcal{H}=\mathbf{H}.g.\mathbf{S}+\mathbf{S}.A.\mathbf{I},$$

where g and A are tensors with principal values g_x, g_y, g_z, and A_x, A_y, A_z, respectively.

Each of the rhombic spectra shows the existence of four inequivalent sites. For both spectra, one of the orthorhombic axes is perpendicular to the c direction, and we call it the y axis. Two sites of each spectrum have y along the [110] direction whereas the other two have it along the $[1\bar{1}0]$ direction. The other two axes lie then in the (110) and $(1\bar{1}0)$ planes, respectively. The sites of the more intense of the two rhombic spectra, which we shall call spectrum one, have the z axis at an angle of $6°\pm1°$ to c, while the sites which belong to the weaker spectrum (number two), have the z axis at an angle of $7°\pm1°$ to c.

Two orientations of z with respect to c are possible in each of the (110) and $(1\bar{1}0)$ planes, giving rise to four inequivalent sites which are interchangeable in pairs by a rotation of 90° about the c axis.

Spectrum number one has the parameters $g_x=3.012\pm0.005$, $g_y=4.788\pm0.005$, and $g_z=0.975\pm0.003$.

Spectrum number two has the parameters $g_x=4.155\pm0.005$, $g_y=3.704\pm0.005$ and $g_z=1.155\pm0.003$. The intensity of the even isotope lines in spectrum number one, was approximately 5% of that in the tetragonal spectrum, and the intensity in spectrum number two was about 2% of that of the tetragonal lines. On account of the four inequivalent sites for each rhombic spectrum it is found that about 16% of the Yb^{3+} ions occupy rhombic sites which correspond to spectrum one, and about 6% occupy sites corresponding to spectrum two.

The relative abundance of the two odd isotopes, 171 and 173, of ytterbium is 14% and 17%, respectively and therefore the hyperfine lines of the rhombic spectra were masked by the hyperfine lines of the tetragonal spectrum in such a way that only a few of the former were observable. Therefore the parameters of A could not be evaluated.

From the results of the tetragonal spectrum we assume that in the rhombic sites also, the admixture of $J=\frac{5}{2}$ is negligible. Since now the symmetry is rhombic, the eigenfunctions are of the form $a|\pm\frac{7}{2}\rangle+b|\mp\frac{1}{2}\rangle+c|\mp\frac{5}{2}\rangle+d|\pm\frac{3}{2}\rangle$. The three g values g_x, g_y, g_z and the normalization of the function give four quadratic equations in the four coefficients (a,b,c,d). In this case therefore the existence of a solution of the four equations does not imply that the admixture of $J=\frac{5}{2}$ is negligible, as opposed to the tetragonal case where there are three equations in two unknowns.

From the g values it can be seen that the deviation of the rhombic field from the tetragonal is not large. Therefore, we have looked for a function which is close to

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

that in the tetragonal case, obtaining for spectrum 1, $0.160|\pm\frac{7}{2}\rangle-0.262|\mp\frac{1}{2}\rangle+0.678|\mp\frac{5}{2}\rangle+0.680|\pm\frac{3}{2}\rangle$ and for spectrum number 2,

$$-0.093|\pm\tfrac{7}{2}\rangle+0.099|\mp\tfrac{1}{2}\rangle+0.708|\mp\tfrac{5}{2}\rangle+0.693|\pm\tfrac{3}{2}\rangle.$$

V. DISCUSSION

The tetragonal spectrum is usually interpreted as being due to ions at substitutional sites of Ca^{2+}. Kedzie and Kestigian[6] explained their rhombic spectra of Fe^{3+} and Nd^{3+} as being due to ions which occupy tungsten sites in the WO_4^{2-} complex. The distortion from tetragonal symmetry is explained by them in these cases by assuming a deformation of one of the oxygen bonds along the bond direction in the substituted WO_4 complex, giving rise to four inequivalent sites.

We disagree with this interpretation of the rhombic spectra for the following reasons.

(1) It seems unlikely that trivalent ions, such as the rare-earth ions should substitute for the hexavalent tungsten, which is part of a covalent complex. Furthermore, the ionic radii of the rare-earth ions are much larger than the radius of W^{6+}.

(2) The W-O bonds in the WO_4^{2-} complex are not situated in any crystallographic plane.[9] A deformation of such a bond, therefore, cannot cause a rhombic distortion with axes lying in the (110) plane, whereas our investigations, as also those of Kedzie and Kestigian, show that such rhombic distortion does actually occur.

(3) There seems to be no reason why the deformation of the complex—which is situated in a tetragonal environment—will be such as to prefer one single direction (namely, a bond direction) which does not coincide with the tetragonal axis.

(4) In our case, *two* rhombic spectra are observed. Even if we assume the W^{6+} substitution, only one of these spectra could be explained. Furthermore, the crystal field at the tungsten sites will be completely different from the tetragonal field, while our results show only a small deformation of the tetragonal field at both rhombic sites. This is evident from the fact that the g values of the rhombic spectra do not differ considerably from those of the tetragonal spectra and that the trace of the g tensor is almost the same in the three cases.

Therefore we assign the rhombic spectra of Yb^{3+} to ions at Ca^{2+} sites where the deformation of the tetragonal field is caused by charge compensation. It is well known that in crystals like CaF_2, where also trivalent ions substitute Ca^{2+}, different charge compensations are possible and these give rise to different local symmetries of the crystal field.

In $CaWO_4$ two forms of charge compensation suggest themselves. These are: (i) Ca^{2+} vacancies, and (ii) substitutional Ca^{2+} sites occupied by monovalent cations when the crystals are grown with such ions.

The nearest-neighbor Ca^{2+} sites lie in the (100) and (010) planes while the orthorhombic axes lie in the (110) planes. The latter is consistent with charge compensation at next-nearest-neighbor Ca^{2+} sites. Cases where charge compensation is affected at more distant sites rather than at nearest-neighbor sites, were observed in CaF_2[10] as well as in SrF_2 and BaF_2.[11]

Hempstead and Bowers[3] and Kedzie and Kestigian[6] found that Mn^{2+} (which does not require charge compensation) is situated exclusively in a tetragonal field. The latter authors found that the isoelectronic Fe^{3+} (which does require charge compensation) shows only an orthorhombic spectrum.

The fact that the spectra of Mn^{2+} and Fe^{3+} are completely different is not, in our opinion, a conclusive indication that Fe^{3+} does not occupy Ca^{2+} sites, as suggested by Kedzie and Kestigian. As these authors pointed out, the spectrum of Fe^{3+} can only be explained by assuming a strong axial field where the Stark splitting is larger than the Zeeman splitting. The following consideration shows that this may occur at the Ca^{2+} sites; it is well known that the Stark splitting in Fe^{3+} is at least one order of magnitude larger than in Mn^{2+}. The splitting[3] between the closest doublets of Mn^{2+} at the Ca^{2+} sites is 0.0275 cm^{-1}. Thus the splitting in Fe^{3+} should be of the order of the Zeeman splitting, or larger.

In view of the present results and the uncertainty in the assignment of the rhombic sites, it seems worthwhile that further investigations be undertaken of other rare-earth ions in $CaWO_4$ as well as in other crystals having the sheelite structure.

(Received 27 January 1964)

A Born-von Karman model has been used to determine the frequency spectrum for a body-centered cubic lattice. The model used contains noncentral angular stiffness forces as well as central forces between nearest and next-nearest neighbors. Frequency distributions have been calculated for vanadium and compared with experimental frequency distributions available from slow neutron experiments. Qualitative agreement was found between the shapes of the experimental and theoretical distributions. The calculated maximum frequency for vanadium was within 2% of that derived from the experimental frequency distribution. Dispersion curves for iron were also calculated, and were found to be in good agreement with experiment.

INTRODUCTION

THE frequency distribution of a body-centered cubic lattice of identical particles has been investigated using the Born-von Karman model of a crystal lattice. The interatomic forces used include noncentral forces of the type introduced by Gazis, Herman, and Wallis[1] in treating surface waves in a simple cubic crystal. These noncentral forces arise from the resistance to deformation of certain angles formed by three lattice points. Also included are central forces between nearest and next-nearest neighbors. Noncentral forces have been employed in recent calculations by Hendricks, Riser, and Clark,[2] which appeared after our work was essentially complete; however, the noncentral forces considered by them are different from those used here.

One of the primary aims of the investigation was to examine the effect of the inclusion of noncentral forces on the frequency distribution. Comparison between the central-force model and the model employed here was made for iron and for vanadium which is one of the more anisotropic body-centered cubic crystals. The central-force calculations for vanadium were available from the work of Clark.[3] The calculations with vanadium were also compared with the frequency distributions obtained by the slow neutron experiments of Stewart and Brockhouse,[4] and Eisenhauer *et al.*[5] Dispersion curves along specified directions were calculated for iron and compared with the experimentally determined dispersion curves of Low.[6]

LATTICE EQUATIONS OF MOTION

Although the equations of motion for central forces appear elsewhere, for example, in DeLaunay,[7] they will be repeated here in order to provide a continuity of notation. Taking a displacement vector with components u, v, and w in the x, y, and z directions, respectively, the force in the x direction on atom (j, m, n) due to the central-force interactions of nearest neighbors is given by

$$F_{x1}=\alpha[U-8u_{j,m,n}+V+W], \tag{1}$$

where

$$\begin{aligned}U=&(u_{j+1,m+1,n+1}+u_{j+1,m+1,n-1}+u_{j+1,m-1,n+1}\\&+u_{j+1,m-1,n-1}+u_{j-1,m+1,n+1}+u_{j-1,m+1,n-1}\\&+u_{j-1,m-1,n+1}+u_{j-1,n-1,m-1}),\\V=&(v_{j+1,m+1,n+1}+v_{j+1,m+1,n-1}-v_{j+1,m-1,n+1}\\&-v_{j+1,m-1,n-1}-v_{j-1,m+1,n+1}-v_{j-1,m+1,n-1}\\&+v_{j-1,m-1,n+1}+v_{j-1,m-1,n-1}),\\W=&(w_{j+1,m+1,n+1}-w_{j+1,m+1,n-1}+w_{j+1,m-1,n+1}\\&-w_{j+1,m-1,n-1}-w_{j-1,m+1,n+1}+w_{j-1,m+1,n-1}\\&-w_{j-1,m-1,n+1}+w_{j-1,m-1,n-1}),\end{aligned} \tag{2}$$

where α is the nearest-neighbor force constant. Similarly, the central-force interaction between next-nearest neighbors gives rise to a force on the atom (j,m,n) in the x direction given by

$$F_{x2}=\beta[u_{j+2,m,n}+u_{j-2,m,n}-2u_{j,m,n}], \tag{3}$$

where β is the next-nearest-neighbor force constant.

For the noncentral forces examined here it is assumed that a change in angle is related to a change in potential energy by a Hooke's law force constant. If V is the potential energy and $\delta\phi$ a change in angle, one obtains

$$V=\tfrac{1}{2}\gamma(\delta\phi)^2, \tag{4}$$

where γ is the force constant. In this treatment two general types of angles were considered; 36 angles of the type ϕ_1 in Fig. 1 associated with a force constant γ_1, and 72 angles of the type ϕ_2 in Fig. 1 associated with a force constant γ_2. The expansion of the potential energy is quite tedious but straightforward, and the total contribution from the angles considered results in a force on the atom of interest, in the x direction, given by

$$\begin{aligned}F_{x3}=&\gamma_1[-20u_{j,m,n}+2U-V-W+4(u_{j+2,m,n}+u_{j-2,m,n})\\&-(u_{j,m+2,n}+u_{j,m-2,n}+u_{j,m,n+2}+u_{j,m,n-2})]\\&-\gamma_2[-30u_{j,m,n}+3U+\tfrac{3}{2}(V+W)\\&+\tfrac{3}{2}(u_{j,m+2,n}+u_{j,m-2,n}+u_{j,m,n+2}+u_{j,m,n-2})],\end{aligned} \tag{5}$$

where U, V, and W are given by Eq. (2). These noncentral forces are invariant under rigid-body rotations.

The equation for the force in the x direction on the atom (j,m,n) due to the central and noncentral forces considered here may now be written as

$$\begin{aligned}F_x=&m\ddot{u}_{j,m,n}\\=&-u_{j,m,n}[8\alpha+2\beta+20\gamma_1+30\gamma_2]\\&+(\beta+4\gamma_1)(u_{j+2,m,n}+u_{j-2,m,n})+(-\gamma_1+\tfrac{3}{2}\gamma_2)\\&\times(u_{j,m+2,n}+u_{j,m-2,n}+u_{j,m,n+2}+u_{j,m,n-2})\\&+U(\alpha+2\gamma_1+3\gamma_2)+(V+W)(\alpha-\gamma_1+\tfrac{3}{2}\gamma_2),\end{aligned} \tag{6}$$

where U, V, and W are given as in Eq. (5). The forces in the y and z directions on the central atom are found by a circular permutation of u, v, and w, as well as the increments of their indices j, m, n.

SOLUTION OF THE EQUATIONS OF MOTION

The solutions of the equations of motion are assumed to be plane waves, where the usual cyclic boundary conditions of Born[8] are applied. The solutions for the motion of, say the nth, atom are written as

$$\begin{aligned}u_n&=X\exp 2\pi i(\nu t+\mathbf{k}\cdot\mathbf{r}_n),\\v_n&=Y\exp 2\pi i(\nu t+\mathbf{k}\cdot\mathbf{r}_n),\\w_n&=Z\exp 2\pi i(\nu t+\mathbf{k}\cdot\mathbf{r}_n).\end{aligned}$$

Here X, Y, and Z are the components of the plane-wave amplitude, and $\mathbf{k}$ is a propagation vector in the reciprocal lattice whose magnitude is the reciprocal of the wavelength. The values of $\mathbf{k}$ are restricted to the first Brillouin zone, as discussed by Brillouin.[9] Substitution of these solutions into the equations of motion gives three homogeneous linear equations in X, Y, and Z.

[9] L. Brillouin, *Wave Propagation in Periodic Structures* (Dover Publications, New York, 1953).

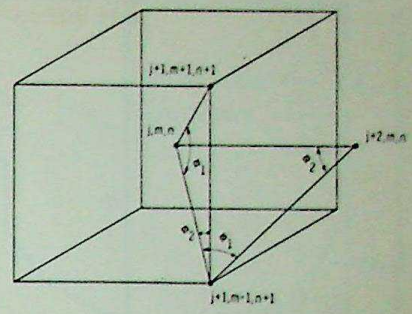

FIG. 1. Body-centered cubic lattice showing primitive (ϕ_1) and secondary (ϕ_2) angles.

A nontrivial solution requires that the determinant of the coefficients of X, Y, and Z vanish. This condition yields the secular equation

$$\begin{vmatrix}A_1-m\omega^2 & B & C\\ B & A_2-m\omega^2 & D\\ C & D & A_3-m\omega^2\end{vmatrix}=0, \tag{7}$$

where

$$\begin{aligned}A_i=&(8\alpha+16\gamma_1+24\gamma_2)(1-\cos\Phi_1\cos\Phi_2\cos\Phi_3)\\&+4\beta\sin^2\Phi_i-2\gamma_1(5\cos 2\Phi_i-\cos 2\Phi_1-\cos 2\Phi_2\\&-\cos 2\Phi_3-2)+3\gamma_2(2+\cos 2\Phi_i-\cos 2\Phi_1\\&-\cos 2\Phi_2-\cos 2\Phi_3),\end{aligned} \tag{8}$$

$$B=8(\alpha-\gamma_1+\tfrac{3}{2}\gamma_2)\cos\Phi_3\sin\Phi_1\sin\Phi_2,$$

$$C=8(\alpha-\gamma_1+\tfrac{3}{2}\gamma_2)\cos\Phi_2\sin\Phi_1\sin\Phi_3,$$

$$D=8(\alpha-\gamma_1+\tfrac{3}{2}\gamma_2)\cos\Phi_1\sin\Phi_2\sin\Phi_3.$$

In Eq. (8), $\Phi_i=\pi ak_i$ $(i=1,2,3)$ where a is the distance between next-nearest neighbors for the body-centered cubic lattice.

Symmetry considerations allow a restriction of the values of Φ_i to points within 1/48 of the first Brillouin zone. The limits on the Φ_i are then given by $0\leq\Phi_1\leq\frac{1}{2}\pi$, $0\leq\Phi_2\leq\frac{1}{2}\pi$, and $0\leq\Phi_3\leq\pi$. This reduces the values of Φ_i to those within the region in Φ space bounded by the planes $\Phi_1=\Phi_2$, $\Phi_2=0$, $\Phi_1=\Phi_3$ and $\Phi_1+\Phi_3=\pi$.

For a cubic equation of the type resulting from the expansion of Eq. (7) Blackman[10] has shown that maxima in $m\omega^2$ can occur only when Φ_1, Φ_2, Φ_3 have some combination of the values 0, $\frac{1}{2}\pi$, π. The point $\Phi_1=\Phi_2=\Phi_3=0$ is excluded as $m\omega^2=0$ at this point. Substitution of those values of Φ_1, Φ_2, Φ_3 which are within the first 1/48 Brillouin zone showed that in most cases considered the maximum occurs at $(\frac{1}{2}\pi,0,\frac{1}{2}\pi)$. This maximum frequency may be found directly from Eq. (7) and is

$$m\omega_{\max}^2=4(4\alpha+\beta+5\gamma_1)+42\gamma_2. \tag{9}$$

It was found in actual calculations that the position of the maximum could be shifted to $(0,0,\pi)$ when certain values of the elastic constants, such as those for sodium, given by Quimby and Siegell,[11] were assumed. In this case the maximum frequency is given by

$$m\omega_{\max}^2=16(\alpha+2\gamma_1+3\gamma_2). \tag{9a}$$

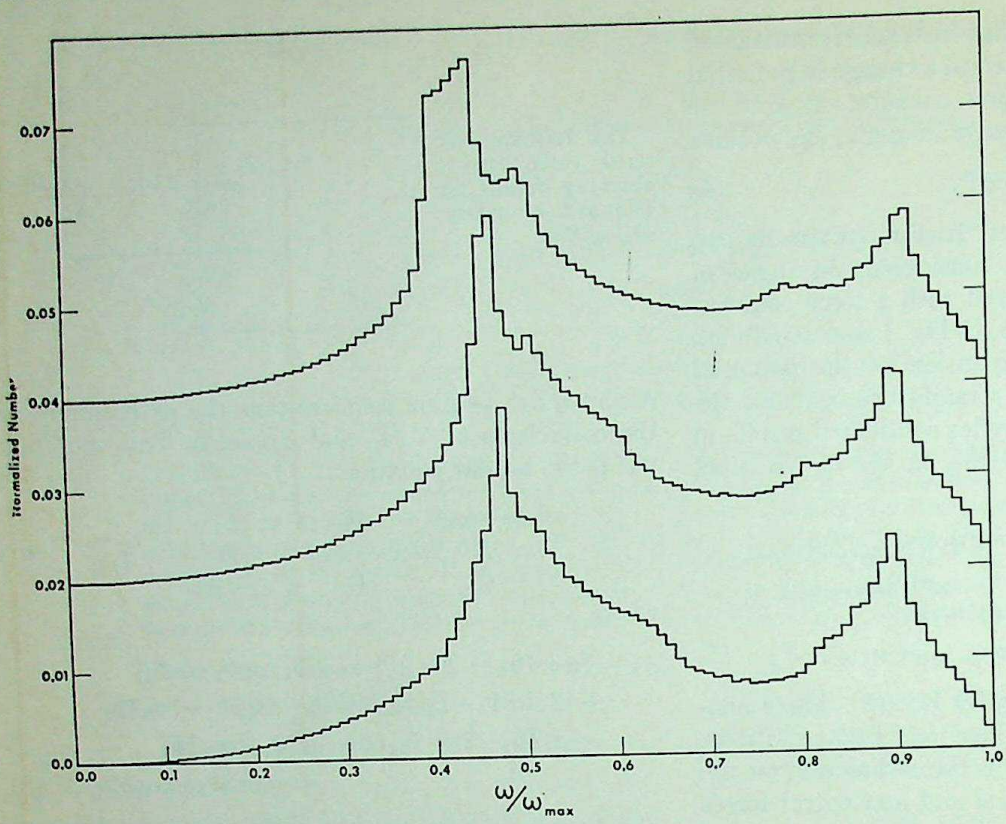

FIG. 2. Three calculated frequency histograms for vanadium with $\gamma_2/\gamma_1=0.0$ (upper curve), $\gamma_2/\gamma_1=0.5$ (middle curve), and $\gamma_2/\gamma_1=1.0$ (bottom curve). *Note:* For display purposes, while the scale of the ordinate is the same for all three curves, the origin for the middle curve is at 0.02 and is at 0.04 for the upper curve.

RELATIONSHIPS BETWEEN ELASTIC CONSTANTS AND LATTICE FORCE CONSTANTS

In the limit of long wavelengths, when the wavelength is much greater than the lattice spacing, the plane waves are effectively propagating as in a continuous medium. This allows the identification of the lattice force constants with the elastic constants of the medium found from measurements of the velocity of sound. These relationships are obtained by expanding the displacement components such as $u_{j+p,m+q,n+r}$ in a Taylor series about $u_{j,m,n}$, substituting into the equation of motion and matching the coefficients of the second order derivatives with those of the continuum equations of motion. The results are:

$$\begin{aligned} ac_{11}&=2(\alpha+\beta+6\gamma_1+3\gamma_2),\\ ac_{12}&=2(\alpha-3\gamma_1+\tfrac{3}{2}\gamma_2),\\ ac_{44}&=2(\alpha+\gamma_1+\tfrac{9}{2}\gamma_2). \end{aligned} \tag{10}$$

If $\gamma_2=0$, the above three equations determine the lattice force constants uniquely; otherwise, the force constants are determined assuming, for example, a given ratio of γ_2/γ_1. The value γ_2/γ_1 is used as a parameter in the sequel. The elastic constants for vanadium are those of Alers.[12] It may be observed that the maximum frequency when it occurs at $(\frac{1}{2}\pi,0,\frac{1}{2}\pi)$, as is usual, is a function of the elastic constants only and is

$$m\omega_{\max}{}^2=2a(c_{12}+2c_{44}+c_{11}). \tag{11}$$

However, when the maximum frequency occurs elsewhere it is also a function of γ_2/γ_1.

[12] G. A. Alers, Phys. Rev. 119, 1532 (1960).

CALCULATION OF THE FREQUENCY DISTRIBUTION

In order to obtain the true distribution of frequencies in a macroscopic crystal Eq. (7) would have to be solved for a very large number of points within the first Brillouin zone, equal to the number of degrees of freedom of the particles in the crystal. A systematic method was used for choosing a relatively small number of solution points within the first zone. It is assumed that solution points are uniformly distributed such that an allowed point exists within a volume element in Φ space, and further that the frequencies at all points within the element are equal to the value of the frequency at the center of the element. The values of Φ_i were chosen in a regular manner by stepping along the axes in intervals of 0.01π. Thus the volume elements were cubes of volume $10^{-6}\,\pi^3$.

Some of the solution points were on the bounding planes and were not, of course, centers of a cube lying entirely within the first Brillouin zone. There was some question of the desirability of including these points without properly weighing their contribution to the frequency distribution in the first zone. A numerical investigation of the most extreme case, that of the frequency distribution obtained with all points on the bounding planes included with the same weight as the interior points, showed that the resulting frequency distribution was essentially the same as the distribution with no boundary points included. Due to this result only points in the interior of the first 1/48th Brillouin zone were finally chosen. These considerations resulted in the inclusion of approximately 39 000 solution points in the 1/48th zone. Histograms representing the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

frequency distribution were prepared from the calculated frequencies by finding the number of frequencies contained in a given frequency interval. The frequency interval chosen was 1.0% of the maximum frequency.

The cubic equation for the square of the frequency was solved using the Cardan method to find the first root, and the remaining quadratic to find the other two roots. A check on the accuracy of this method of calculating the frequency showed that six figures of accuracy were present for most cases. In the case of two equal roots the accuracy could be reduced to five figures; however, an error of this magnitude is not significant in the construction of the frequency histogram. The calculations were performed on an IBM-7090 computer.

RESULTS

The elastic constants for vanadium at 300°K are given by Alers[12] as

$$c_{11}=22.795\times10^{11}\ \text{dyne-cm}^{-2},$$
$$c_{12}=11.870\times10^{11}\ \text{dyne-cm}^{-2},$$
$$c_{44}=4.255\times10^{11}\ \text{dyne-cm}^{-2}.$$

The maximum frequency calculated from Eq. (11), using these elastic constants, is 8.87×10^{12} cps which compares well with the experimental value of 9×10^{12} cps extrapolated from the curve given by Eisenhauer.[5] The two constant central-force model gives a maximum frequency of 7.07×10^{12} cps. Thus the three constant model gives a better result for the maximum frequency. The calculated and experimental frequency distributions are, however, quite different with regard to the location of the two major peaks, with the calculated frequency distribution having more widely spread maxima. The parameter γ_2/γ_1 may be varied without destroying the good agreement with the experimental maximum frequency. Figure 2 shows the frequency historgrams for vanadium for ratios of γ_2/γ_1 of 0.5 and 1.0, along with the case for $\gamma_2=0$. Figure 2 indicates that increasing the ratio of γ_2/γ_1 reduces the intensity of the first peak and moves the two maxima closer together producing better agreement with experiment. In view of those results, the frequency histogram for $\gamma_2/\gamma_1=1.5$ was also calculated and a smoothed curve obtained from these results is shown in Fig. 3 together with the experimental curve of Eisenhauer. For comparison the smoothed curve for the central-force model of Clark is also presented.

To indicate the effect that an uncertainty regarding the elastic constants might play in the determination

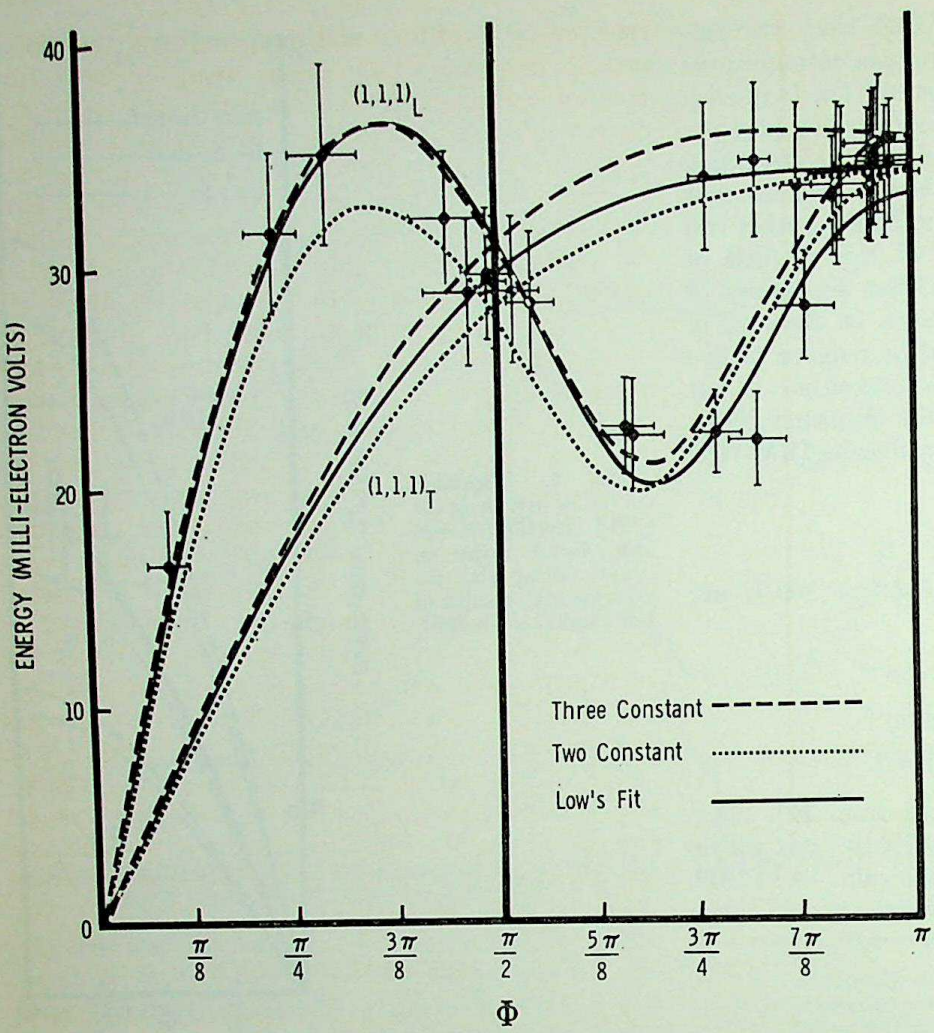

FIG. 5. Dispersion curves for iron along the [111] direction, $\Phi_1=\Phi_2=\Phi_3=\Phi$, where $\Phi_1=\pi a k_1$ along with the experimental results of Low, and Low's best fit.

of the frequency distribution, vanadium distributions were calculated using elastic constants varied by $\pm 10\%$ independently and assuming $\gamma_2=0$. Briefly, it was noted that increasing c_{12} and c_{11} by 10% tends to spread the peaks while increasing c_{44} brings the maxima together slightly. It was also apparent that increasing c_{11} and c_{44} by 10% increased the sharpness of the low-frequency peak while increasing c_{12} had the opposite effect. None of these frequency distributions seem to fit the experimental one appreciably better than the distribution with the unchanged elastic constants, and the calculated maximum frequencies are all in the neighborhood of the experimental maximum.

In addition to the frequency spectra discussed above, the model was used to calculate frequency dispersion curves. The calculations were compared with dispersion curves for iron as determined by Low.[6] Using the elastic constants given by Low for iron at 16°C as

$$c_{11}=2.332\times10^{12}\ \text{dyne-cm}^{-2},$$
$$c_{12}=1.355\times10^{12}\ \text{dyne-cm}^{-2},$$
$$c_{44}=1.180\times10^{12}\ \text{dyne-cm}^{-2},$$

dispersion curves were calculated along the [101], [111], and [001] directions. For comparison the same calculations were performed using a two-constant central-force model. The results of these calculations are shown in Figs. 4–6 along with the experimental results of Low. These calculations showed that the maximum frequency of 9.735×10^{12} cps for the three-constant model was higher than the maximum frequency of 8.711×10^{12} cps found for the two-constant model. Comparison with Low's curves shows that the three-constant model matches the experiment better than the two-constant model; however, both are, in general, well within the experimental error. The results of the three-constant model within the first zone, are essentially indistinguishable from the fit to the experimental data given by Low. The largest discrepancies occur for dispersion curves along the [111] direction, and even here the difference is apparent only for values of Φ outside the first zone. The inclusion of the angular stiffness terms has, in general, improved the agreement with experiment in this case.

CONCLUSION

The dynamical properties of a body-centered cubic lattice of identical particles have been investigated using the Born-von Karman model of a crystal lattice. The model employed contained noncentral as well as

central forces, namely, noncentral angular stiffness forces and central forces between nearest and next-nearest neighbors.

Frequency distribution histograms have been constructed for vanadium and compared with the experimental frequency distributions available from slow neutron experiments. The calculated maximum frequency for vanadium was in good agreement with that derived from the experimental frequency distributions, an improvement over the results of the central-force model. Our model containing a single angular stiffness interaction ($\gamma_2/\gamma_1=0$) gives a frequency distribution which is very similar to that obtained by Hendricks *et al.*[2] with their noncentral model. Both distributions yield a separation between the two major peaks which is significantly larger than that found experimentally. Inclusion of a second angular stiffness interaction into our model ($\gamma_2/\gamma_1\neq 0$) gives a small improvement but not enough to produce agreement with experiment. The disagreement in the experimental and theoretical values of the separation between the two major peaks in the frequency distribution might possibly be removed by including additional interactions in the model. It may well be; however, that short-range forces are inadequate, and that long-range forces are required. Since vanadium is a metal, the effects of the electron gas may be significant as discussed by DeLaunay.[7] The recent calculation of Hendricks, Riser, and Clark,[2] however, indicates that the use of DeLaunay's model does not resolve this difficulty. Failure of the adiabatic approximation in a metal might also be a factor which should be taken into account.

ACKNOWLEDGMENTS

We wish to thank Dr. Robert Herman and Dr. David H. Evans for their many helpful discussions throughout the course of this work. In addition, one of us (B.C.C.) is grateful to Professor Basil Curnutte for his constant encouragement.

Paramagnetic Resonance and Relaxation of Trivalent Rare-Earth Ions in Calcium Fluoride. I. Resonance Spectra and Crystal Fields

M. J. Weber and R. W. Bierig
Raytheon Research Division, Waltham, Massachusetts

(Received 3 January 1964)

The energy level structures arising from the crystal-field splitting of the free-ion ground states of trivalent rare-earth ions in CaF_2 are determined from a survey of the optical and electron paramagnetic resonance spectra. The predicted ground states are in agreement with existing paramagnetic resonance data. Estimates are made of the magnitude of the cubic crystal-field parameters and their variation throughout the rare-earth series. Axial crystal fields of tetragonal and trigonal symmetries, due to nearest-neighbor charge compensation, are found to cause large perturbations on the cubic-field energy levels. The paramagnetic resonance spectra of all rare-earth ions are reviewed and new resonances for Ce^{3+}, Sm^{3+}, Er^{3+}, and Yb^{3+} are reported. Expressions for the calculation of crystal-field matrix elements in terms of 3-j and 6-j symbols and their relationship to the operator equivalent approach are given in an Appendix.

INTRODUCTION

RARE-EARTH ions of the lanthanide series can be introduced into a calcium fluoride host lattice substitutionally at divalent calcium sites. Although several of the rare earths can be stabilized in the divalent state in alkaline earth halide lattices, we shall be concerned almost exclusively with the trivalent rare-earth ions. In the case of the trivalent rare earths, a question arises regarding the compensation of the additional positive charge associated with a trivalent ion substituted in a divalent site. Several different charge compensation mechanisms have been found in CaF_2 which depend upon the growth conditions, impurity concentrations, and thermal treatments of the sample. The crystalline electrostatic fields at the rare-earth sites have correspondingly different magnitudes and symmetries. In this paper and the one to follow[1] (henceforth denoted as II), the electron paramagnetic resonance and spin-lattice relaxation properties of rare-earth ions in sites of different crystal-field symmetries will be examined and compared.

The interpretation of the spin-lattice relaxation results in II requires knowledge of the strength of the crystal fields, the energy level structure of the resonant ion, and the wave functions of the lower states. Unfortunately, such information for the trivalent rare-earth series in CaF_2 is still incomplete. We have made estimates of the cubic crystal-field parameters, their variation throughout the lanthanide series, and the relative size and effect of axial field perturbations from a survey of available optical spectra of rare-earth ions in CaF_2. This information, while not precise, is nevertheless valuable in analyzing paramagnetic resonance spectra, calculating the magnitude of spin-lattice coupling, and estimating the crystal-field splittings when direct measurements are lacking. The predicted crystal-field splitting, ground state, and excited states of the lowest J multiplet of rare earths in various symmetry sites are correlated with the findings of paramagnetic resonance studies. For this purpose a review of the paramagnetic resonance spectra is made which will also provide a basis for the discussion of the relaxation properties of the ions in II.

CHARGE COMPENSATION AND CRYSTAL-FIELD SYMMETRY

Calcium fluoride has the fluoride structure with O_h^5 space group symmetry. This may be visualized as a cubic lattice of fluorine ions in which every other body-center position is occupied by a divalent calcium ion. Rare-earth ions can enter the lattice substitutionally at Ca^{2+} sites. At such sites divalent rare-earth ions experience a cubic crystalline electric field of 8-fold fluorine coordination. Trivalent rare earths, however, experience crystal fields of differing strengths and symmetries depending upon how and where the additional positive charge is compensated. The occurrence of the different charge compensation mechanisms is dependent upon many factors associated with the total crystal growth process. Several resultant distributions of ions which generate crystal-field environments of cubic, tetragonal, trigonal, and orthorhombic symmetry are described

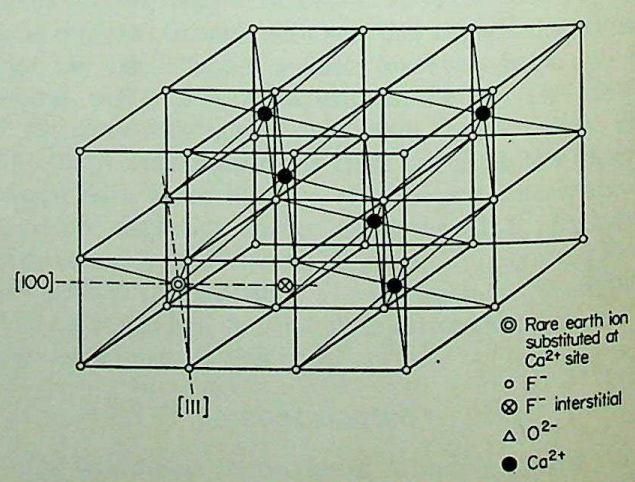

FIG. 1. A portion of the CaF_2 lattice showing the site of substitutional trivalent rare-earth ions and locations of charge compensating ions.

below and can be visualized by inspection of the CaF_2 lattice shown in Fig. 1.

The most commonly found trivalent rare-earth site in CaF_2 is one of tetragonal (C_{4v}) crystal-field symmetry. Charge compensation is attained by the presence of an F^- ion in one of the six nearest-neighbor interstitial sites at a distance $a/2=2.73$ Å, where a is the lattice constant. The three crystal-field symmetry axes are the [100] crystallographic directions. This charge compensating mechanism has been well substantiated from investigations of density and lattice constants by x-ray methods,[2,3] ionic conductivity,[4] as well as by the early paramagnetic resonance results of Bleaney *et al.*[5] and others.[6]

Paramagnetic resonance spectra exhibiting cubic symmetry are observed when charge compensation is not achieved locally. Since the excess F^- in the interstitial site is not tightly bound to the rare earth, it can diffuse through the crystal at high temperatures.[4] Friedman and Low[7] have used this mobility to convert from tetragonal to cubic sites. The sample is heated to disorder the rare-earth $-F^-$ pairs and then rapidly quenched. Whether the interstitial fluorine can diffuse to an energetically favorable site near a trivalent rare-earth ion or gets trapped elsewhere in the lattice depends upon the rate of cooling. Trivalent rare-earth ions of the second half of the $4f^n$ shell have been found in sites of cubic symmetry more frequently than ions of the first half. The stability of the former in cubic sites may be associated with their smaller ionic radii and different local distortions.

A crystal field of trigonal symmetry (C_{3v}) arises from the replacement of one of the eight nearest-neighbor F^- at a distance $\sqrt{3}a/4=2.36$ Å by O^{2-}, a mechanism discussed by Feofilov.[8,9] The symmetry axes are the four [111] cube-body diagonals. The formation of this type of site is a function of the oxidation-reduction conditions during growth. Sierro[10,11] has studied the effects of thermal treatment and hydrolysis at high temperatures on the trigonal resonance spectra of rare earths in alkaline earth halides. If samples are heated in an atmosphere containing a small amount of water vapor, H_2O molecules dissociate at the surface, OH^- replacing F^- which goes off as HF. Trigonal spectra corresponding to OH^- substituted for F^- have been observed. With further thermal treatment, OH^- dissociates, the resulting O^{2-} diffusing through the crystal to compensate a trivalent rare-earth ion as above.

A paramagnetic resonance spectrum having trigonal symmetry has been observed[12,13] from U^{4+} in CaF_2, which is attributed to the replacement of two F^- ions at opposite corners of the fluorine cubic by two O^{2-} ions. Although a resonance from a lanthanide series ion in a similar site has not been reported, Ce, Pr, and Tb are known to exhibit tetravalent states.[14,15]

Recently an orthorhombic spectrum of U^{3+} in CaF_2 has been reported by Mahlab *et al.*[16] The X-Y axes are in a (110) plane, the X axes being at an angle of 19° with respect to [110]. There are twelve inequivalent magnetic sites. Several models for the charge compensation are suggested, the most likely one being an F^- in a fourth nearest-neighbor interstitial site.

In addition to lines which can be explained by the above charge compensation mechanisms, other lines have appeared in both the optical and paramagnetic resonance spectra of rare-earth ions in CaF_2, particularly at higher rare-earth impurity concentrations. From an inspection of Fig. 1, it is not difficult to conjure up other charge compensating ion distributions at sites more distant than described above which may possibly produce measurable deviations from cubic-field symmetry. For example, F^- ions in second nearest-neighbor interstitial sites could produce a [111] trigonal spectrum. [*Note added in proof.* Such trigonal spectra have been reported for Yb^{3+} in SrF_2 and BaF_2 by U. Ranon and A. Yaniv, Phys. Letters 9, 17 (1964).] The replacements of two Ca^{2+} ions by a trivalent rare earth and a monovalent impurity,[17] or three Ca^{2+} ions by two trivalent rare-earth ions have been suggested.[18] The appearance of many new lines as the rare-earth concentration is increased may be due to the presence of energetically favored pairs or clusters of ions. Some of the lines may also be associated with other impurity ions or crystal defects.

Rare-earth-doped, alkaline earth halides exhibit additional interesting properties. For example, several trivalent rare-earth impurities have been converted to divalent ions by exposure to ionizing radiation,[15,19–21] the resulting divalent ion being in a field of cubic sym-

metry. Observations[22] of optical absorption and conductivity due to free electrons in single crystals of CdF_2 doped with rare earths indicate charge compensation by means of electrons in conduction bands or shallow traps. Recently, optical detection of phototransfer of electrons in (Sm, Eu) doped CaF_2 of the form,

$$Eu^{2+}+Sm^{3+}\xrightarrow{h\nu}Eu^{3+}+Sm^{2+},$$

has been reported[23] and interpreted as due to electrons localized at vacancies in the vicinity of the trivalent rare earth. Photoconductivity of divalent rare-earth-doped CaF_2 has also been studied.[24]

CRYSTAL-FIELD PARAMETERS

Information about the crystalline electric field splitting of the free-ion states can usually be derived from studies of optical absorption and fluorescence spectra. For the trivalent rare-earth series in CaF_2, such data is in general incomplete, widely scattered, and a detailed interpretation frequently lacking or not warranted. Among the factors contributing to this status[25,26] are that the spectra are complicated due to the presence of vibrational satellite lines, complex structure appears at moderate-to-high impurity concentrations, different types of spectra exist which are sensitive to changes in neighboring ion distributions and growth conditions, the centroids of crystal-field levels from a given state for different point symmetries do not coincide, the spectral intensities may be weak, and there is no polarized absorption to aid in the identification of cubic-field energy levels.[27,28]

The determination of crystal-field parameters from optical data requires that the site symmetry and energy level assignments be established. Subsequent fitting procedures and numerical computations employed to obtain consistent and meaningful parameters are frequently nontrivial for the multilevel rare-earth energy structures. It may be necessary to include crystal-field admixing between states of different quantum number J and the breakdown of ideal Russell-Saunders coupling. Such detailed calculations are, with a few possible exceptions, not warranted for rare earths in CaF_2, since much of the published data is not complete and the site symmetries are not well established. We shall therefore content ourselves in the next section with less refined estimates of the crystal-field parameters.

The optical spectra of several divalent rare-earth ions in cubic sites in CaF_2 have been studied. Although the crystal-field parameters for these ions will differ from those of their isoelectronic trivalent neighbor, due principally to the influence of the larger effective nuclear charge, they can be of value if a suitable correlation can be found. Since some empirically derived guidance is available for extrapolating the crystal-field parameters of a divalent ion to the corresponding isoelectronic trivalent ion, we shall include several divalent ions in the survey of optical spectra.

Crystal-field parameters can also be obtained from analysis of such factors as the g values, g-value shifts, and hyperfine constants observed in paramagnetic resonance experiments.[29] The results, however, are in general quite sensitive to the accuracy of the measurements; for example, a small uncertainty in g value can give rise to a large variation in the derived crystal-field parameters. We shall be interested principally in a qualitative correlation between paramagnetic resonance data and the crystal-field parameters determined from optical spectra.

The Hamiltonians describing the crystal-field potentials of cubic, tetragonal, and trigonal symmetry may be written as

$$\mathcal{H}_{\text{cubic}}=B_4(O_4^0+5O_4^4)+B_6(O_6^0-21O_6^4), \quad (1)$$

where $B_4^4=5B_4^0$, $B_6^4=-21B_6^0$,

$$\mathcal{H}_{\text{tetra}}=B_2^0O_2^0+B_4^0O_4^0+B_4^4O_4^4+B_6^0O_6^0+O_6^4O_6^4, \quad (2)$$

and

$$\mathcal{H}_{\text{trig}}=B_2^0O_2^0+B_4^0O_4^0+B_4^3O_4^3+B_6^0O_6^0+B_6^3O_6^3+B_6^6O_6^6. \quad (3)$$

The parameters B_n^m are related to the strength of the crystal-field components and, in the notation of Elliott and Stevens,[30] are equal to $\zeta_n A_n^m\langle r^n\rangle$, where ζ_n is the operator equivalent factor, α, β, γ for $n=2$, 4, 6, respectively. The O_n^m's are angular momentum operators transforming as the corresponding spherical harmonics.

In a very useful paper, Lea, Leask, and Wolf[31] (henceforth referred to as LLW) have determined the eigenfunction and eigenvalue solutions of Eq. (1) for various angular momentum J. Their diagrams of the eigenvalues are plotted as a function of a quantity x defined by

$$\frac{x}{1-|x|}=\frac{F(4)B_4}{F(6)B_6}=\frac{F(4)\beta A_4\langle r^4\rangle}{F(6)\gamma A_6\langle r^6\rangle}, \quad (4)$$

where $-1<x<1$ and the F's are multiplicative factors given by LLW. The ordering of states within a J manifold is dependent upon the ratio of the fourth- and sixth-order cubic-field parameters B_4/B_6, and hence from Eq. (4) upon x. The free-ion ground states of the trivalent rare earths and their decomposition in a cubic field are given in Table I. Also listed are estimated x values obtained using approximate cubic-field parameters for CaF_2 and their variation throughout the rare-earth series, which are discussed later. The predicted or experimentally observed cubic field ground states are given in the final column of Table I.

The determination of the parameters $A_n{}^m\langle r^n\rangle$ requires the evaluation of various crystal-field matrix elements. This may be performed easily for the lowest LSJ state using the "operator equivalent" approach of Stevens[32] and existing tables of matrix elements; however, when treating the crystal-field splitting of excited states $L'S'J'$ and matrix elements between different J states, it is convenient to use a more general approach which utilizes the tabulated 3-j and 6-j symbols.[33] This approach and its relationship to that of operator equivalence are developed in the Appendix. A formula is also given, in terms of 6-j symbols, which relates the operator equivalent factors for two different J states. Thus, given x for a state J, it can be used together with Eq. (4) to derive x for other states J', and thereby, from LLW, the expected ordering of levels.

TABLE I. Crystal-field splitting of the free-ion ground state of trivalent rare-earth ions in a cubic field in CaF_2. The x values are obtained using estimated crystal-field parameters in Eq. (4). * denotes ground state based upon estimated x value.

Rare-earth ion	Configuration ground state	Decomposition in cubic field	Estimated x value	Lowest state in CaF_2

ELECTRON PARAMAGNETIC RESONANCE AND OPTICAL SPECTRA

A summary of measured paramagnetic resonance g values for trivalent rare-earth ions in various symmetry sites is given in Table II. Additional features of the resonances together with reported optical spectra, estimated crystal-field parameters and energy level structures, and expected resonances spectra for all rare earths are discussed below.

TABLE II. Paramagnetic resonance g values of trivalent rare-earth ions in CaF_2. Numbers in parenthesis following the g values denote references given in the text.

Rare-earth ion	Cubic[a]	Crystal-field symmetry tetragonal	Trigonal
Ce^{3+}	Γ_8: 2.00, 3.1±0.1 (34) Γ_7: 1.297±0.001 (34) (b)	$g_{\parallel}=3.038\pm0.003$ (35) $g_{\perp}=1.396\pm0.002$ (35)	$g_{\parallel}=2.38\pm0.03$ (c) $g_{\perp}<0.1$ (c)
Nd^{3+}	(42) (b)	$g_{\parallel}=4.412\pm0.008$ (5) $g_{\perp}=1.301\pm0.002$ (5)	
Sm^{3+}	See (46)	$g_{\parallel}=0.907\pm0.01$ (46) $g_{\perp}=0.544\pm0.15$ (46)	
Gd^{3+} Tb^{3+}	g:1.991±0.002 (49)	$g_{\parallel}=g_{\perp}=1.992\pm0.001$ (52) $g_{\parallel}=17.768\pm0.020$ (54) $g_{\perp}<0.25$ (54)	$g_{\parallel}=1.992\pm0.001$ (53) $g_{\parallel}=17.28\pm0.01$ (54) $g_{\perp}<0.25$ (54)
Dy^{3+}	Γ_8: 2.63±0.05 (55) 5.48±0.15 (55) 13.7±0.3 (46) Γ_7: 7.47±0.03 (56)	$g_{\parallel}=1.7\pm0.1$ (55) $g_{\perp}=2.82\pm0.05$ (55)	(I) $g_{\parallel}=16\pm1$ (55) $g_{\perp}<1$ (55) (II) $g_{\parallel}=4.93\pm0.05$ (55) $g_{\perp}=1.50\pm0.05$ (55)
Er^{3+}	$g=6.785\pm0.002$ (35)	(I) $g_{\parallel}=7.76\pm0.02$ (35) $g_{\perp}=6.253\pm0.006$ (35) (d) $g_{\parallel}=6.76\pm0.02$ (35) $g_{\perp}=9.11\pm0.01$ (35) (II) $g_{\parallel}=1.746\pm0.002$ (59) $g_{\perp}=9.16\pm0.01$ (59)	(I) $g_{\parallel}=3.30\pm0.01$ (59) $g_{\perp}=8.54\pm0.02$ (59) (II) $g_{\parallel}=2.206\pm0.007$ (59) $g_{\perp}=8.843\pm0.010$ (59) (b)
Yb^{3+}	$g=3.443\pm0.002$ (18) (b)	$g_{\parallel}=2.423\pm0.001$ (c) $g_{\perp}=3.878\pm0.001$ (c)	$g_{\parallel}=1.323\pm0.001$ (65) $g_{\perp}=4.389\pm0.004$ (65)

Cerium

The cubic crystal-field ground state of Ce^{3+} in CaF_2 should be a Γ_8 quartet. Resonances from an isolated Γ_8 derived from $J=\frac{5}{2}$ would have g values of Λ, $7\Lambda/3$, and $11\Lambda/3$ ($\Lambda=6/7$ for Ce^{3+}) for a magnetic field $H\|[100]$. Dvir and Low[34] have reported broad, anisotropic resonances at 4°K and 1.2 cm with $g=2.00$ and 3.1 ± 0.1, which were interpreted as due to Ce^{3+} in cubic sites. At high fields a line was observed with $g_{\|}=1.297\pm0.001$ and was ascribed to the excited Γ_7 doublet which has a predicted g value of 10/7. Since the line was seen at 4°K, they conjectured that the cubic-field splitting must be very small, not much larger than the Zeeman energy. As we shall see, however, the cubic field splittings of isolated rare-earth ions in CaF_2 are, in general, very much larger. We have examined several $Ce:CaF_2$ samples but have not been able to positively identify any cubic-field resonances.

The resonance of Ce^{3+} in sites of tetragonal symmetry has been reported by Baker *et al.*[35] The observed g values are derivable from a ground-state doublet of the form $\cos\theta|\pm\frac{5}{2}\rangle-\sin\theta|\mp\frac{3}{2}\rangle$, where $\cos\theta\approx0.91$. Using this result and the tetragonal field Hamiltonian Eq. (2) yields

$$\tan2\theta=(2\times5^{1/2}B_4^4)/(B_2^0+20B_4^0)=1.15. \qquad (5)$$

This is very close to the cubic field value, $\tan2\theta=(5)^{1/2}/2=1.12$, obtained by setting $B_2^0=0$ and $B_4^4=5B_4^0$, thereby implying the tetragonal perturbation may be very small. This, however, is in contradiction to results from other rare earths in CaF_2, where axial fields arising from nearest-neighbor charge compensation greatly perturb the cubic-field energy level structure. Also no evidence of a small energy level splitting has been found from the spin-lattice relaxation of Ce^{3+} in tetragonal sites.[1] Thus the above agreement may be coincidental, particularly since any admixing from the $^2F_{7/2}$ excited state, which should be important for $Ce^{3+}:CaF_2$, has been neglected in obtaining this result and since we do not have sufficient information to evaluate B_2^0, B_4^0, and B_4^4 separately. The above ground-state wave function and the eigenvalues for $J=\frac{5}{2}$ in a tetragonal field, Eq. (6), are consistent with a case where the second-order crystal-field term does not dominate and $A_2^0\langle r^2\rangle$ is positive.

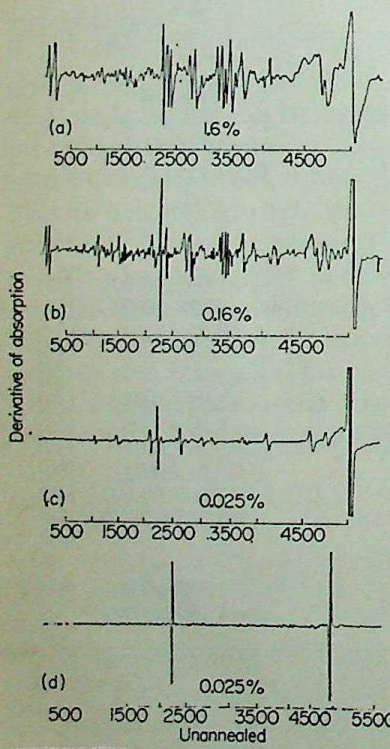

FIG. 2. Paramagnetic resonance spectrum of $Ce^{3+}:CaF_2$ at 9.6 kMc/sec and 4.2°K for various Ce concentrations. Spectrum (d) is from an unannealed sample (see text). The magnetic field, in Oe, is approximately $\|[100]$.

We have observed resonances arising from Ce^{3+} in sites of trigonal symmetry. The g values given in Table II can be compared with those expected for a doublet of the form $|\pm\frac{3}{2}\rangle$ for which $g_{\|}=18/7=2.57$, $g_{\perp}=0$; the differences are probably due mainly to admixing with states from $^2F_{7/2}$. The trigonal field eigenvalues for an isolated $J=\frac{5}{2}$ state are given in Eq. (7).

At higher rare-earth impurity concentrations, many additional lines frequently appear in the paramagnetic resonance spectrum as in the case of the optical spectra.[27] The increasing spectral complexity with concentration is illustrated in Fig. 2 where three spectra from samples[36] containing cerium dopings, each differing by approximately one order of magnitude, are shown. Such additional spectra may be attributed speculatively to the simultaneous existence of several different charge compensation mechanisms and ion arrangements, crystal imperfections, or clusters of ions, but additional work is needed to clarify the situation. The effects of annealing conditions upon the number of lines, linewidth, and line shape is also evident. Traces (a), (b), (c) are from samples which were annealed at 1200°C for 12 h and cooled at a rate of 20°C/h. Trace (d) is from an "as-grown" sample cooled at a rate of ~200°C/h. Note the presence of the two extremely low-field resonances in Figs. 2 (a), (b), which correspond to the zero-field resonances at 9.37 and 9.48 kMc/sec reported by Kaplan.[37]

The optical spectra of $Ce^{3+}:CaF_2$ has been reported by several authors[34,38–40]; however, no complete crystal-field analysis has been attempted. Whereas the free-ion $^2F_{5/2}$ and $^2F_{7/2}$ states are separated by 2250 cm^{-1}, the infrared absorption spectrum[39] of $Ce^{3+}:CaF_2$ is characterized by two broad bands centered around

2200 and 3200 cm^{-1}. Estimates of the fourth- and sixth-order cubic-field parameters for Ce^{3+}, based upon extrapolations of results for other rare-earth ions in CaF_2, suggest an x value for $^2F_{7/2}$ which in LLW is near the crossing of the Γ_6 and Γ_8 energy levels. Assuming the cubic field is dominant, the above lines could correspond to transitions from the $^2F_{5/2}$ Γ_8 ground state to the Γ_6-Γ_8 and Γ_7 states of $^2F_{7/2}$, respectively. At low temperatures several observers have noted a complex line structure about the 2200-cm^{-1} region with a spread $\sim$350 cm^{-1}. In addition to vibrational satellites, this structure could arise from a small Γ_6-Γ_8 separation or a combination of this and additional splitting of the Γ_8 quartet of $^2F_{7/2}$ due to axial crystal fields, since the site symmetries in the samples are not reported.

If one assumes the $\sim$1000 cm^{-1} spectral separation is due mainly to the cubic-field splitting of $^2F_{7/2}$ and equates it to the Γ_7-Γ_6 energy difference and furthermore assumes $x\approx 0.8$, which is near the Γ_6-Γ_8 crossover, crystal-field parameters $A_4\langle r^4\rangle \sim -320$ cm^{-1} and $A_6\langle r^6\rangle \sim 45$ cm^{-1} are obtained. Using these parameters, an energy separation of $\sim$700 cm^{-1} is predicted between the Γ_8 and Γ_7 states of $^2F_{5/2}$. The above results can only be considered as coarse estimates, however, and may differ greatly from the actual values because, assuming the transitions are assigned correctly: (1) the over-all $^2F_{7/2}$ splitting may not be due solely to the cubic field; (2) the x value used was only an estimate; and (3) no account has been made of the off-diagonal elements of the crystal field connecting the $^2F_{5/2}$ and $^2F_{7/2}$ states. The last is certainly not negligible if the crystal field is as large as estimated above. When the site symmetry and various transitions are established, the crystal-field parameters may be determined by solving the combined spin-orbit and crystal-field problem using a representation in which L_z and S_z are diagonal[41] rather than using the more usual perturbation approach with a $|J,J_z\rangle$ basis.

Praseodymium

The cubic-field ground state of Pr^{3+} in CaF_2 should be either a Γ_1 or a Γ_5 state depending upon the ratio of the fourth- and sixth-order crystal-field parameters. The estimated x value in Table I predicts that the magnetic Γ_5 triplet is lowest. The cubic field wave functions describing the Γ_5 state for $J=4$ are

$$(\tfrac{7}{8})^{1/2}|\pm 3\rangle - (\tfrac{1}{8})^{1/2}|\mp 1\rangle,$$
$$(\tfrac{1}{2})^{1/2}(|2\rangle - |-2\rangle).$$

This state behaves like a spin-1 triplet in a magnetic field yielding an isotropic g value of 2.00.

We have searched for resonances at 9.6 kMc/sec and 2–4°K in a CaF_2 sample containing 0.57% Pr. A weak signal was observed with an isotropic g value $\sim$2 which consisted of a single line of width $\sim$20 G superimposed upon a broad line of width $\sim$100 G. Hyperfine structure due to the one stable isotope Pr^{147}, nuclear spin $I=\frac{5}{2}$, which should be a distinguishing feature was not evident. It was not known whether Pr^{3+} was actually present in sites of cubic symmetry in the sample studied. The absence of a cubic resonance could be due to the difficulty encountered in getting trivalent rare earths belonging to the first half of the $4f$ shell into cubic sites. An additional broad intense resonance corresponding to a zero-field splitting of $\sim$0.3 cm^{-1} was also observed which is being investigated further.

Neodymium

The cubic-field ground state of Nd^{3+} in CaF_2 is a Γ_8 quartet for all x ($x<0$). The g values for the Γ_8 resonances depend upon the ratio B_4/B_6 and possible admixing from excited states. A cubic field resonance spectrum for Nd^{3+}:CaF_2 was reported by Vincow and Low[42]; however, there has been some controversy[43] regarding the interpretation of the spectrum which indicates $x\simeq -1.0$. In a tetragonal field the $^4I_{9/2}$ free-ion ground state is decomposed into five Kramers doublets. Resonances for Nd^{3+} in sites of tetragonal field symmetry were found by Bleaney *et al.*[5] and fitted to a wave function of the form $a|\pm\frac{9}{2}\rangle + b|\pm\frac{1}{2}\rangle + c|\mp\frac{7}{2}\rangle$ with $c\approx 0$.

The optical absorption and fluorescence spectra of Nd^{3+} in cubic sites have been studied by Kiss.[27] The crystal-field parameters determined from the measured splittings of the $^4I_{9/2}$ and $^4I_{11/2}$ states, neglecting certain off-diagonal terms, are

$$A_4\langle r^4\rangle = -415 \text{ cm}^{-1}, \quad A_6\langle r^6\rangle = 33 \text{ cm}^{-1}.$$

Using these results in Eq. (4) yields x values of ≈ -0.70 and ≈ -0.91 for $^4I_{9/2}$ and $^4I_{11/2}$, respectively. The observed energy level spacings are similar but do not correspond exactly to those in the diagrams of LLW for these x values, thereby indicating that consideration of the admixing of states of different J may be required to determine satisfactory crystal-field parameters. The cubic field energy levels of $^4I_{9/2}$ are $\Gamma_8^{(2)}-0$, $\Gamma_8^{(1)}-180$ cm^{-1}, and Γ_6-700 cm^{-1}.

We have examined the fluorescence spectrum[44] in a CaF_2 sample which, from an examination of the paramagnetic resonance spectrum, had Nd^{3+} predominantly in tetragonal sites. Transitions between $^4F_{3/2}$ and $^4I_{9/2}$ were observed at 8680, 8750, 8940, 9048, 9078, 9220, and 9465 Å at liquid helium temperatures (these may include vibrational satellites). Lines were also observed at 8860, 9150, and 9335 Å at room temperature which became much smaller or had disappeared at 77°K. In an axial field, the upper fluorescence state $^4F_{3/2}$ decomposes into two Kramers doublets separated by $6B_2^0$, where $B_2^0=\alpha(4f^3, {}^4F_{3/2})A_2^0\langle r^2\rangle$. If the disappearing lines

are caused by thermal depopulation of the upper doublet, this implies a relatively large tetragonal field splitting and an estimated $|A_2^0\langle r^2\rangle|$ of several hundred cm^{-1}. Such a field would greatly perturb the two Γ_8 quartets of $^4I_{9/2}$. Measurements[1] of the spin-lattice relaxation of Nd^{3+} in tetragonal sites indicate an excited state at $\sim 65\ cm^{-1}$.

Promenthium

Neither the paramagnetic resonance nor optical spectrum of $Pm^{3+}:CaF_2$, which does not occur naturally, has been reported. In a cubic field the lowest state from $^5I_4$ is a Γ_1 singlet for all values of x ($x<0$). The remaining excited states should be relatively far removed.

Samarium

We have searched for resonances at 16 kMc/sec and 4.2°K in an $\sim 0.1\%$ Sm-doped CaF_2 crystal. The sample was prepared so as to enhance the occurrence of trivalent rather than nonresonant divalent samarium ions.[45] The only resonance observed was one exhibiting tetragonal symmetry about the [100] axes which probably arises from interstitial fluorine charge compensation. The measured g values are $g_{11}=0.93\pm0.04$, $g_1=0.57\pm0.05$, which can be fitted by an approximate ground doublet wave function $\cos\theta|\pm\frac{5}{2}\rangle-\sin\theta|\mp\frac{3}{2}\rangle$, where $\cos\theta\approx 0.88$. The hyperfine structure of Sm^{147} and Sm^{149} (nuclear spins $I=\frac{7}{2}$) was observed for $H\|[100]$ where $A^{147}\approx 170\times10^{-4}\ cm^{-1}$. Low[46] has recently confirmed these measurements and has also reported seeing additional resonances exhibiting cubic and trigonal symmetry; however, their interpretation is not yet complete. In the cubic field of CaF_2 the Sm^{3+} ground state is a Γ_8 quartet.

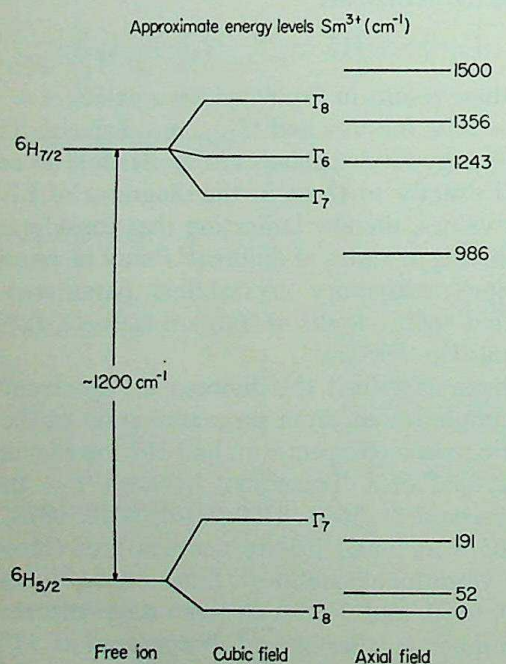

FIG. 3. Crystal-field splitting of the two lowest states of Sm^{3+} in CaF_2. The cubic-field energy level structure is estimated; the axial field values are from Rabbiner (Ref. 18).

A complex fluorescence spectrum from Sm^{3+} in a field of axial symmetry in CaF_2 has been observed and analyzed by Rabbiner.[18] The energy levels for $^6H_{5/2}$ and $^6H_{7/2}$ are shown in Fig. 3. Although no optical spectra of Sm^{3+} in cubic sites have been reported, the ordering of levels within the two lowest ^6H states is expected to be approximately as shown (no significance should be attached to the relative energy level spacings, however, which require knowledge of the cubic field parameters and treatment of crystal-field admixing between J states). From Fig. 3 it can be seen qualitatively that the axial field removes the degeneracy of the Γ_8 states and produces a large perturbation on the cubic-field energy level structure. This is also evident from the resonance results where for tetragonal sites $\tan 2\theta$ in Eq. (5) equals 1.46 compared to the cubic-field value of 1.12.

The symmetry of the axial field present in the above fluorescence spectrum was not established. In a tetragonal field, the energies of the three Kramers doublets for an isolated $J=\frac{5}{2}$ state are, from Eq. (2),

$$\begin{aligned} E(\pm\tfrac{1}{2}) &= -8B_2^0+120B_4^0, \\ E(\pm\tfrac{5}{2},\mp\tfrac{3}{2}) &= 4B_2^0-20B_4^0 \\ &\quad \pm 6[(B_2^0+20B_4^0)^2+20(B_4^4)^2]^{1/2}. \end{aligned} \tag{6}$$

In a trigonal field the three doublets from Eq. (3) are

$$\begin{aligned} E(\pm\tfrac{3}{2}) &= -2B_2^0-180B_4^0, \\ E(\pm\tfrac{5}{2},\mp\tfrac{1}{2}) &= B_2^0+90B_4^0 \\ &\quad \pm 3[(3B_2^0-10B_4^0)^2+10(B_4^3)^2]^{1/2}. \end{aligned} \tag{7}$$

These energies are for isolated J states. The crystal-field splitting for $Sm^{3+}:CaF_2$ in Fig. 3, however, are not negligible compared to the separations of the various J states. Crystal-field admixing must be taken into account in this case to obtain meaningful parameters B_n^m and predicted g values.

The fluorescence spectrum of Sm^{3+} in a tetragonal field of CdF_2 has also been reported.[47] Since CdF_2 has (1) an isomorphic lattice structure, (2) a lattice constant very nearly equal to that of CaF_2, 5.40 Å versus 5.451 Å, and (3) the Pauling ionic radii of Cd^{2+} and Ca^{2+} are approximately equal, 0.97 Å versus 0.99 Å, the crystal-field splittings and ordering of states in the two crystals should be similar. This is indeed found for $Sm^{3+}:CdF_2$, where, in place of the energy levels in Fig. 3, the corresponding levels in CdF_2 from $^6H_{5/2}$ are at 0, 54, and 147 cm^{-1} and from $^6H_{7/2}$ at 959, 1169, 1381, and 1586 cm^{-1}. We shall include data from CdF_2 when similar results for CaF_2 are lacking.

Europium

The ground state of Eu^{2+} is a singlet $^7F_0$. From the fluorescence spectrum of Eu^{3+} in isomorphic CdF_2, energy levels from the first excited J state $^7F_1$ are reported[48] at 307–309 and 400 cm^{-1}. In a crystal field of axial symmetry a $J=1$ state is split into a singlet and a doublet with an energy separation $3\alpha A_2{}^0\langle r^2\rangle$. Setting this equal to the observed 92 cm^{-1} separation and using $\alpha(4f^6, {}^7F_1)=-\frac{1}{5}$, yields $A_2{}^0\langle r^2\rangle\approx 150$ cm^{-1}.

Gadolinium

Resonances from Gd^{3+} have been observed in sites of cubic,[49,50] tetragonal,[51,52] and trigonal[10,11,53] symmetry. Since it is an S-state ion, the over-all crystal-field splittings are small, being 0.149 cm^{-1} in a cubic field. In an axial field the $^8S_{7/2}$ ground state is split into 4 doublets with a total splitting of about 2 cm^{-1} for tetragonal and trigonal (O^{2-}) sites.

Terbium

The cubic-field ground state of $Tb^{3+}(^7F_6)$ should be either a Γ_2 singlet or a nonmagnetic Γ_3 doublet, thus no cubic-field resonances are expected nor have they been reported. For $x\gtrsim 0.8$, as estimated in Table I, the ground state is a Γ_3 with a relatively near Γ_5 excited state. Terbium resonances and hyperfine structure for ions in sites of tetragonal and trigonal symmetry have been investigated in detail by Forrester and Hempstead.[54] The resonances for this non-Kramers ion arise from states of principally $|\pm 6\rangle$ character which have a g_{11} of $12\Lambda=18$.

Dysprosium

We have reported[55] the resonance spectrum of Dy^{3+} in sites of cubic, tetragonal, and trigonal symmetry elsewhere. The cubic-field ground state is a Γ_8 quartet with g values corresponding closely to those calculated from the $J=15/2$ wave functions of LLW for $\Gamma_8{}^{(1)}$ and $x=0.6$. The first excited state is a Γ_7 doublet located ~ 8 cm^{-1} above the ground state. Using this energy separation and the above x value, the cubic-field parameters are $A_4\langle r^4\rangle=-(200\text{–}300)$ cm^{-1} and $A_6\langle r^6\rangle=30\text{–}40$ cm^{-1}. The large uncertainty in the values arises from the fact that since we are near the crossover of the Γ_7 and Γ_8 levels and are using the Γ_7-Γ_8 energy separation as a scale factor, a small change in x can give rise to a large change in the over-all crystal-field splitting of the ground state. Recently, Low[56] has repeated measurements of the cubic-field spectrum at higher frequency and fields with accordingly more accuracy. He finds $A_4\langle r^4\rangle=-242\pm 20$ cm^{-1}, $A_6\langle r^6\rangle=41\pm 5$ cm^{-1}, where any admixing from $^6H_{13/2}$ at ~ 3500 cm^{-1} was neglected.

Rabbiner[57] has reported measurements of the fluorescence spectrum of Dy^{3+}:CaF_2. The assigned cubic-field splitting of $^6H_{15/2}$ is ≈ 615 cm^{-1} with a Γ_7 ground state and a first excited Γ_8 state at 53 cm^{-1}. The discrepancy with the above may arise from the presence of additional spectral lines from ions in different symmetry sites.

Holmium

The possible cubic-field ground states of Ho^{3+} in CaF_2 are a nonmagnetic $\Gamma_3{}^{(2)}$ doublet and a $\Gamma_5{}^{(2)}$ triplet (g value ≈ 5). In the region $0.5\lesssim x$, where the Γ_3 state is lowest, the first excited state is a $\Gamma_4{}^{(2)}$ triplet which in the energy level diagram of LLW is nearly coincident with the $\Gamma_3{}^{(2)}$ doublet.

We have searched for a resonance at X band and 2–4°K in a CaF_2 sample grown by Optovac, Inc., containing a nominal Ho concentration of $\sim 0.1\%$. No resonances were observed. Hayes *et al.*[20] have searched for resonances at K band and 4°K in 0.01 and 1% Ho-doped CaF_2 samples which exhibited optical absorption spectra charactersitic of Ho^{3+}. Again no resonances were found suggesting the ground state is a Γ_3 state.

Dy^{2+} is isoelectronic with Ho^{3+}. At 77°K the fluorescence spectrum[58] of Dy^{2+} from $^5I_7$ to the $^5I_8$ ground state exhibits a group of lines between 0–100 cm^{-1} and another group around 400–500 cm^{-1}. Laser action has been observed to a terminal state 90 cm^{-1} above the ground state. From an examination of the energy level diagram for $J=8$ in LLW, the above spectrum indicates that $-0.6<x<-0.4$. Assuming an over-all crystal-field splitting of 450 cm^{-1} for $^5I_8$ and an x value of -0.5, yields cubic-field parameters of $A_4\langle r^4\rangle\sim -400$ cm^{-1} and $A_6\langle r^6\rangle\sim 40$ cm^{-1} for Dy^{2+}.

Erbium

Resonances from Er^{3+} in sites of cubic,[35] tetragonal (I)[35,59] and (II),[59] and trigonal (I) and (II)[59] symmetry have been reported. We have examined several CaF_2 crystals at X-band frequencies containing 0.1–1.0% Er and have identified cubic, tetragonal (I) and trigonal (II) resonances. The spectrum at these frequencies and moderately high Er concentrations is complex and consists of many broad, anisotropic lines with overlapping

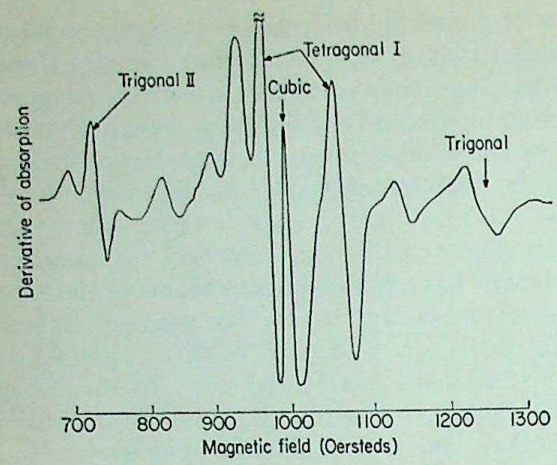

FIG. 4. Low-field portion of the paramagnetic resonance spectrum of Er^{3+}: CaF_2 arising from ions in cubic, tetragonal, and trigonal crystal fields. Hyperfine structure from Er^{167} ($I=\frac{7}{2}$) is also present. Measurements were made at 9.58 kMc/sec, 4.2°K, and with $H\|[110]$.

hyperfine structure, as evident from the low-field portion of the spectrum shown in Fig. 4. Studies of the angular dependence of the spectrum in both the (100) and (111) planes reveal the presence of several unaccounted for resonances which do not correspond to those reported above. One resonance exhibits trigonal symmetry with $g_{\|}=6.31\pm0.05$ and $g_{\perp}=2.14\pm0.04$; however, these g values do not satisfy the relationship $(g_{\|}+2g_{\perp})\approx 3g_{\text{cubic}}(\Gamma_7)$ as do the axial symmetry Er^{3+} resonances observed previously.[59] The total spectrum was examined with increasing temperature up to ~50°K. The trigonal (II) resonance exhibited rapid line broadening in the vicinity of 30°K. The cubic-tetragonal (I) group of lines also exhibited broadening, the cubic line showing the more rapid temperature dependence. By 40°K the cubic and $g_{\|}$, $g_{\perp}$ tetragonal resonances could no longer be distinguished as separate lines. No definite evidence of the tetragonal (I) excited-state resonance reported by Baker *et al.*[35] was noted, although it may have been partially masked by other lines in the spectrum. No other excited-state resonances were detected. Measurements[1] of the temperature dependence of T_1 for the trigonal (II) resonance indicate the presence of an excited state at ~ 50 cm^{-1}.

Paramagnetic resonance studies[60] have shown that the cubic-field ground state of Ho^{2+} in CaF_2 is a Γ_6 doublet in contrast to the Γ_7 ground state found for isoelectronic Er^{3+}. Since the change in the ratio of the fourth- and sixth-order cubic-field parameters is expected to be small between a divalent ion and its isoelectronic trivalent neighbor, the above result suggests that for both Ho^{2+} and Er^{3+} we are in the vicinity of the crossover of the Γ_6 and Γ_7 levels which for $J=15/2$ occurs at $x=-0.46$.

The lowest excited crystal-field states in Ho^{2+}: CaF_2 are[61] a quartet at 30.1 cm^{-1} and a doublet at 33.8 cm^{-1} which from LLW suggest an x value ≈ -0.52. Using these values, the crystal-field parameters for Ho^{2+} are $A_4\langle r^4\rangle\approx -190$ cm^{-1} and $A_6\langle r^6\rangle\approx 16$ cm^{-1}, where any admixture from $^4I_{13/2}$ is probably small and has been neglected. Since x is smaller for Er^{3+}, the sixth-order term must be correspondingly more important.

Pollack[62] has reported a total separation of about 400 cm^{-1} for the 8 crystal-field levels of $^4I_{15/2}$ for Er in an axial field. As an order-of-magnitude estimate, assume a total cubic-field splitting of approximately the same size, 400 cm^{-1}, and an x value of -0.4. These yield $A_4\langle r^4\rangle\approx -310$ cm^{-1} and $A_6\langle r^6\rangle\approx 44$ cm^{-1}, which, while not based upon direct spectroscopic data, are, nevertheless, consistent with expected values extrapolated from results for other ions.

Thulium

The cubic-field ground state of Tm^{3+} may be either Γ_2 or Γ_3. The estimated x value in Table I predicts a Γ_2 singlet lowest. Hayes and Twidell[19] did not observe any resonances in a 0.05% Tm sample at X band and 20°K, but did observe a Tm^{2+} resonance after x irradiation. It has been reported that an axial spectrum of Tm^{3+} has been seen.[15,63]

Ytterbium

The ground state of Yb^{3+} in cubic sites in CaF_2 is a Γ_7 doublet. The wave function describing the Γ_7 doublet for $J=\frac{7}{2}$ is $(\sqrt{3}/2)|\pm\frac{5}{2}\rangle-(\frac{1}{2})|\mp\frac{3}{2}\rangle$ which yields an isotropic g-value of $24/7=3.429$. Low[64] has measured $g=3.426\pm0.001$; Hayes and Twidell[19] report 3.443 ± 0.002. We find a g value of 3.441 ± 0.004. This resonance is observable up to temperatures ~100°K, which implied a comparatively long spin-lattice relaxation time.[1]

We have also observed resonances due to Yb^{3+} in tetragonal sites. The g values in Table II are consistent with a doublet derived from the cubic Γ_7, since $(g_{\|}+2g_{\perp})\approx 3g_{\text{cubic}}(\Gamma_7)$ and indicate that the other states of $^2F_{7/2}$ are sufficiently far removed to have little effect on the g values.[60] They can be fitted by an approximate doublet wave function $0.806|\pm\frac{5}{2}\rangle-0.591|\mp\frac{3}{2}\rangle$. Two trigonal field resonances have been reported by Low and co-workers.[21,65]

Kiss[39] has investigated the absorption and fluorescence spectrum of isoelectric Tm^{2+} in CaF_2. The $^2F_{7/2}$ ground state is split into a Γ_7 doublet lowest, a Γ_6 doublet at 547 cm^{-1}, and a Γ_8 quartet at 556 cm^{-1}. The cubic-field parameters derived from these values are $A_4\langle r^4\rangle=-180$ cm^{-1} and $A_6\langle r^6\rangle=35$ cm^{-1}, which correspond to an x value of 0.74.

The absorption spectrum of Yb^{3+} was also examined

briefly by Kiss. Two dominant lines were observed at 10 240 cm^{-1} and 10 870 cm^{-1}, which have also been observed by others.[28,64,66] If these lines are ascribed[39] to transitions to the two cubic-field levels of the $^2F_{5/2}$ excited state, an $A_4\langle r^4\rangle$ value of -280 cm^{-1} is found. Comparing the crystal-field splitting of isoelectronic Tm^{2+} and Yb^{3+}, the larger value for the latter reflects the effect of the additional nuclear charge of the trivalent ion. Approximate cubic-field energy levels for Yb^{3+}, based upon Kiss' assignment and assuming $x\sim0.7$, are shown in Fig. 5 together with expressions from the eigenvalues. The estimated over-all crystal-field splitting of $^2F_{7/2}$ is ~800 cm^{-1}.

Low has investigated the electron paramagnetic resonance spectra[64] and the fine structure in optical spectra[28,64] of Yb:CaF_2 and suggested that the cubic field was relatively weak with an over-all ground-state splitting of ≈12 cm^{-1}. Interpretations based upon such fine structure are, in general, inconsistent with the present results and estimates of the magnitude of the cubic field for other rare-earth ions. The existence of such small splittings for Yb:CaF_2 are also not evident from measurements of the g value[19] and the rate and temperature dependence of the spin-lattice relaxation.[1] Measurements[67] of the g shift, temperature dependence, intensity, and infrared aborption of Yb^{3+} in cubic sites in CdF_2 indicate an excited state at ≈50–70 cm^{-1} and an over-all $^2F_{7/2}$ splitting of ≈116 cm^{-1}. We do not understand why these values are so much smaller than those estimated for Yb:CaF_2. Further work to confirm the measurements and verify the interpretations in the two cases are needed.

The eigenvalues for a $J=\frac{7}{2}$ state in a tetragonal field are given by

$$E(\pm\tfrac{5}{2},\mp\tfrac{3}{2})=-b_2^0-8b_4^0+2b_6^0 \pm[(2b_2^0-5b_4^0-7b_6^0)^2+3(5b_4^4-7b_6^4)^2]^{1/2}, \quad (8)$$

$$E(\pm\tfrac{7}{2},\mp\tfrac{1}{2})=b_2^0+8b_4^0-2b_6^0 \pm[(6b_2^0-b_4^0+3b_6^0)^2+35(b_4^4+3b_6^4)^2]^{1/2},$$

where

$$b_2^0=3B_2^0, \quad b_6^0=1260B_6^0,$$
$$b_4^0=60B_4^0, \quad b_6^4=60B_6^4.$$
$$b_4^4=12B_4^4,$$

The observed ground state is of the form $\cos\theta|\pm\frac{5}{2}\rangle -\sin\theta|\mp\frac{3}{2}\rangle$ for which, from Eq. (2) and the doublet wave function found experimentally,

$$\tan2\theta=\sqrt{3}(5b_4^4-7b_6^4)/(2b_2^0-5b_4^0-7b_6^0)=-3.18. \quad (9)$$

The difference between this value and the cubic-field value $\tan2\theta=-\sqrt{3}$, corresponding to $b_2^0=0$, $b_4^4=b_4^0$, and $b_6^4=-b_6^0$, again reveals qualitatively that nearest-neighbor charge compensation produces a large change in the crystal field at the trivalent rare-earth site.

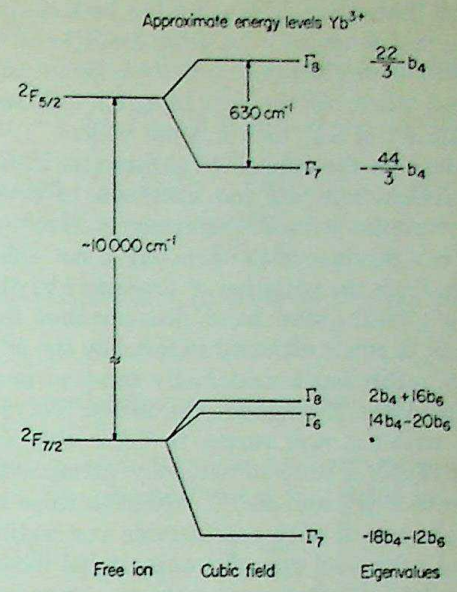

FIG. 5. Estimated cubic-field splitting of Yb^{3+} in CaF_2, assuming $A_4\langle r^4\rangle=-280$ cm^{-1} and $x=0.7$.

CONCLUSIONS

The cubic field in CaF_2 at trivalent rare-earth sites appears to be characterized by parameters in the order of magnitude

$$-A_4\langle r^4\rangle\sim250\text{–}430 \text{ cm}^{-1},$$
$$A_6\langle r^6\rangle\sim30\text{–}45 \text{ cm}^{-1}.$$

The extrapolation of data from divalent ions to the isoelectric trivalent ions is made subject to two assumptions based upon limited experimental evidence, namely that the ratio of the fourth- and sixth-order parameters of the trivalent ion is in the order of, or less than, that of the divalent ion, and that the trivalent ion parameters are larger than those of the divalent ion. The axial field parameters for nearest-neighbor charge compensation are more difficult to estimate from existing data. The $A_2^0\langle r^2\rangle$ term, however, probably has a magnitude of several hundred cm^{-1} for both tetragonal (n.n. F^- interstitial) and trigonal (O^{2-}) fields and hence produces a large perturbation on the cubic-field energy levels. The data are usually insufficient to evaluate the A_4^3, A_4^4, A_6^3, and A_6^4 terms for the noncubic crystal fields.

The parameters $A_n^m\langle r^n\rangle$ are expected to vary throughout the rare-earth series. If one assumes the A_n^m's are constants determined by appropriate lattice sums, then any variation of the crystal-field parameters would be due to $\langle r^n\rangle$. In the early work of Elliott and Stevens,[30] this variation was approximated by a multiplicative factor $(Z-55)^{-n/4}$, where Z is the atomic number. Application of this formula has not been universally

successful,[68] however. This point has been discussed by Freeman and Watson[69] who, from analyses of data for rare earths in trichlorides and ethylsulfates and using calculated values of the $\langle r^n \rangle$ integrals, conclude that the constancy of $A_n{}^m$ with Z is not valid.

The data on the cubic-field parameters in CaF_2 for most trivalent ions are too uncertain to derive any explicit variation with Z. Qualitatively, $A_4\langle r^4 \rangle$ appears to exhibit a decrease with increasing Z not unlike that predicted from the variation of Freeman and Watson's $\langle r^4 \rangle$. $A_6\langle r^6 \rangle$, on the other hand, does not show the large, monotonic decrease expected from solely the $\langle r^6 \rangle$ variation, but rather has a moderately constant or slightly increasing value throughout the series. The x values for the trivalent rare earths in cubic sites in CaF_2 given in Table I are estimated by extrapolating the behavior of $A_4\langle r^4 \rangle$ and $A_6\langle r^6 \rangle$. Although these x values must be accepted with considerable reservations, the predicted cubic-field ground states are not inconsistent with available paramagnetic resonance data, and they explain the absence of observed cubic-field resonances for Tb^{3+}, Ho^{3+}, and Tm^{3+}.

APPENDIX: CALCULATION OF CRYSTAL-FIELD MATRIX ELEMENTS USING 3-j AND 6-j SYMBOLS

The crystal-field potential V at a rare-earth ion site can be expanded as

$$V=\sum_{k,q} V_k{}^q=\sum_{k,q} A_k{}^q\langle r^k \rangle Y_k{}^q(\theta,\phi)\,, \qquad \text{(A1)}$$

where $Y_k{}^q(\theta,\phi)$ is the spherical harmonic of degree k and azimuthal quantum number q, $\langle r^k \rangle$ is the mean value of the kth power of the $4f$-electron radius, and the $A_k{}^q$'s are parameters related to the strength of the crystal field. Using the concept of operator equivalents, a general term in the crystal-field Hamiltonian may be rewritten as

$$\zeta_k A_k{}^q\langle r^k \rangle O_k{}^q\,, \qquad \text{(A2)}$$

where the ζ_k is Stevens' operator equivalent factor[32] α, β, γ for $k=2$, 4, 6, respectively, and the $O_k{}^q$'s are angular momentum operators, a complete list of which has been given by Orbach.[70] Tables of matrix elements of these operators within a J manifold and operator equivalent factors for the ground states of the trivalent rare-earth ions are located in various places in the literature. While this approach is convenient for the ground-state computations, when calculating the crystal-field matrix elements of excited states, crystal-field admixing between different J states, and in the treatment of spin-lattice relaxation where all values of k and q may be allowed, the more general approach given below which takes advantage of the tabulated 3-j and 6-j symbols of Rotenberg *et al.*[33] has been useful.

Elliott, Judd, and Runciman[71] have shown how the crystal-field matrix elements of a rare-earth ion in a configuration f^n can be calculated using the tensor operator techniques developed by Racah.[72] Their expression for the matrix elements of $U_q{}^k$, defined as $(4\pi/2k+1)^{1/2}Y_k{}^q$, rewritten in terms of 3-j symbols $(:::)$ and 6-j symbols $\{:::\}$ is

$$\begin{aligned}(f^n WUSLJJ_z|U_q{}^k|f^n W'U'S'L'J'J_z')&=\delta(SS')(-1)^{J_z+S+L'}[(2J+1)(2J'+1)]^{1/2}\\ &\times\begin{pmatrix} J & k & J' \\ -J_z & q & J_z' \end{pmatrix}\begin{Bmatrix} L & J & S \\ J' & L' & k \end{Bmatrix}\\ &\times(f^n WUSL\|U^k\|f^n W'U'S'L')\,, \qquad \text{(A3)}\end{aligned}$$

where for a rare-earth ion within a given configuration only $k=2$, 4, 6 need be considered. The reduced or double bar matrix element at the end of Eq. (A3) are

TABLE IV. Normalization factors $N_k{}^q$ for Eq. (A4). Numbers in column F are multiplicative factors common to all elements in the row. Other column headings denote q values.

$N_k{}^q$	F	0	1	2	3	4	5	6
$N_2{}^q$	$-4(7/3\times5)^{1/2}$	1	$1/(2\times3)^{1/2}$	$1/2(2\times3)^{1/2}$				
$N_4{}^q$	$8(2\times7/11)^{1/2}$	1	$1/4(5)^{1/2}$	$1/2(2\times5)^{1/2}$	$1/4(5\times7)^{1/2}$	$1/(2\times5\times7)^{1/2}$		
$N_6{}^q$	$-160(7/3\times11\times13)^{1/2}$	1	$1/2(2\times3\times7)^{1/2}$	$1/(3\times5\times7)^{1/2}$	$1/2(3\times5\times7)^{1/2}$	$1/3(2\times7)^{1/2}$	$1/6(7\times11)^{1/2}$	$1/(3\times7\times11)^{1/2}$

tabulated in Table III for the lowest L-S term of the trivalent rare-earth ions, where τ denotes the remaining quantum numbers required to specify the state. Many of the reduced matrix elements for the various ions are related by simple multiplicative factors derivable from the relationships discussed by Judd.[73] The reduced matrix elements of U^k for other L-S terms may be calculated using Racah's fractional parentage coefficients as shown by Elliott, Judd, and Runciman. Nielson and Koster[74] have recently tabulated these matrix elements for f^n configurations.

In Stevens' operator equivalence approach, certain normalization factors have been absorbed into the definition of the $A_k{}^q$. Thus if Eq. (A3) is used to evaluate crystal-field parameters and the $A_k{}^q$'s are to be compared with those derived elsewhere using operator equivalent factors, then (A2) should be replaced by

$$N_k{}^q A_k{}^q \langle r^k \rangle U_q{}^k. \tag{A4}$$

The normalization factors $N_k{}^q$ for the various k's and q's are listed in Table IV.

In terms of the 6-j symbols, the operator equivalent factors, ζ_k, for different J states are related by

$$\frac{(SLJ'\|\zeta_k\|SLJ')}{(SLJ\|\zeta_k\|SLJ)} = (-1)^{J'-J}\frac{2J'+1}{2J+1} \times\left[\frac{(2J'-k)!(2J+k+1)!}{(2J-k)!(2J'+k+1)!}\right]^{1/2} \times\begin{Bmatrix} J' & J' & k \\ L & L & S \end{Bmatrix}\Big/\begin{Bmatrix} J & J & k \\ L & L & S \end{Bmatrix}, \tag{A5}$$

where $k=2$, 4, 6 correspond to α, β, γ, respectively.

Paramagnetic Resonance and Relaxation of Trivalent Rare-Earth Ions in Calcium Fluoride. II. Spin-Lattice Relaxation

R. W. Bierig, M. J. Weber, and S. I. Warshaw
Raytheon Research Division, Waltham, Massachusetts

(Received 3 January 1964)

The temperature dependence of the spin-lattice relaxation time T_1 of trivalent rare-earth impurities in CaF_2 has been measured at 9.6 kMc/sec using pulse saturation techniques. The rare earths investigated include Kramers ions (Ce^{3+}, Nd^{3+}, Dy^{3+}, Er^{3+}, Yb^{3+}), one non-Kramers ion (Tb^{3+}), and one S-state ion (Gd^{3+}). The relaxation of ions in lattice sites of cubic, tetragonal, and trigonal crystal-field symmetries have been studied and are found to be different. At liquid-helium temperatures the relaxation usually exhibits a T^{-1} temperature dependence; however, the magnitudes are approximately two orders-of-magnitude shorter than estimated single-phonon relaxation times based upon the orbit-lattice interaction. Measurements of the Ce^{3+} relaxation in five samples containing from 0.08 to 1.6% Ce combined with results from other ions show that T_1 decreases with increasing rare-earth concentration. Multiple exponential recoveries from saturation are observed at low temperatures and are discussed with respect to possible cross-relaxation within inhomogeneous spin systems and to other faster relaxing systems. At higher temperatures examples of both Raman and Orbach two-phonon relaxation processes are found. Calculations of two-phonon relaxation times using estimated values of the dynamic crystal fields, energy level structures, and ion wave functions yield coarse order-of-magnitude agreement with experimental values.

INTRODUCTION

SPIN-LATTICE relaxation of rare-earth ions has been the subject of considerable attention in the past few years, prompted by the discovery of the importance of two-step relaxation processes involving low-lying excited states[1] and the subsequent theoretical treatment by Orbach.[2] The relaxation of several different rare-earth ions has been measured in ethyl sulfate,[3] double nitrate,[3] and garnet crystals[4] and compared with theory with varying degrees of success. We have investigated the temperature dependence of the spin-lattice relaxation time, T_1, of trivalent rare-earth ions in CaF_2, including examples of Kramers (Ce^{3+}, Nd^{3+}, Dy^{3+}, Er^{3+}, Yb^{3+}), non-Kramers (Tb^{3+}) and S-state (Gd^{3+}) ions. This crystal is of additional interest since trivalent rare earths can enter the lattice substitutionally in sites having cubic, tetragonal, and trigonal crystal-field symmetry; thus one can compare the characteristics of the relaxation of ions in different symmetry sites in the same host lattice.

Calculations of the rate of spin-lattice relaxation and predictions of the relative importance of various relaxation mechanisms require knowledge of the energy level structures, ion wave functions, and strength of dynamic crystalline fields. Unfortunately, such information is not well established for most rare-earth ions in CaF_2. In the preceding paper[5] (henceforth referred to as I), available optical and electron paramagnetic resonance data were reviewed to obtain estimates of the cubic- and axial-crystal-field parameters and electronic energy levels. These results are used to estimate the magnitude and importance of various one- and two-phonon relaxation processes. Pertinent details of the resonance spectra, g values, etc., are also given in I.

The temperature dependence of T_1 for the above rare-earth ions has been measured from 2°K to as high a temperature as the time resolution (~ 3 μsec) and signal amplitude would permit. These results are presented following a brief review of the theory of spin-lattice relaxation in CaF_2 arising from modulation of the crystal field by thermal lattice vibrations and a discussion of the experimental approach. The T_1's at liquid-helium temperatures usually exhibit a T^{-1} temperature dependence characteristic of one-phonon relaxation processes; however, the magnitudes are about two orders-of-magnitude shorter than estimated relaxation times based upon the orbit-lattice interaction. In the case of Ce^{3+}, the low-temperature relaxation times are found to be a function of rare-earth concentration. Some possible mechanisms which may account for the enhanced and concentration-dependent relaxation rates are discussed qualitatively. At higher temperatures T_1 decreases rapidly with increasing temperature. In most cases the magnitude and temperature dependence of the relaxation times are in reasonable order-of-magnitude agreement with those for two-phonon Orbach and Raman processes calculated by using estimates of the crystal-field parameters and energy level splittings obtained in I.

THEORY

We are interested in the spin-lattice relaxation rate of the lowest resonant doublet of a rare-earth ion in a crystal field. Since no evidence of a phonon bottleneck[3] was observed in our experiments, we shall be concerned with the true spin-lattice rather than the lattice-bath relaxation rate. If the excited states are relatively far removed from the resonant ground doublet, then, following a short intense rf pulse applied to excite the spin

system from its equilibrium Boltzmann population, this two-level system will exhibit a simple exponential recovery with a characteristic time T_1.

There are several spin-lattice relaxation mechanisms which may be operative for rare-earth ions. The theory of rare-earth-ion relaxation has been developed by Orbach[2] and reviewed by Scott and Jeffries.[3] We shall only quote the final results here; the reader is referred to the above papers for more detail.

The simplest relaxation mechanism is a one-phonon direct process in which the spin-relaxation transition is accompanied by the absorption or emission of a single, energy-conserving phonon. The expression for T_1 due to the interaction between a spin and the fluctuating electric crystal field is given by

$$\frac{1}{T_{1D}}=\frac{3}{2\pi\rho v^5\hbar}\left(\frac{\delta}{\hbar}\right)^3|\langle a|\sum_{n,m}V_n{}^m|b\rangle|^2\coth(\delta/2kT), \quad (1)$$

where ρ is the mass density of the sample, v an average phonon velocity, δ the energy of the resonant transition between spin states $|a\rangle$ and $|b\rangle$, and the $V_n{}^m$'s are components of the dynamic crystal-field potential. The orbit-lattice interaction does not connect time conjugate states; consequently, if $|a\rangle$ and $|b\rangle$ are zero-order state functions, Eq. (1) is applicable only to non-Kramers ions, since for a Kramers ion the ground state is at least doubly degenerate and the crystal-field interaction between these states obviously vanishes. A Zeeman field may, however, admix states of the ground doublet with an excited state $|c\rangle$ at an energy Δ_c. Spin-lattice relaxation transitions are now allowed at a reduced rate governed by the magnitude of the Zeeman perturbation and given by

$$\frac{1}{T_{1D}}=\frac{3}{2\pi\rho v^5\hbar}\left(\frac{\delta}{\hbar}\right)^3\left(\frac{2\beta\Lambda}{\Delta^c}\right)^2\{|\langle a|\mathbf{H}\cdot\mathbf{J}|c\rangle\langle c|\sum_{n,m}V_n{}^m|b\rangle + \langle a|\sum_{n,m}V_n{}^m|c\rangle\langle c|\mathbf{H}\cdot\mathbf{J}|b\rangle|\}^2\coth(\delta/2kT), \quad (2)$$

where one must sum over all effective states $|c\rangle$. At temperatures above $\sim 1°$K, δ is usually $\ll 2kT$ and hence the direct process relaxation time, T_{1D}, is characterized by a T^{-1} temperature dependence.

An important relaxation mechanism for many rare-earth ions is the so-called Orbach process. This is essentially a two-step process involving real transitions to and from an excited state $|c\rangle$ accompanied by the creation and annihilation of two high-energy phonons. For this mode of resonance relaxation between the phonons and crystal-field splitting, one requires $\Delta_c<k\theta$ where θ is related to the cutoff frequency for phonons and is approximated by the Debye θ. The relaxation rate for this process is

$$\frac{1}{T_{1O}}=\frac{3}{2\pi\rho v^5\hbar}\left(\frac{\Delta_c}{\hbar}\right)^3\times\frac{|\sum_{\substack{n,n'\\m,m'}}\langle a|V_n{}^m|c\rangle\langle c|V_{n'}{}^{m'}|b\rangle|^2}{|\sum_{n,m}\langle a|V_n{}^m|c\rangle|^2+|\sum_{n',m'}\langle c|V_{n'}{}^{m'}|b\rangle|^2}\times\left(\exp\frac{\Delta_c}{kT}-1\right)^{-1} \quad (3)$$

and is characterized by an exponential temperature dependence at low temperatures, $T\ll(\Delta_c/k)$.

A two-phonon Raman relaxation process is one in which the energy of the spin transition is conserved during an inelastic phonon scattering. If the first-order term in the dynamic crystal-field interaction is used in second-order perturbation theory to calculate the transition probability, one finds that for non-Kramers ions at low temperatures, where $T\ll\theta$,

$$\frac{1}{T_{1R}}=\frac{9\times 6!}{4\rho^2\pi^3v^{10}\Delta_c{}^2}|\sum_{\substack{n,m\\n',m'}}\langle a|V_n{}^m|c\rangle\langle c|V_{n'}{}^{m'}|b\rangle|^2\times\left(\frac{kT}{\hbar}\right)^7. \quad (4)$$

For Kramers ions, again due to the consequences of time-reversal symmetry, there is a partial "Van Vleck cancellation"[6] such that in place of Eq. (4) one has

$$\frac{1}{T_{1R}}=\frac{9!\hbar^2}{\pi^3\rho^2v^{10}\Delta_c{}^2}|\sum_{\substack{n,m\\n',m'}}\langle a|V_n{}^m|c\rangle\langle c|V_{n'}{}^{m'}|b\rangle|^2\left(\frac{kT}{\hbar}\right)^9. \quad (5)$$

Another two-phonon Raman contribution arises from the use of the second-order term, in the variation of the crystal field caused by lattice vibrations, in first-order perturbation theory and is given by

$$\frac{1}{T_{1R}}=\frac{9\times 6!}{4\rho^2\pi^2v^{10}}|\sum_{n,m}\langle a|V_n{}^m|b\rangle|^2\left(\frac{kT}{\hbar}\right)^7, \quad (6)$$

for non-Kramers ions at low temperatures. This term is the same order of magnitude and additive to the result in Eq. (4). As for the direct process, the above interaction is active for Kramers ions only via the eigenstate admixing caused by the Zeeman field. This introduces a multiplicative factor, $(2\Lambda\beta H/\Delta_c)^2$, into Eq. (6). In general, the dominant Raman relaxation process for Kramers ions is given by Eq. (5) with a T_{1R} proportional to T^{-9} compared to the T^{-7} temperature dependence for non-Kramers ions.

When a four-level Γ_8 quartet is lowest or in the case of an S-state ion, the effective spin system may not.

[6] J. H. Van Vleck, Phys. Rev. **57**, 426 (1940).

consist simply of a single isolated doublet. The relaxation modes in such multilevel systems are, in general, more complex. At low temperatures the dominant relaxation process between pairs of levels may occur via multistep direct processes and exhibit a transient time dependence proportional to a linear combination of several exponential terms.[7] Also, at the low-temperature end of the Raman relaxation region, a T_1 mechanism proportional to T^{-5} may be dominant.[8] These cases, however, are somewhat specialized examples of rare-earth-ion relaxation.

To evaluate T_1 from the expressions in Eqs. (1)–(6) the matrix elements of V_n^m are required. For the rare earths, one need only consider n even and ≤ 6. Which components of V_n^m enter into the calculation of the relaxation time in a given crystalline environment can be determined from a normal-mode analysis[2] of the vibrations of the paramagnetic ion and the nearest-neighbor surrounding charges, these being assumed to generate the principal orbit-lattice coupling. The vibrational modes transform as some combination of the irreducible representations of the crystal symmetry group. For CaF_2, which has cubic symmetry, the vibrational motion of the rare-earth ion and the eight nearest-neighbor F^- ions transform according to the following irreducible representations of the O_h group:

$$\Gamma_{\rm vib}(O_h)=A_{1g}+A_{2u}+E_g+E_u+2T_{1u}+2T_{2g}+T_{2u}, \quad (7)$$

where for transitions within a given electronic configuration only the even vibrations need be considered and the translational and rotational terms have been subtracted out. Similarly, for the tetragonal and trigonal site symmetries described previously,[5]

$$\Gamma_{\rm vib}(C_{4v})=5A_1+A_2+2B_1+4B_2+6E, \quad (8)$$

and

$$\Gamma_{\rm vib}(C_{3v})=6A_1+A_2+7E. \quad (9)$$

Comparison of the irreducible representations in (7), (8), and (9) and those according to which the V_n^m's transform, shows that in all cases the vibrational motion is factored into a number of representations such that all V_n^m's are allowed. Thus there is no reduction and simplification in the number of terms which must be considered in applying the above theoretical expressions to the evaluation of T_1 for ions in the different symmetry sites in CaF_2.

Attempts to make explicit calculations of spin-lattice relaxation times are plagued by the necessity of making numerous assumptions and approximations. Given expressions for T_1 as in Eqs. (1)–(6), which are derived using a simplified treatment of the lattice vibrations, estimates must be made of the dynamic crystal-field components. Two approximations which have been used[2,3] in making such estimates are that (1) the orbit-lattice interaction parameters may be approximated by static crystal-field parameters, i.e., $|(x\partial A_n^m/\partial x)| \approx |A_n^m(x_0)|$, where x is a ligand coordinate displacement, and (2) $|A_n^m| \approx |A_n^0|$. Although the latter rule was based upon empirical data, it is not universally satisfied. Other approaches[9] include estimates of the strength of the orbit-lattice parameters obtained from uniaxial stress and ultrasonic spin-phonon absorption experiments. Convincing calculations of the parameters would require knowledge of the nature of the ligand fields, shielding effects, and vibrational motion. In the following we shall consider those combinations of matrix elements of the orbit-lattice interaction which appear in the expressions for the direct, Orbach, and Raman T_1's as parameters to be determined experimentally. These are compared later with rough order-of-magnitude estimates using the above approximations and the crystal-field parameters and energy level splittings found in I.

For a resonance frequency of 9.6 kMc/sec and taking $\rho=3.18$ g/cm^3 and a mean phonon velocity, $v=4\times10^5$ cm/sec for CaF_2, T_1 for the direct process in Eq. (1) becomes

$$T_{1D}=(1.5/TM_D^2)(\sec), \quad (10)$$

where for non-Kramers ions,

$$M_D^2\equiv|\langle a|\sum_{n,m}V_n^m|b\rangle|^2(\text{cm}^{-2}), \quad (11)$$

and for Kramers ions,

$$M_D^2\equiv(2\beta\Lambda/\Delta_c)^2\{|\langle a|\mathbf{H}\cdot\mathbf{J}|c\rangle\langle c|\sum_{n,m}V_n^m|b\rangle + \langle a|\sum_{n,m}V_n^m|c\rangle\langle c|\mathbf{H}\cdot\mathbf{J}|b\rangle|\}^2(\text{cm}^{-2}). \quad (12)$$

For the Orbach process, from Eq. (3),

$$T_{1O}\approx\frac{\exp(\Delta_c/kT)}{4\Delta_c^3(\text{cm}^{-3})M_O^2}(\sec), \quad (13)$$

where

$$M_O^2\equiv\frac{|\sum_{\substack{n,m\\n',m'}}\langle a|V_n^m|c\rangle\langle c|V_{n'}^{m'}|b\rangle|^2}{|\sum_{n,m}\langle a|V_n^m|c\rangle|^2+|\sum_{n'm'}\langle c|V_{n'}^{m'}|b\rangle|^2}(\text{cm}^{-2}). \quad (14)$$

A summation is to be made over all effective excited states $|c\rangle$ in (12) and (14). For Kramers salts, the T^{-9} Raman relaxation mechanism in Eq. (5) is usually dominant and reduces to

$$T_{1R}\approx(10^7\Delta^4/T^9M_R^4)(\sec), \quad (15)$$

where

$$M_R^2\equiv|\sum_{\substack{n,m\\n',m'}}\langle a|V_n^m|c\rangle\langle c|V_{n'}^{m'}|b\rangle|(\text{cm}^{-2}). \quad (16)$$

Scott and Jeffries[3] found from the actual computation of sums of the type $\sum_{n,m}|\langle a|V_n{}^m|c\rangle|^2$ (assuming the individual terms to be incoherent), that for several rare earths these sums were of the same order of magnitude. Thus one might expect that $M_D{}^2$ (allowing for Zeeman admixing), $M_O{}^2$, and $M_R{}^2$ would not differ greatly. Exceptions are always possible, however, and would depend upon the actual state wave functions. Note, also, that if the magnitudes of $|\sum\langle a|V_n{}^m|c\rangle|^2$ and $|\sum\langle c|V_n{}^m|b\rangle|^2$ in Eq. (14) are very different, $M_O{}^2$ will be determined by the smaller of the two.

EXPERIMENTAL

A schematic representation of the pulse saturation X-band spectrometer used in measuring spin-lattice relaxation is shown in Fig. 1. The principles of operation are straightforward. A VA 153 reflex klystron is used as a main rf power source. The klystron environment is a temperature-stabilized oil bath, an important improvement for obtaining good low-noise klystron operation. The VA 153 is frequency stabilized to the sample cavity resonance. Relatively high-power rf pulses are generated by two states of X-band amplification obtained using VA 824B klystron amplifiers driven by the VA 153. The rf pulse width can be varied from 2–500 μsec and peak output power is $\approx$20 W. Klystron amplifiers have the advantage that their output pulse is monochromatic to the extent that the driving element is frequency stabilized, hence there are no high-peak power FM signals reflected from the sample cavity to interfere with detection of the low-level transient relaxation signals. A portion of the VA 153 output is used as a low-level cw monitor of the sample cavity reflection coefficient. The cw power level incident on the sample cavity is normally kept between 0.1 and 10 μW.

The transient signals generated by relaxation of the spin system, following a high-power saturating pulse, are detected in a standard mixer; subsequent amplification is performed at 30 mc, the difference frequency at which the local oscillator is stabilized. The transient relaxation signals are displayed on a Tektronix oscilloscope and photographed. The VA 153 stabilization loop has a variable bandwidth (1–100 kc/sec) to permit rapid correction of the output frequency so that the sample cavity may be transiently tracked. If this is not done and care is not exercised so that the sampling frequency is at the center of cavity resonance, a mixture of time-dependent absorption and dispersion may be detected. The decay times of the real and imaginary components of the reflection coefficient are not necessarily the same, hence considerable confusion in the data may occur if this admixture is not taken into account. An alternative to rapid stabilization is to measure the decay time of the observed transient signal far out in the tail where the dispersion is small.

Diminution of pulse power incident on the mixer is accomplished by synchronously switching a double-diode switch to reflect pulse power back into an absorbing isolator. The time resolution of the spectrometer, which is a few microseconds, is determined by the "turn-off" time of the klystron pulse amplifiers and by the recovery time of the preamplifier "front end" from saturation.

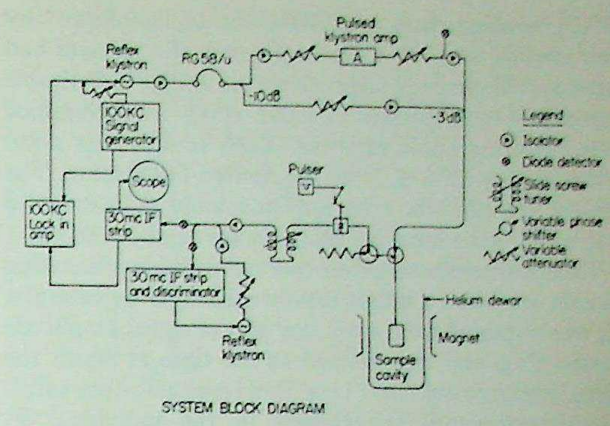

FIG. 1. Schematic diagram of pulse saturation X-band spectrometer.

The sample cavity resonates in the TE011 circular electric mode and has a loaded $Q\approx$8000–10 000. The sample under study is mounted axially in the resonant chamber on a sapphire tube. At low temperatures the sapphire provides excellent thermal coupling to the cavity which, in turn, is in thermal contact with the helium bath via helium exchange gas. The cavity mass acts as the thermal reservoir to which the spin system relaxes. The cavity temperature is carefully monitored by a set of 3 thermometers; two 47-Ω carbon resistors and a platinum resistance thermometer. The carbon resistors were individually calibrated between 1.5 and 20°K; the platinum resistance thermometer was calibrated from 4.2–300°K. These three thermometers were used together with a gold-cobalt differential thermocouple connected between one of the carbon resistors and the sample mount to verify that the sample temperature did indeed track the cavity temperature in the range 2–50°K. The maximum temperature differential was found to be less than 0.1°K in this temperature range. This was important, since all relaxation measurements at temperatures above 4.2°K were made by simply allowing the cavity structure to warm toward 77°K. The total time available for measurements between 4.2 and 50°K is typically 3.5 h.

Most of the CaF_2 crystals used in these experiments were grown in this laboratory by the Czochralski method[10a] or by a modified Stockbarger[10b] technique. The melts were contained in molybdenum crucibles and the growth ambient consisted of dry argon gas [dew point <-100°F]. Other samples were purchased from Optovac, Inc. The crystals were annealed by sealing them in evacuated quartz ampoules [10^{-6} mm Hg at

20°C], heating them to 1200°C for 12 h, followed by slow cooling at ~20°C/h. In general, the samples had rare-earth dopings of the order of 0.1 wt.%; undesirable impurities were present $\lesssim$0.001 wt.% as determined from spectrographic analysis. Each sample was x-ray oriented to within ±2° of the desired orientation. The typical sample size was approximately 0.1×0.1×0.3 cm, which gave a cavity filling factor of about 0.001.

Except where noted, the observed transient relaxation signals exhibited a single exponential time dependence. T_1 was obtained from a semilog plot of signal amplitude versus time and was defined as the time at which the signal had recovered to $(1-e^{-1})$ of its equilibrium value. The experimental uncertainty in the individual T_1 determinations is typically ~10%. The electron paramagnetic resonance (EPR) spectrum was examined as a function of cw power level to insure that the sampling signal intensity was always at least 20 dB below the power level at which steady-state saturation could be observed. For a few of the samples (Ce^{3+} and Gd^{3+}) the incident power had to be reduced to a few tenths of a microwatt. The saturating pulse width τ_p was always adjusted such that $\tau_p \lesssim T_1$.

RESULTS

Cerium

Spin-lattice relaxation of Ce^{3+} in tetragonal sites in CaF_2 was investigated in the temperature range 2–15°K for five samples having different Ce concentrations ranging from 0.08 to 1.6 wt.% cerium. In all samples the tetragonal site resonances were the most intense. Additional lines were usually present in the resonance spectrum, particularly at the higher Ce concentrations (see Fig. 2 of I); however, they were generally too weak for relaxation measurements. T_1 measurements were made with the magnetic field H applied in a (100) crystallographic plane.

Figure 2 shows the over-all temperature dependence of T_1 for several different Ce^{3+} concentrations. The transient recovery from saturation of the signal from the 1.6% sample displayed a single exponential time dependence with a characteristic time which was approximately temperature-independent at low temperatures. The recovery of the other samples, however, could not be fitted by a single exponential term at low temperatures but rather by a sum of two or three exponential terms. An initial rapid recovery was usually observed which was more or less temperature-independent but concentration-dependent. This component had a characteristic time varying from ≈100 μsec for the 0.34% sample to ≈300 μsec for the 0.08 and 0.18% samples. When saturation pulses of several hundred microseconds duration were applied, this component was diminished. Thus it appears to be associated with the establishment of internal equilibrium within the spin system[11] and not

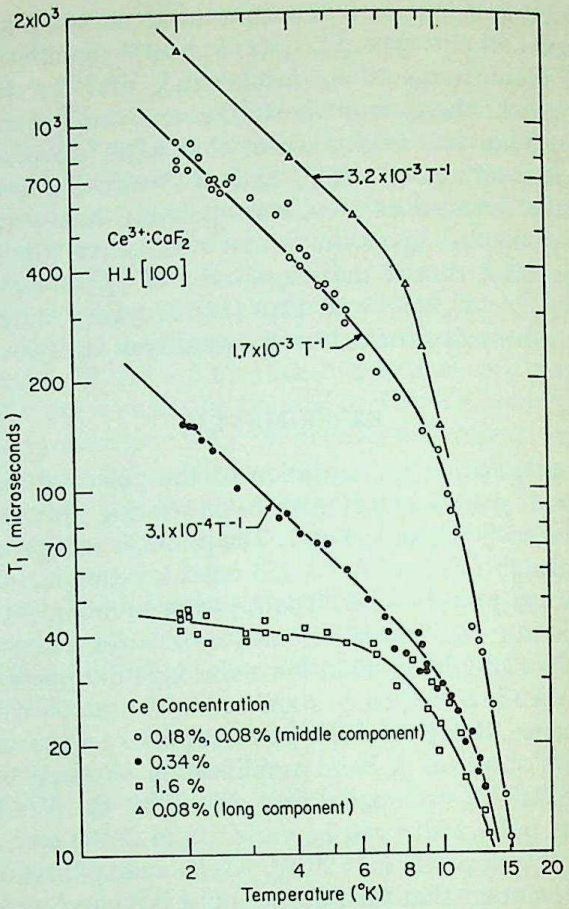

FIG. 2. Temperature dependence of relaxation time T_1 of Ce^{3+} in tetragonal sites in CaF_2 for several different Ce concentrations.

spin-lattice relaxation. Following it was a temperature-dependent recovery composed of one or two exponential terms. The dominant temperature-dependent component of the recovery is concentration-dependent and is plotted as T_1 in Fig. 2. A final rather weak temperature-dependent component of the recovery is also plotted in Fig. 2 for the 0.08% sample. Except for the most concentrated 1.6% sample, the relaxation in the low-temperature region is characterized by a T^{-1} temperature dependence and a concentration-dependent magnitude.

At higher temperatures, $T>10$°K, the data for the different samples tend to converge to a value independent of the cerium concentration. The asymptotic T_1 temperature dependence can be fitted to a T^{-9} law for Raman relaxation of a Kramers ion using $T_{1R}\approx 4\times 10^5\ T^{-9}$ sec. The data can also be fitted to an exponential law with $\Delta\sim 150$ cm^{-1}; however, the fit is poorer.

For several of the rare-earth ions studied it is difficult to establish an unambiguous temperature dependence at high temperatures since the magnitude of T_1, after subtracting out the T^{-1} dependence at low temperatures is not known accurately over a sufficiently broad range of temperature.

If the asymptotic T_1 temperature dependence is fitted to be a T^{-9} law for Raman relaxation, we find from Eq. (15) that $M_R^2\approx 5\Delta^2$. The first excited state for Ce^{3+}

in tetragonal sites should be of form $|\pm\frac{1}{2}\rangle$. Sums of the type $\sum|\langle a|V_n^m|c\rangle|^2$ connecting this state to the ground state have values $\approx 1.5\times10^4$ cm^{-2} for $A_2^m\langle r^2\rangle\sim200$ cm^{-1} and $A_4^m\langle r^4\rangle\sim400$ cm^{-1}. (More correct wave functions, including admixtures of states from $^2F_{7/2}$, would introduce terms involving V_6^m; however, they are not expected to change the order of magnitude of the above result.) An M_R^2 of this magnitude, however, implies a small Δ which is inconsistent with the dominance of Raman relaxation. If we consider Orbach relaxation via an excited state at ~150 cm^{-1}, we find from the data and Eq. (13), $M_O^2\sim10^4$ cm^{-2}. Although the fit to an exponential temperature dependence is poorer, the magnitude agreement is better. A comparable Raman relaxation rate for $\Delta\sim150$ cm^{-1} requires orbit-lattice matrix elements $M_R^2\sim10^5$ cm^{-1}. Although there is a large uncertainty in our estimates of the V_n^m's, the above values of M_O^2 and M_R^2 are not unreasonable. Also an excited-state separation of a few hundred cm^{-1} for Ce^{3+} is possible if the tetragonal fields are as large as they appear to be for other rare earths in CaF_2.[5] Thus the above estimates are inconclusive in establishing whether the high-temperature relaxation is Raman or Orbach. The former, however, requires the larger orbit-lattice interaction.

The angular variation of T_1 with magnetic field direction in a (100) plane is shown in Fig. 3. The measurements were made using a 0.34% Ce sample at 2°K. The same ratio of T_1's for the $g_{\parallel}$ and $g_{\perp}$ resonances, i.e., for the magnetic field H applied along [100] and [010], was observed from the 0.18% sample, while for the 1.6% sample the two T_1's were equal. Since the $g_{\parallel}$ resonance is weaker than the $g_{\perp}$ resonance, the relaxation could not be measured in the former orientation for the 0.08% sample.

If the first excited tetragonal state is $|\pm\frac{1}{2}\rangle$, direct relaxation should be highly anisotropic since there is no Zeeman admixing for $\theta=0$. The over-all shape of the curve in Fig. 3, however, does not correspond exactly to that expected for an excited state of either $(\pm\frac{1}{2})$ or $(\pm\frac{5}{2}, \mp\frac{3}{2})$ and may be related to the concentration-dependent effects. The dip in T_1 near $\theta=80°$ occurs in the vicinity of the crossover of the resonances from Ce^{3+} in sites of tetragonal and trigonal symmetries. This suggests the possibility of cross-relaxation effects, although such effects are not observed when cubic and tetragonal Yb^{3+} resonances are overlapped, as we report later. Within experimental error, the relaxation at this orientation exhibited a simple exponential recovery.

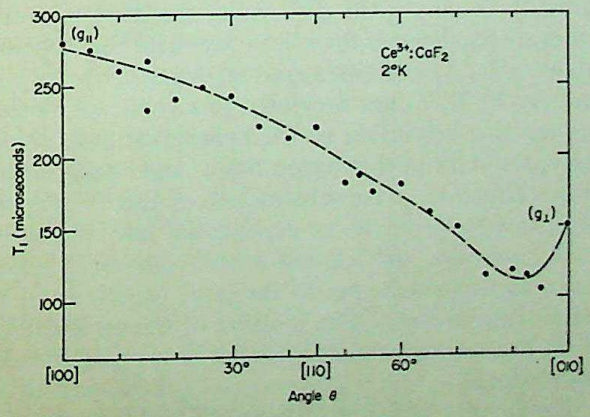

FIG. 3. Angular variation of T_1 for Ce^{3+} in tetragonal sites in CaF_2. The magnetic field is applied at an angle θ with respect to a [100] axis in a (100) plane.

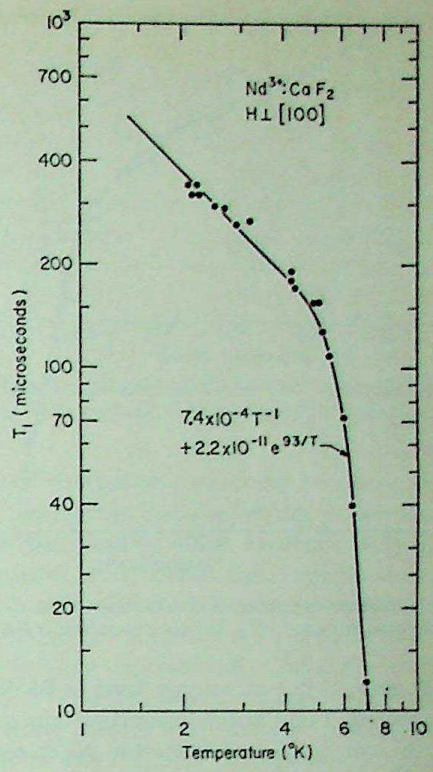

FIG. 4. Temperature dependence of relaxation time T_1 of Nd^{3+} in tetragonal sites in CaF_2. Nd concentration is 0.28%.

Neodymium

The temperature dependence of T_1 for Nd^{3+} in tetragonal sites is shown in Fig. 4, where the $g_{\perp}$ resonance for $H\perp[100]$ has been measured. Several weak broad ($\sim$40–100 G) lines whose origin and nature were not established were present in the resonance spectrum. At 2°K the relaxation time of the $g_{\parallel}$ resonance is about twice as long as that of the $g_{\perp}$ resonance. At low temperatures T_1 exhibits a T^{-1} dependence. At the higher temperatures, $T>4$°K, a relaxation mechanism decreasing more rapidly than T^{-9} with increasing temperature begins to dominate. It can be fitted to an exponential temperature dependence given by $T_1=2.2\times10^{-11}\exp(93/T)$ sec. This suggests relaxation via an excited state or states effectively at ≈65 cm^{-1} above the ground state. The optical fluorescence data in I indicates a first excited state at ≈90 cm^{-1}. Within experimental error the two results are probably compatible. A tetragonal crystal-field component $A_2\langle r^2\rangle$ of a few hundred cm^{-1} would greatly perturb the two cubic-field Γ_8 quartets at

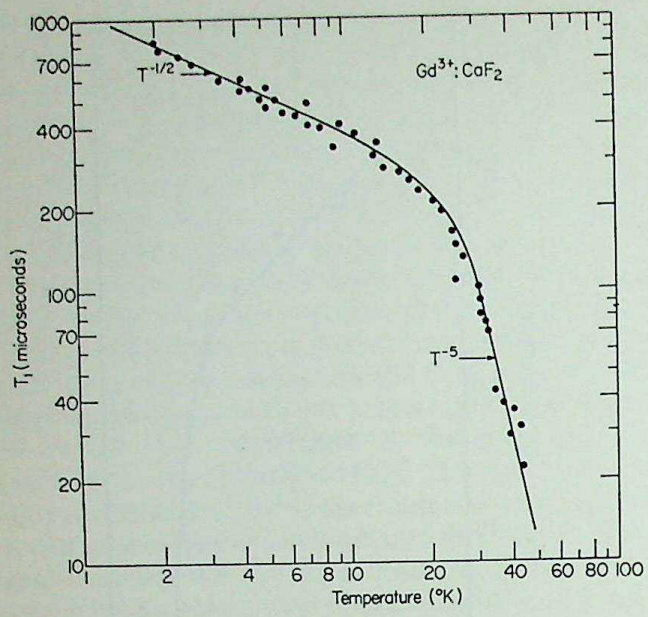

FIG. 5. Temperature dependence of relaxation time T_1 of Gd^{3+} in tetragonal sites in CaF_2. Gd concentration is 0.03%.

0 and 180 cm^{-1}, hence an energy level at 65–90 cm^{-1} is not unexpected. For Orbach relaxation via an excited state $\Delta=65$ cm^{-1}, we find from the Nd^{3+} results and Eq. (13), $M_0^2\approx 4\times 10^4$ cm^{-2}.

Gadolinium

The relaxation of Gd^{3+} ions in tetragonal sites was investigated. At liquid-helium temperatures the relaxation times of all transitions observable at X-band frequencies were essentially equal. Extensive measurements from 2 to 45°K were made of the temperature dependence of T_1 for the $\frac{1}{2}\leftrightarrow-\frac{1}{2}$ transition with $H\|[100]$ and are shown in Fig. 5. The over-all temperature dependence of the T_1 data can be fitted by $T_1=1.1\times10^{-3}$ $T^{-1/2}+4\times10^3$ T^{-5} sec. The transient recoveries were essentially single exponentials. Gadolinium ions were also present in sites of trigonal symmetry in the sample used; however, the relaxation was not examined.

Since an S state is unperturbed by a crystal field in first order, the crystal-field splittings and relaxation rates are usually very small. This is indeed observed for Gd:CaF_2, although the relaxation times below $\sim$10°K are unexpectedly short, again, as in the case of other rare-earth ions in CaF_2, less than 1 msec. This rapid T_1 and its $T^{-1/2}$ temperature dependence suggests that the low-temperature relaxation rate is not associated with the normal direct process and orbit-lattice interactions. The relaxation times at higher temperatures are longer than those for other non-S-state ions. The T^{-5} dependence may arise from two-phonon relaxation processes involving excited states within the $S_{7/2}$ multiplet[8] or relaxation of time conjugate states associated with a lattice defect site.[12] Since the measurements were made in a range where $T\lesssim 0.1\theta$ and θ_D for CaF_2 is $\approx$480°K, a $T_1\propto T^{-5}$ region is not expected at these temperatures for normal Raman relaxation processes.

Orbach and Blume[8] have shown that for a multilevel spin system at low temperatures, Raman relaxation via excited states within the multiplet will be proportional to T^{-5} and can be more important than T^{-7} and T^{-9} processes involving higher excited states. In general, when the excited-state energy is very small compared to the energy of the most important phonons for relaxation, the denominator of the second-order Raman process is $\approx(\hbar\omega_p)^2$ rather than Δ^2 as in Eq. (4). Thus one has in place of Eq. (4),

$$\frac{1}{T_{1R}}=\frac{9}{4\pi^3\rho^2v^{10}}\frac{4!}{\hbar^2}\left(\frac{kT}{\hbar}\right)^5 M_R{}^4. \tag{17}$$

$M_R{}^4$ is again given by Eq. (16), but now $|c\rangle$ is a state within the ground multiplet.

The energy levels for Gd^{3+} in a tetragonal field in CaF_2 and for a resonance frequency of 9.6 kMc/sec for the $\frac{1}{2}\leftrightarrow-\frac{1}{2}$ transition can be derived from the parameters given by Vinokurov *et al.* (see I). They form a multilevel system in which the Orbach-Blume mechanism may be operative. If the effective dynamic crystal-field interactions have the same relative importance as the static crystal-field parameters in the spin Hamiltonian, then the $b_2{}^m$ terms should dominate and Raman relaxation would proceed principally via the $|\pm\frac{3}{2}\rangle$ states. Comparison of Eq. (17) with the experimental T_1's for Gd:CaF_2 yields $M_R{}^2\approx 1.4\times10^3$ cm^{-2}. This value while smaller than for Kramers ions, is, however, several orders of magnitude larger than that predicted using the static crystal-field parameters.

Terbium

Trivalent terbium is the only non-Kramers ion studied. A plot of T_1 versus T for an $H\perp[111]$ sample orientation is shown in Fig. 6. The relaxation times of each of the four Tb^{159} hyperfine components were essentially equal. In the T^{-1} region the Tb^{3+} relaxation times are much faster than those found for the other ions. Above 4°K, T_1 exhibits a gradual departure from a T^{-1} law. By 10°K, T_1 has decreased to a value approaching the limiting resolution of the apparatus; and, accordingly, the data in this region has a larger experimental error. The data, after substraction of the T^{-1} dependence, can be fitted to an exponential law with $\Delta\sim20$ cm^{-1}; however, one cannot attach too much significance to this result due to the large experimental uncertainties involved. The location of the excited levels of $^7F_6$ in a tetragonal field have not been reported to our knowledge.

The angular variation of T_1 at 2°K and for a magnetic field applied in a (111) plane is shown in Fig. 7. Broad anisotropic resonances previously reported by Forrester

[12] J. G. Castle, D. W. Feldman, P. G. Klemens, and R. A. Weeks, Phys. Rev. **130**, 577 (1963).

and Hempstead[13] in Tb:CaF_2 were also observed in the sample used. The presence of Tb^{3+} in sites of trigonal symmetry, which are not observable at X-band frequencies, was not established.

Terbium, being a non-Kramers ion, is expected to relax faster at low temperatures than Kramers ions, which is indeed observed. The M_D^2 determined from Eq. (10) is $\approx 3\times10^4$ cm^{-2}. The resonant doublet, however, is composed principally of $J_z=\pm6$ states which are not connected by the orbit-lattice interaction. Relaxation may be allowed, for example, by admixing of $J_z=\pm2$ states. This small admixture would reduce the value of M_D^2 relative to that for other ions.

The above measurements were made in a sample containing 0.5% Tb. The relaxation from a 1.4% Tb sample was also measured between 2–4°K, where T_1 ~5 μsec, independent of temperature.

Dysprosium

Two different samples of dysprosium-doped CaF_2 ($\sim$0.1–0.2% Dy) each containing Dy^{3+} in sites of cubic tetragonal, and trigonal symmetries were examined. No measurable relaxation recoveries were observed from any of the resonances for temperatures 2–4°K. Based upon the limiting resolution of the apparatus, this result suggests that the relaxation times of the Dy^{3+} resonances in the samples studied are $\gtrsim3$ μsec.

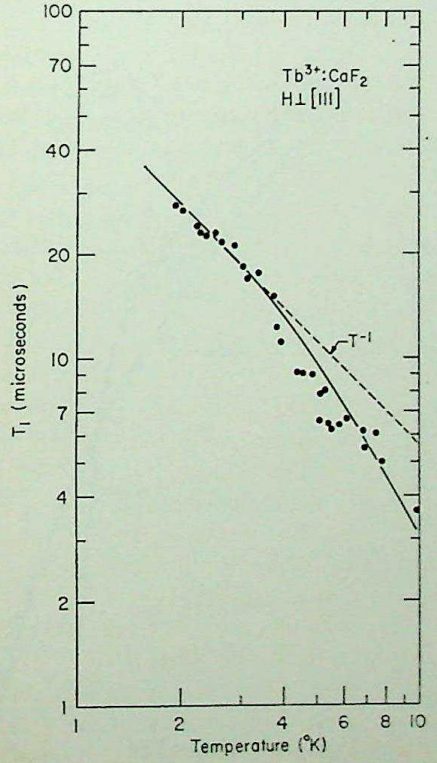

FIG. 6. Temperature dependence of relaxation time T_1 of Tb^{3+} in tetragonal sites in CaF_2. Tb concentration is 0.5%.

[13] P. A. Forrester and C. F. Hempstead, Phys. Rev. **126**, 923 (1962).

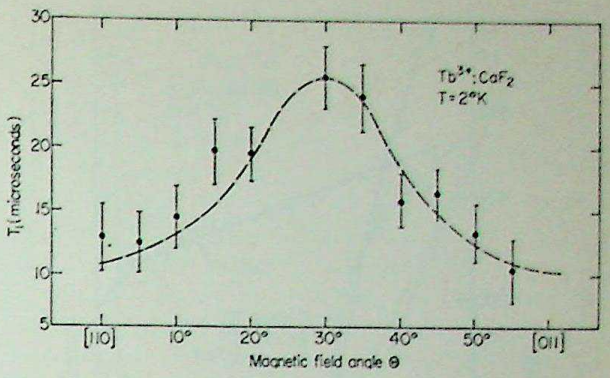

FIG. 7. Angular variation of T_1 for Tb^{3+} in tetragonal sites in CaF_2. The magnetic field is applied in a (111) plane.

The Dy^{3+} relaxation rates may be faster than those of other rare earths because of the presence of a relatively low-lying excited state. In a cubic field the relaxation of pairs of levels within the ground-state Γ_8 quartet may occur via an Orbach process involving the Γ_7 excited state at $\Delta\approx8.5$ cm^{-1}. A T_1 of 1 μsec, which would account for the unresolved relaxation transient, is predicted at 4°K for such a process if $M_O^2\approx10^4$ cm^{-2}. Corresponding times for Raman relaxation require $M_R^2\approx4\times10^5$ cm^{-2}. If this process was dominant, however, lifetime broadening of the Γ_8 resonances should be evident by $T\approx10$°K, which is not observed. At $T=2$°K, the major relaxation mechanism may be two-step relaxation processes involving states within the Γ_8 quartet, as discussed elsewhere.[7]

The relaxation rate of the cubic field Γ_7 excited state would also be fast if the strength of the orbit-lattice interaction is as strong as required above, the temperature dependence of an Orbach process changing from a constant at low temperatures, $T\ll\Delta$, to a T^{-1} law at high temperatures. At temperatures $\lesssim15$°K, lifetime broadening of the Γ_7 resonance linewidth is observed. From the estimated magnitude and slow temperature variation of the Γ_7 Orbach process, the broadening probably arises from the dominance of Raman relaxation at these temperatures. From Eq. (15), a T_{1R} of 10^{-3} sec, and hence line broadening, is predicted at $T=15$°K if $M_R^2\approx4\times10^4$ cm^{-2}.

Erbium

The temperature dependence of the relaxation of Er^{3+} in sites of tetragonal (I) and trigonal (II) symmetry are recorded in Fig. 8. The position and relative intensities of the resonances in the low-field portion of the spectrum of the 1.0% Er^{3+} sample used are shown in Fig. 5 of I for $H\|[110]$. Due to the strong overlap and relative intensities of the tetragonal (I) and cubic resonances, only a common transient decay was observed when the magnetic field was set in the region $\approx$950–1070 Oe, the amplitude varying as the magnetic field was adjusted to line center. The transient signal, which appears to be dominated by the tetragonal (I)

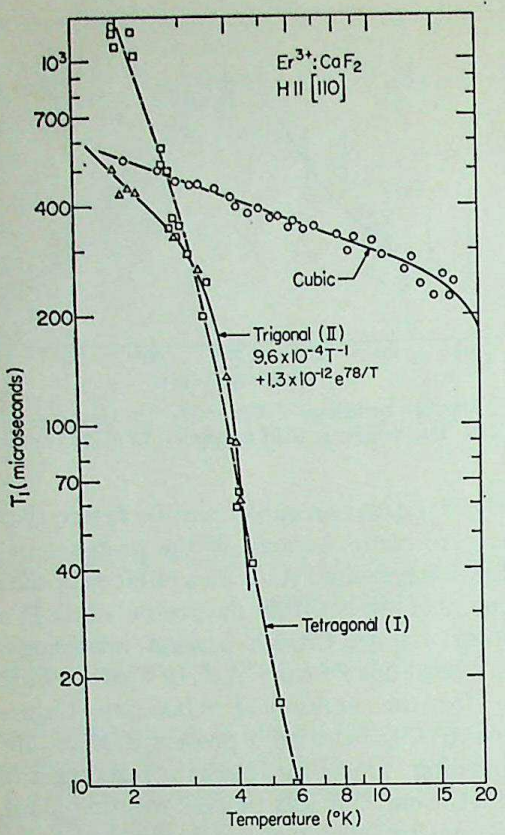

FIG. 8. Temperature dependence of relaxation time T_1 of Er^{3+} in tetragonal and trigonal sites in CaF_2. Er concentration is 1.0%. Cubic T_1 is from another sample (see text).

resonance, is characterized by a temperature-independent component ($\sim$100 μsec) and a strongly temperature-dependent component which is plotted as T_1 (tetragonal) in Fig. 8. The variation of T_1 with angle of the magnetic field in a (100) plane is at most 20%; there is no measurable variation of the initial decay component. At low temperatures, $\sim$2°K, a third decay component is evident having a characteristic time $\sim$2–5 msec. The amplitude of this signal, however, is so small that the experimental uncertainty in the decay time is very large.

The high-temperature portion of the tetragonal (I) T_1 versus T curve can be fitted by an exponential law given by $T_1\approx10^{-7}\exp(27/T)$ sec. At low temperatures the data deviates from the exponential curve; however, the data is not sufficient to establish a reliable temperature dependence for the competing relaxation process, which might be expected to have a $1/T$ law. An effective tetragonal excited state at $\sim$27°K from relaxation data is not unreasonable in view of the crystal-field splittings in I and the excited state at $\sim$35°K reported by Baker *et al.* from measurements of the temperature dependence of the intensity of the tetragonal excited-state resonance. Assuming an Orbach process is operative, the Mo^2 derived from the above result and Eq. (13) is $\approx10^3$ cm^{-2}. Line broadening of the cubic-tetragonal (I) group of resonances occurs for $T\gtrsim30$°K; by 40°K the individual lines are no longer resolvable.

The trigonal (II) relaxation was measured with the magnetic field applied in a [110] direction to separate the g_1 trigonal resonance as far as possible from the other spectral lines. The results in Fig. 8 show a T^{-1} region and a rapidly decreasing T_1 at higher temperatures which can be fitted to an exponential law. The over-all temperature dependence can be fitted by

$$T_1=9.6\times10^{-4}T^{-1}+1.3\times10^{-12}\exp(78/T)\text{ sec.}$$

Comparing this result with an Orbach process in Eq. (13) yields $Mo^2\approx10^6$ cm^{-2}. The linewidth of the trigonal (II) resonance increased rapidly for temperatures $\lesssim$25°K and became unobservable above 30°K indicative of lifetime broadening and $T_1\lesssim10^{-9}$ sec.

T_1 measurements were made earlier[14] in another Er:CaF_2 crystal which was less heavily doped than the above sample and in which Er^{3+} ions in cubic sites were approximately twice as numerous as those in tetragonal (I) sites. T_1 data for ions in trigonal (II) sites, which were also present, agreed with the data presented above. Data taken in the vicinity of the isotropic cubic resonance is shown in Fig. 8. For this sample the tetragonal (I) resonances could not be sufficiently well isolated to yield unambiguous results. Between 2 and 15°K, T_1 for the cubic resonance exhibited very little temperature dependence and can be fitted by $T_1\propto T^{-n}$, where $n\approx\frac{1}{3}$. This rather unexpected result was reproduced under varied experimental conditions and appears to be

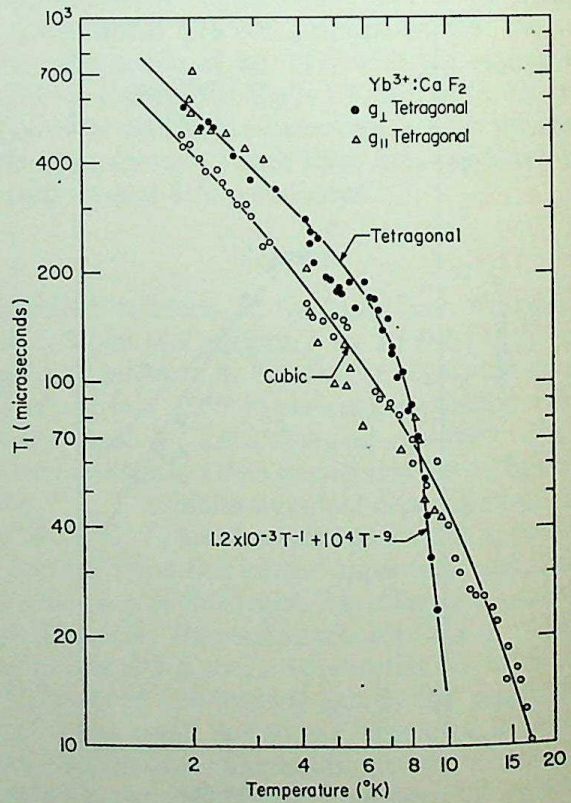

FIG. 9. Temperature dependence of relaxation time T_1 of Yb^{3+} in cubic and tetragonal sites in CaF_2. Yb concentration is 0.17%.

intrinsic to the sample. Since there should be cubic-field excited states within 100 cm^{-1} of the ground state, such long T_1's for $T>10°K$ are very unusual.

The relaxation of Er^{3+} in tetragonal sites in CdF_2 has been measured by Zverev *et al.*[15] at *X*-band frequencies, and the results are reviewed here for comparison. The Er concentration was ~0.1%. For $T<4.2°K$, T_1 varied inversely with temperature, where $T_1 \approx 5.5\times10^{-4}\ T^{-1}$ sec. Between 4.2 and 9°K, T_1 exhibited a rapid decrease from a T^{-1} law; lifetime broadening was observed above 16°K. Combining the last two data the authors conclude that T_1 cannot be described by a power law of the type $T_1 \propto T^{-n}$. Instead, the relaxation appears to be influenced by the presence of a nearby excited state.

Ytterbium

In Fig. 9 are shown the temperature dependences of T_1 for Yb^{3+} in cubic and tetragonal crystal fields. The resonance spectrum for this 0.17% Yb sample was very clean, consisting only of approximately equally intense cubic and tetragonal resonances. Both the $g_{\parallel}$ and $g_{\perp}$ tetragonal resonances exhibited nearly equal relaxation rates inversely proportional to T at the lowest temperatures. With increasing temperature the $g_{\perp}$ resonance T_1 decreases rapidly reaching a T^{-9} dependence by 10°K. Within experimental error, the high-temperature data may also be fitted by an exponential law with an exponent $\approx 125/T$. T_1 for the $g_{\parallel}$ resonance shows an anomalous behavior for $3.5<T<10°K$, which we do not understand at present.

The cubic resonance T_1 gradually departs from a T^{-1} law with increasing temperature. The data for $5°<T<20°K$, after subtraction of the T^{-1} dependence, can, within experimental accuracy, be fitted to either a $T^{-(3.5\pm0.5)}$ or $\exp(38/T)$ temperature dependence. The cubic Yb^{3+} resonance is unique among the rare-earth ions studied in that it is observable up to ≈115°K; the tetragonal Yb^{3+} resonances are not observable at 77°K. The temperature dependence of the cubic resonance linewidth was examined between 50–105°K. At low temperatures the peak-to-peak linewidth of the derivative of absorption is temperature-independent with a value of ≈25 G. The additional temperature-dependent linewidth $\Delta H(T)$ above 50°K is plotted in Fig. 10. If this width is attributed to lifetime broadening, its temperature dependence should reflect that of T_1 in this temperature range. The data in Fig. 10 shows a slow departure from a T^{-9} law. The temperature dependence for Raman relaxation of a Kramers ion, assuming a simple Debye lattice and characteristic temperature θ_D, is $T^9 \int_0^{\theta_D/T} [x^8 e^x dx/(e^x-1)^2]$, the T^9 limit applying only when $T<0.1\theta_D$. Since $\theta_D \approx 480°K$[16] for

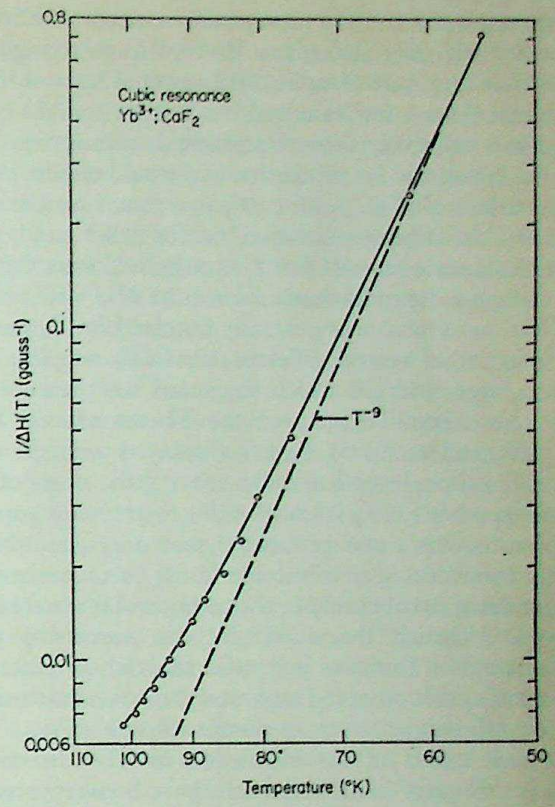

FIG. 10. Additional temperature dependence component $\Delta H(T)$ of the linewidth of Yb^{3+} in cubic sites in CaF_2.

CaF_2, the deviation from T^{-9} is expected; however, it should be more pronounced. The above integral expression with $\theta_D \sim 680°K$ provides a better fit to the data. There are several possible sources of this discrepancy; the validity of considering $\Delta H(T)$ as a simple additive contribution, the inadequacy of a simple Debye vibrational frequency spectrum for CaF_2 and the above integral expression,[17] and the possible enhanced Raman relaxation rate due to the mass excess of the rare-earth impurity.[18]

From estimates in I (see Fig. 5), the first excited state for Yb^{3+} in a cubic field in CaF_2 may be ≈600–700 cm^{-1} above the ground state. Thus T_{1R}, which is proportional to Δ^4, would be much longer than for other rare earths. This would account for the cubic-field resonance being observable at such comparatively high temperatures. Since a Δ of this size is probably greater than the highest energy branch in the phonon spectrum of CaF_2, a simple Orbach process would not be allowed. Comparing the observed broadening with Raman relaxation, a value of $M_R^2 \approx 10^5$ cm^{-2} is obtained, which is necessarily uncertain due to the lack of good agreement in fitting the temperature dependence. Extrapolating this relaxation mechanism for $T=10-20°K$ yields T_1 values several orders of magnitude longer than observed. If the higher

temperature T_1's for the tetragonal resonances are fitted to a T^{-9} law, Eq. (15) gives $M_R^2 \approx 30\Delta^2$. A tetragonal field is not expected to split the Γ_8 excited state of $^2F_{7/2}$ by more than a few hundred cm^{-1}. This would again suggest a relatively large first excited-state separation for the tetragonal ion relaxation and would require very large values of M_R^2, $\lesssim 10^6$ cm^{-2}, to account for the observed T_1's. Orbach relaxation, on the other hand, via an excited state at ≈ 100 cm^{-1}, as suggested from the T_1 temperature dependence, would require $M_O^2 \approx 10^5$ cm^{-2}.

Good agreement was generally obtained for T_1 measurements from several different Yb:CaF_2 samples. No effects were observed which suggested the presence of any cross-relaxation between the Yb resonances. For $H \| [100]$, all transient signals displayed a single exponential time dependence. By varying the angle of H with respect to [100], it was possible to gradually superimpose the cubic and tetragonal resonances, at which point a short decay attributable to the cubic line and a longer decay attributable to the tetragonal line were observed. Although the uncertainty in measuring the decay times in this case is greater than when either of the transients is observed separately, the measurements are of sufficient accuracy to permit identification.

Measurements of the relaxation of Yb^{3+} in cubic sites in CdF_2 at X-band frequencies have been reported.[19] At liquid helium temperatures the relaxation of a 0.1% Yb sample is described by $T_1 = (6.7 \pm 0.7) \times 10^{-4}\, T^{-1}$ sec. No resonances were observed at liquid hydrogen temperatures. More recent investigations[20] at 3.2 and 9.1 kMc/sec in samples containing 0.01, 0.05, and 0.1% Yb demonstrate that resonances are observable at 57°K. The low-temperature relaxation times are concentration-dependent as we have noted for Ce^{3+} and show an unexpected and unexplained dependence upon resonance frequency, $T_1 \propto \delta$. From g shift, intensity and optical measurements, an excited state at $\simeq$50–70 cm^{-1} and an over-all $^2F_{7/2}$ splitting of ≈ 116 cm^{-1} is inferred. These values are much smaller than those estimated for Yb:CaF_2.

DISCUSSION

The magnitude and temperature dependence of T_1's for Kramers ions at higher temperatures, where T_1 deviates from a T^{-1} law, have been compared with theoretical expressions for two-phonon relaxation processes in Eqs. (13)–(16). A single excited state was considered with an energy Δ obtained either from the exponential temperature dependence for Orbach relaxation or from estimates in I. The experimental results indicate that for Orbach and Raman relaxation, the effective sums of orbit-lattice matrix elements M_O^2 and M_R^2 are typically in the order of 10^4–10^5 cm^{-2}. These values are comparible with those obtained using the static crystal-field parameters in I and the approximations discussed earlier relating them to the strength of the orbit-lattice coupling. The accuracy of the determination of M^2 is dependent upon estimates made in arriving at Eqs. (10), (13), and (15). For example, since the average phonon velocity v enters to the fifth and tenth powers, respectively, in the Orbach and Raman T_1's, a small error in the choice of an effective v can greatly affect the magnitude of the predicted T_1. Because of this and the uncertainty in Δ, only the magnitude of M^2 is significant.

TABLE I. Comparison of low-temperature relaxation times and impurity concentration for several rare earths in tetragonal sites in CaF_2. The rare-earth concentration is the total concentration, not the number in the particular axial site.

Ion	Concentration (%)	T_1T (sec °K)
Ce^{3+}	0.08	3.2×10^{-3}
Yb^{3+}	0.17	1.2×10^{-3}
Ce^{3+}	0.18	1.7×10^{-3}
Nd^{3+}	0.28	7.4×10^{-4}
Ce^{3+}	0.34	3.1×10^{-4}
Tb^{3+}	0.5	5.5×10^{-5}
Ce^{3+}	1.6	4×10^{-5} (2–4°K)

The above value of M^2 should be useful in estimating the magnitude and dominant relaxation process for other rare earths in CaF_2 when the excited-state energies are known. It should be noted, however, that some apparent discrepancies exist. M_O^2 for the tetragonal (I) and trigonal (II) Er resonances are very different and are beyond the extremes of the above range of M^2 values. The large M_O^2 for the trigonal resonance may arise from the strong crystalline fields associated with the O^{2-} substituted at a nearest-neighbor F^- site; however, Er was the only ion in a trigonal site whose relaxation was studied, and hence this conjecture could not be verified. The relaxation of Yb in cubic sites at temperatures 10–20°K is inconsistent with the magnitude and temperature dependence of normal two-phonon processes, if our picture of the energy levels is correct. Enhanced relaxation rates having different temperature dependences arising from the presence of lattice defects and paramagnetic empurities have been discussed[12]; however, for a Kramers salt a T^{-5} dependence is expected which is beyond the estimated error of the temperature dependence for Yb^{3+}. The relaxation may be associated with the same mechanism responsible for the low-temperature relaxation discussed below.

When Eqs. (10)–(16) are compared with measured T_1's for Kramers ions, it is immediately apparent that the present theory is insufficient to account for the fast relaxation times observed in the low-temperature region, $T \lesssim 4$°K, where T_1 is usually proportional to T^{-1}. As an estimate, consider a Zeeman admixing coefficient $(2\beta\Lambda/\Delta)\langle a|\mathbf{H}\cdot\mathbf{J}|c\rangle \approx 10^{-2}$ and sums $\sum|\langle a|V_n{}^m|c\rangle|^2 \approx 10^5$ cm^{-2}. Substitution into Eqs. (10) and (12) yields

$T_{1D} \approx 0.1$ sec for Kramers ions at 2°K compared to observed values of ≈ 1 msec. If one assumes that the effective summations of dynamic crystal field matrix elements in direct, Orbach, and Raman relaxation have approximately equal values, i.e., M_D^2 (non-Kramers) $\sim M_O^2 \sim M_R^2$, then the predicted relative magnitudes of the one- and two-phonon relaxation processes are incompatible with experiment. In the case of Ce^{3+}, the value of T_1 at low temperatures is concentration-dependent. A tabulation of T_1T for other rare earths in CaF_2 is given in Table I and shows a correlation with rare-earth concentration. (Concentration-dependent T_1's have been observed in other crystals containing rare-earth and iron transition group elements.[21]) Finally, equally fast low-temperature T_1's have been reported for trivalent rare earths in CdF_2[15,19] and for divalent rare earths in CaF_2.[22,23] Therefore, although the relaxation times at low temperatures generally exhibit a T^{-1} dependence characteristic of one-phonon processes, their magnitude and concentration dependence indicate that they are not derived from normal direct relaxation arising from orbit-lattice interactions.

An adequate explanation of the fast low-temperature relaxation rates of trivalent rare-earth ions in CaF_2 must account for the T^{-1} dependent of T_1, the concentration-dependent effects, the variation of T_1 with angle of the applied magnetic field, and the absence of any apparent phonon bottleneck. Also, the fast relaxation has been observed for Kramers ions in lattice sites having cubic, tetragonal, and trigonal crystal-field symmetries.

The possibility exists that some divalent rare-earth ions may be introduced into CaF_2 along with the trivalent ions. If they are non-Kramers ions, they should relax quickly and could possibly influence the relaxation of trivalent Kramers ions via cross-relaxation. This explanation is insufficient for several ions studied, however, since the accompanying non-Kramers ions have nonmagnetic ground states, an example is Yb^{2+} which is isoelectric with diamagnetic $Lu^{3+}(^1S_0)$. Divalent ion resonances were not readily apparent in the resonance spectrum. (Cross-relaxation could occur to excited state doublets, however, depending upon Δ, they would be depopulated at low temperatures which would reduce their effectiveness.) Finally, the orbit-lattice coupling for divalent ions would probably be less than for equivalent trivalent ions due to the smaller effective nuclear charge.

Enhanced relaxation rates may be caused by local vibration amplitude variations associated with the introduction of the paramagnetic impurity. In our case, this lattice defect has both a mass and charge difference and, for axial sites, has related substitutional or interstitial impurity defects. The relaxation would exhibit a T^{-1} temperature dependence and be a function of impurity concentration in certain ranges. Although some studies have been made of relaxation associated with defect sites,[12,24,25] detailed calculations applied to specific examples are needed to establish the importance of this mechanism at low temperatures where one-phonon processes are dominant.

Multiexponential transient recoveries were frequently observed at low temperatures in the T^{-1} region. We shall consider two cases where such behavior may be expected, cross-relaxation within an inhomogeneous spin system and cross-relaxation to another faster relaxing spin system. If a short, intense rf pulse applied to an inhomogeneously broadened spin system excites only a portion of it, then a decay time associated with the attainment of internal equilibrium within the total spin system may exist in addition to the time required to attain equilibrium with the lattice. The linewidths of rare earths in CaF_2 are usually larger than calculated dipolar widths and are believed to be inhomogeneously broadened. Several ions show transient recoveries from rf saturation having an initial fast temperature-independent but concentration-dependent exponential component. As the rf excitation pulse is lengthened, the initial recovery component became less prominent relative to the longer temperature-dependent component ascribed to spin-lattice relaxation. For Ce^{3+} at low temperatures, the initial component has characteristic times of ≈ 300, 130, and 40 μsec, respectively, for Ce concentrations of 0.18, 0.3, and 1.6%. This dependence is qualitatively as expected from the cross-relaxation theory of Bloembergen *et al.*[26]

If some paramagnetic species having a faster spin-lattice relaxation time is present, rare-earth ions in CaF_2 may lose their energy more rapidly via cross-relaxation to the other system than by relaxing directly to the lattice. Depending upon the nature of the fast relaxing system and the relative spin-lattice and cross-relaxation rates, an observed T_1 having a variety of concentration and temperature dependences can be obtained.[27–30] Rannestad and Wagner[30] have discussed some simple rate equations and time-dependent solutions pertinent to the expected behavior of such coupled spin systems. The reader is referred to their article,

pp. 1958–1960, for an example of the type and range of arguments that can be presented to explain T_1 results. Their general extension to rare-earth-ion relaxation in CaF_2 is straightforward and will not be repeated here.

Although qualitative agreement might be obtained for our CaF_2 results using the above approach and appropriate models, it would be less than convincing without some knowledge regarding the origin and nature of the fast-relaxing species. The presence of other paramagnetic impurities, particularly fast-relaxing iron transition-group elements, could be important for relaxation. These impurities, however are definitely present in concentrations of less than one part in 10^4 by weight as determined by spectrochemical analysis. No distinct resonances characteristic of such ions were generally observed, although they may have been broad and hence escaped detection. Pairs, possibly exchange coupled, or clusters of rare-earth ions may be present and may account for some of the additional spectral lines observed in CaF_2 at higher rare-earth concentrations. Relaxation transitions between relatively near non-time-conjugate states associated with such clusters could be very rapid. Finally, fast relaxing centers may also be associated with the zero-field resonances noted[5,31] in Ce:CaF_2.

If the temperature-dependent relaxation times at low temperatures are characteristic of some fast-relaxing species, then the cross-relaxation time must be very fast and not the over-all relaxation bottleneck. The results for Ce^{3+}, however, show that for 1.6% Ce, an approximately temperature-independent time of ≈ 45 μsec is observed at 2–4°K suggestive of a cross-relaxation bottleneck. When the spin-lattice and cross-relaxation rates have comparable magnitudes, the relaxation of the coupled spin systems is expected to exhibit a multiexponential decay in which the relative importance of each term and its characteristic decay rate will be a function of the lattice temperature.

Until more is known about the numerous, concentration dependent lines in the EPR and optical spectra of rare-earth ions in CaF_2 and the importance of other paramagnetic impurities, the above explanation of the fast low-temperature relaxation times via cross-relaxation to other spin systems is only speculative, albeit a reasonable possibility at present.

CONCLUSIONS

We have surveyed the temperature dependence of spin-lattice relaxation of several trivalent rare earths in CaF_2. The relaxation times of Kramers ions at low temperatures, which usually vary as T^{-1} and exhibit a concentration dependence, are about two orders of magnitude faster than predicted for orbit-lattice coupling. The nature of the operative relaxation mechanism which explains these results remains to be established. More intensive, detailed study of selected examples would be helpful. The magnitude and temperature dependence of two-phonon relaxation processes are generally in reasonable order-of-magnitude agreement with predictions of relaxation times using estimated crystal-field interactions. As expected, ions in lattice sites having different crystal-field symmetry and strength have different relaxation properties. The comparison between theory and experiment must of necessity be only approximate since current spin-lattice relaxation theory involves a simplified treatment of the lattice vibrational properties, but more important for rare earths in CaF_2, detailed knowledge of the energy levels, ion wave functions, and strength of the dynamic crystal field are lacking. The interpretation of the present results will benefit greatly as spectroscopic data on the crystal-field energy levels becomes available, at which time many uncertainties in the present comparison of theory and experiment will be removed.

ACKNOWLEDGMENTS

Arnold Fine's assistance in all phases of gathering the experimental data was very valuable, and the able efforts of Frederick G. Garabedian in the preparation and growth of the single crystals are greatly appreciated. Also we acknowledge valuable discussions with C. D. Jeffries, D. E. Kaplan, Z. Kiss, W. Low, P. Nutter, and L. Ultrasonic Absorption at Microwave Frequencies and at Low Temperatures* in MgO and Al_2O_3

I. S. CICCARELLO† AND K. DRANSFELD
Department of Physics, University of California, Berkeley, California
(Received 22 January 1964)

Measurements are presented of the ultrasonic absorption in MgO and Al_2O_3 for transverse and longitudinal waves in the low-temperature region. In contrast to some theoretical expectations, the absorption of longitudinal waves is not negligible but even stronger than for transverse waves. In the theoretical discussion it is shown that this strong longitudinal absorption probably is caused by three-phonon processes.

INTRODUCTION

THE interaction of ultrasonic waves with thermal phonons in dielectric crystals shows a very different behavior at high and at low temperatures. At high temperatures when the ultrasonic period $2\pi/\omega$ is much larger than the lifetime θ of most termal phonons the measured absorption can be well described by a mechanism first proposed by Akhiezer.[1-3] However, in the low-temperature region, defined by ($\omega\theta \gg 1$) experimental difficulties have prevented until recently a careful study of the hypersonic absorption, although a theory for the absorption process was already published by Landau and Rumer[4] more than 25 years ago. They pointed out that through the anharmonic cubic terms in the elastic lattice energy *transverse* acoustic waves or phonons can interact with thermal phonons in processes involving three phonons. For the absorption of *longitudinal* acoustic waves these three-phonon processes were considered unimportant on the basis of energy and momentum conservation as will be discussed later. A finite absorption was thought to result only when according to Pomeranchuk[5] fourth-order terms in the elastic energy were taken into account (so-called four-phonon processes), or when according to Herring[6,7] the elastic anisotropy of the crystal was properly considered (Herring mechanism).

In the present paper we present measurements of the absorption of transverse and longitudinal ultrasonic waves in magnesium oxide and sapphire in the low-temperature region ($\omega\theta > 1$). The interesting result is that not only the transverse but also the longitudinal absorption follows the pattern expected for a three-phonon process. The magnitude of the longitudinal absorption as well as its dependence on frequency and temperature are not compatible with a four-phonon process or the Herring mechanism mentioned above.

By these results we are led to believe that longitudinal ultrasonic waves also are able to interact strongly with thermal phonons in three-phonon processes. We have already shown in a classical calculation,[8] referred to here as paper I, that these "collinear" processes lead to a strong ultrasonic absorption, and the same result will be derived here by a quantum-mechanical argument.[8a]

This strong absorption of longitudinal waves in three-phonon processes also solves the problem of a diverging thermal conductivity which was discussed in the literature[9] under the assumption that longitudinal waves cannot be absorbed in three-phonon processes. Since they are, however, absorbed, their contribution to the heat conductivity remains finite, and no problem arises in this context.

EXPERIMENTS AND RESULTS

We have measured the attenuation of sound waves in magnesium oxide and ruby at the two frequencies of 500 and 3000 Mc/sec between 4.2 and about 100°K. The samples were single crystals of rectangular shape, 4×4×25 mm, with the 4×4-mm faces polished optically flat and parallel within a few seconds. The rod axes were oriented within one degree, parallel to the [100] axis of MgO and to the c axis of ruby. The MgO samples were colorless and quoted[10] as pure while the ruby rods contained up to 0.01% of Cr_2O_3. Care was taken to avoid resonant absorption of sound by the paramagnetic ions.[11]

For the generation and detection of the ultrasonic waves we used two methods: At 500 and at 3000 Mc/sec two x-cut quartz disks with a fundamental resonance frequency of 10 Mc/sec were bonded to the sample and excited in a high harmonic. For some experiments at 3000 Mc/sec both sides of our samples were plated with films of permalloy, 90% Ni, 10% Fe,

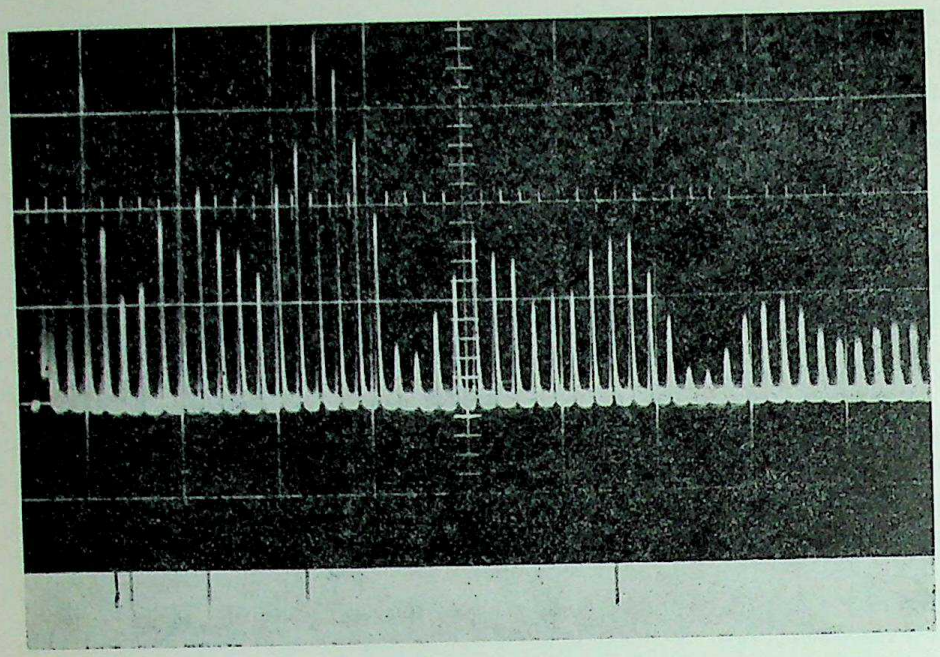

FIG. 1. Pulse pattern of 3-kMc/sec longitudinal waves in ruby at 4.2°K. The waves are excited and detected ferromagnetic resonance in thin films of permalloy (90% Ni-10% Fe) on each side of the ruby rod.

about 5000 Å thick for the generation and detection of sound by ferromagnetic resonance.[12] By using standard pulse methods sometimes more than 100 acoustic echo pulses were received.

Figure 1 shows a typical pulse pattern, the time between two consecutive pulses corresponds to the time for one round trip in the rod. The decay of the pulse pattern is hardly ever exponential. The reasons for the irregular amplitudes of the various pulses are several: the end faces may not be sufficiently parallel, the rod may not be elastically homogeneous, etc., all of these effects being temperature-independent. The absorption at a temperature T was determined from the decrease of an echo pulse relative to its magnitude at 4.2°K.

With ferromagnetic excitation we occasionally observed a drastic change in the relative amplitude of the peaks on varying the intensity or direction of the magnetic field. We believe that this is caused by interference effects which arise from mechanical or magnetic nonuniformities of the films, or the excitation of Walker modes. By improving our deposition methods and by using films of small cross section these phenomena could be avoided.

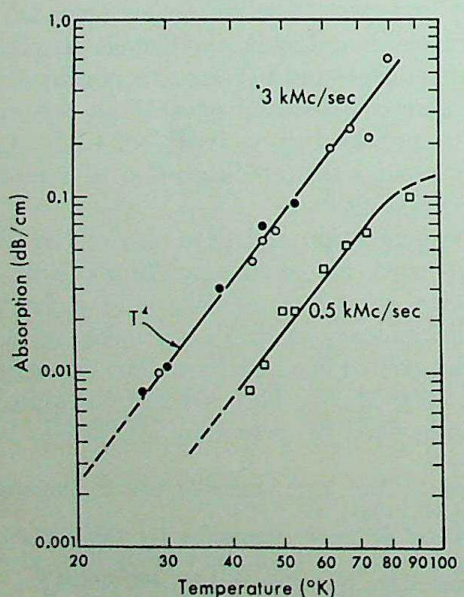

FIG. 2. Attenuation of longitudinal waves in ruby as a function of temperature.

Through our long ruby rod only longitudinal waves could be transmitted well. The propagation of transverse waves proved to be considerably more difficult. In general, only one transverse echo could be seen. This difficulty probably arise from the acoustical birefringence, so that along the c axis the acoustic wave vector and Poynting vector are not parallel, and the acoustic energy does not travel parallel to the rod axis. The absorption of longitudinal waves versus temperature is plotted in Fig. 2. Several runs at 3000 Mc/sec, with different ruby rods carrying different magnetic films gave the reproducible results of Fig. 2: The absorption increases with temperature approximately as T^4. For the investigation of the frequency dependence, measurements at 500 Mc/sec, which agree with the results of Fitzgerald and Truell,[13] are also included in Fig. 2; the frequency dependence is close to linear.

The absorption of longitudinal and transverse waves in MgO is plotted versus temperature in Figs. 3(a) and 3(b). The data for longitudinal waves, although not as accurate as the transverse data, clearly indicate that the frequency dependence is again close to linear, and the temperature dependence not far from T^4.

With longitudinal waves the acoustic power level was kept low enough to avoid the nonlinear effects reported by Shiren,[14] and for transverse waves such a power-dependent absorption could not be observed even

at considerably higher power levels than those used by Shiren. To our knowledge, for shear waves in the kMc/sec range, these are the first data on the temperature dependence in a material other than quartz.

Both for transverse and longitudinal waves in MgO a noticeable additional absorption occurred around 15°K, when the absorption was measured in zero magnetic field. Figure 3(a) also shows this extra absorption at 3000 Mc/sec, which could be removed by applying a magnetic field of the order of 1000 Oe. A similar phenomenon was observed by Bolef *et al.*[15] at lower frequency and lower temperature in a more drastic way in heavily doped MgO. More experiments are planned for a detailed investigation of this anomaly which is probably caused by paramagnetic impurities.

DISCUSSION

Our experiment results may be summarized by saying that at low temperatures for both transverse and longitudinal waves the absorption increases linearly with frequency and with the fourth power of the temperature. In perfect crystals the absorption is due only to scattering by other thermal phonons, and is possible only if the potential energy developed in powers of the strain contains cubic or higher order terms. Landau and Rumer[4] considering the cubic terms only calculated the absorption of transverse waves for low temperatures, when $\omega\theta \gg 1$. They found

$$\alpha_t \approx \tfrac{1}{4}(2Q+6R)^2(1-V_t/V_L)^2 \frac{k^4}{\rho^3 V_L{}^{10}\hbar^3}\omega T^4, \qquad (1)$$

where Q and R are constants of the order of 5×10^{12} for ruby and MgO, k is the Boltzmann constant, and ρ the density. The agreement with our results on MgO is satisfactory. The absorption is of the right order of magnitude and varies with temperature as T^4, as expected. Expression (1) was derived only for *transverse* waves, with the observation that the conservation of energy and momentum rules out three-phonon processes for the absorption of *longitudinal* waves.

Pomeranchuk[5] invoked the much smaller fourth-order terms of the elastic energy to account for the scattering of longitudinal phonons. The absorption according to his calculations should be proportional to ω^2T^7, which is in strong disagreement with our experiments, both for ruby and MgO. In addition, Orbach[16] has already estimated, for the case of quartz, that Pomeranchuk's calculations give an absorption which is several orders of magnitude smaller than the observations. We may therefore safely conclude that a four-phonon process is not responsible for the observed absorption of longitudinal waves.

On the other hand, the Herring mechanism[6] also cannot account for our results. The absorption due to this process was calculated by Simons[7] for cubic crystals. For a longitudinal wave propagating parallel to the (100) axis he found

$$\alpha = A\omega^2T^3. \qquad (2)$$

The quadratic frequency dependence is not compatible with our observations. The factor A depends on the crystal and can be estimated for MgO, with the result that for our frequencies and temperatures the absorption according to (2) is about three orders of magnitude smaller than the measured values. For ruby the absorption by the Herring mechanism has not been calculated numerically, but should be proportional to ω^3T^2, which agrees even less with our experiments.

In view of the fact that our data with longitudinal waves behave as if they are caused by three-phonon processes, and in view of the difficulty in explaining them in any other way, we proceed to re-examine in more detail the absorption of longitudinal waves by three-phonon processes. We have already shown classically in paper I that in isotropic solids the absorption of longitudinal waves by three-phonon processes is of similar magnitude as the absorption of transverse waves. But the fact that a longitudinal acoustic wave can interact in three-phonon processes with almost as many thermal phonons as a transverse wave may be shown in a simpler argument, which will be presented here:

The conservation of energy and momentum requires

$$\omega_1+\omega_2=\omega_3, \qquad (3)$$

$$\mathbf{k}_1+\mathbf{k}_2=\mathbf{k}_3, \qquad (4)$$

where the index "1" refers to the ultrasonic phonon. Since in our temperature range $|k_1| \ll |k_{2,3}|$ the momentum conservation (4) can be expressed in terms of the angle α between the acoustic wave vector $\mathbf{k}_1$ and $\mathbf{k}_2$ (see Fig. 4).

$$\cos\alpha = (|k_3| - |k_2|)/|k_1|,$$

or, because of

$$|k_1| = \omega_1/v_1, \quad |k_{2,3}| = \omega_{2,3}/v_{\rm ph},$$

we can write for (4)

$$\cos\alpha = \frac{v_1}{v_{\rm ph}}\left(\frac{\omega_3-\omega_2}{\omega_1}\right), \qquad (5)$$

where α is the angle under which a thermal phonon with velocity $v_{\rm ph}$ can interact with an acoustic wave of velocity v_1 with conservation of energy and momentum.

But if energy is not exactly conserved because of the uncertainty in the energy arising from a finite relaxation time of θ of the thermal phonons, we find

$$\omega_3-\omega_2-\omega_1 \leqq 1/\theta$$

and $\cos\alpha$, according to (5), can assume any value between the two limits

$$\cos\alpha_{\max} = \frac{v_1}{v_{\rm ph}}\left(1-\frac{1}{\omega_1\theta}\right); \quad \cos\alpha_{\min} = \frac{v_1}{v_{\rm ph}}\left(1+\frac{1}{\omega_1\theta}\right). \qquad (6)$$

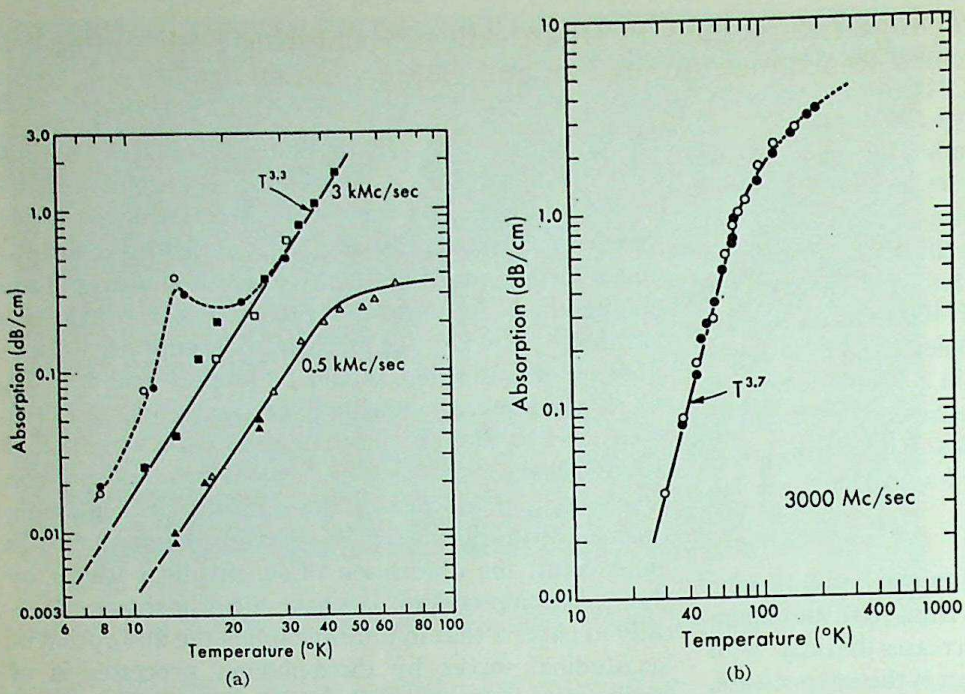

FIG. 3. Attenuation of ultrasonic waves in MgO as a function of temperature. The dashed curve gives the attenuation in zero external magnetic field; the continuous ones in a field of about 4500 Oe. (a) Longitudinal waves, (b) transverse waves.

Clearly, because of the uncertainty in energy, a thermal phonon can interact with an acoustic phonon between the angles $\alpha_{\max}$ and $\alpha_{\min}$ without violating the conservation of energy and momentum. For *transverse* waves, for example, we find from (6)

$$\alpha_{\max}-\alpha_{\min}=\Delta\alpha=\frac{2\cos\alpha}{\sin\alpha}\frac{1}{\omega_1\theta}. \tag{7}$$

This corresponds to a relative solid angle

$$\frac{\Delta N}{N}=\frac{2\pi\sin\alpha}{4\pi}\frac{2\cos\alpha}{\sin\alpha}\frac{1}{\omega_1\theta}=(\cos\alpha)\frac{1}{\omega_1\theta}. \tag{8}$$

For *longitudinal* waves ($v_1=v_{\rm ph}$, $\alpha_{\min}=0$, collinear case) we find from (6)

$$\tfrac{1}{2}(\Delta\alpha)^2=1/\omega_1\theta,$$

and for the relative solid angle

$$\frac{\Delta N}{N}=\frac{\pi\alpha_{\max}^2}{4\pi}=\frac{1}{2}\left(\frac{1}{\omega_1\theta}\right). \tag{9}$$

On comparing (8) and (9) it is evident that the two solid angles are almost identical for any relaxation time θ, as long as $\omega_1\theta>1$, and the dispersion is neglected.

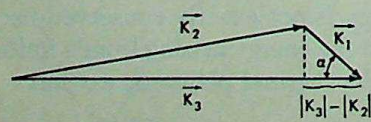

FIG. 4. Momentum conservation for the absorption of an acoustic phonon with wave vector $\mathbf{k}_1$ by a thermal phonon of wave vector $\mathbf{k}_2$. $\mathbf{k}_3$ is the wave vector of the final phonon in this three-phonon process.

One should therefore expect that a quantum-mechanical treatment of the ultrasonic absorption due to three-phonon processes should give very similar results for transverse and longitudinal waves. We made such a calculation, following the method of Landau and Rumer,[4] and we found for the absorption of longitudinal waves due to the interaction with collinear thermal phonons:

$$\alpha_L\approx\tfrac{1}{2}[6P]^2\frac{k^4}{\rho^3V_L{}^{10}\hbar^3}\omega T^4. \tag{10}$$

P is a constant of the same order of magnitude as Q and R in Eq. (1), and therefore the absorption of longitudinal waves is not too different from the absorption of transverse waves.

In his argument we have neglected the dispersion. As shown in paper I this neglect is justified as long as

$$\omega\theta\leqq 2\pi(T_D/T)^2,$$

with T_D being the Debye temperature of the crystal. For our samples below 60°K $2\pi(T_D/T)^2\approx 1500$ and for our frequencies $\omega\theta$ is indeed smaller than 1500, if the mean free path of the thermal phonons remains below 1 mm. Thus, the dispersion can be neglected.

It seems to be a characteristic feature of cubic crystals that the absorption of longitudinal waves is noticeably stronger than for transverse waves. This is evident from our measurements on MgO and was also found in Ge by Dobbs *et al.*[17]

Role of *s-d* Exchange Interactions in Dilute Alloys Exhibiting Both Low-Temperature Resistance Anomalies and Superconductivity*

E. W. COLLINGS, F. T. HEDGCOCK, AND Y. MUTO†
The Franklin Institute Laboratories for Research and Development, Philadelphia, Pennsylvania
(Received 28 October 1963; revised manuscript received 28 February 1964)

Measurements of the magnetic susceptibility of some dilute Zn-Mn alloys are reported in the temperature range where this alloy system is known to exhibit low-temperature resistance anomalies. All of the alloys studied obey a Curie law with the most concentrated alloy (0.43-at.% Mn) exhibiting deviations in the neighborhood of 6°K. The Curie constant indicates that manganese when dissolved in zinc has a spin value of $\frac{5}{2}$ which is temperature-independent between 5 and 273°K. Calculations of the exchange integral J from the magnetic properties of dilute Zn-Mn alloys have been made from the Néel temperature, the magnetoresistivity as a function of field strength and the suppression of the superconducting critical temperature based on theoretical equations which assume a scalar *s-d* interaction between the paramagnetic ions and conduction electrons. All of the derived values of J lie in the range of $(1.4\pm0.2)\times10^{-12}$ erg which would lead one to conclude that the magnetic interaction giving rise to these various effects is of the same nature. A graphical method for separating the resistance minimum from the total resistivity, in the presence of a resistance maximum produced by magnetic ordering in the Zn-Mn system, is presented.

INTRODUCTION

THEORY predicts[1,2] and some experiments substantiate[3–5] the fact that the critical temperature is suppressed in superconducting elements containing small concentrations of transition metal impurities. Recently, measurements have been reported[5] on the suppression of the superconducting transition temperature in a system that had been earlier reported to exhibit a low-temperature resistive anomaly.[6] It has been shown theoretically[7,8] and illustrated experimentally for the[9] Zn-Mn system that a sharply energy-dependent conduction-electron relaxation time in the neighborhood of the Fermi energy will produce a resistance rising with decreasing temperature to some finite value at absolute zero. It is observed in the Zn-Mn system that the resistive characteristic flattens off following the so-called resistance minimum.[9] A preliminary report[10] of the magnetic properties of this system show a weak antiferromagnetism and it is believed that although the resistivity is decreased by the decrease of spin scattering on ordering, the decrease is not sufficiently great to result in a resistive maximum. It is the purpose of the present paper to present more complete data on the spin value of manganese in zinc and to calculate and compare values for the *s-d* exchange integral J found from electron transport and magnetic properties. A comparison of the value of J found for the Zn-Mn system will be made with the values of J found for a system possessing only a resistive anomaly (Cu-Mn) and only a superconducting transition (Al-Mn).

MAGNETIC SUSCEPTIBILITY RESULTS AND DISCUSSION

Table I lists the results of the magnetic susceptibility measurements.

Nominal manganese concentration was obtained from a plot of "relative residual resistance" versus "weighed-out" concentration. Figure 1(a) shows the collected data from several series of alloys. In Fig. 1(b) the room temperature susceptibilities of some rolled strips and the cast pieces used in the present temperature runs are plotted against concentration obtained from relative residual resistances of rolled strips. The susceptibility measurements were regarded as being the most accurate and deviations of the points from the best straight line were attributed to concentration errors. Figure 1(b) was therefore used to obtain the sample concentration used in subsequent calculations.

In the temperature runs, relative susceptibility was measured and converted to susceptibility from the separately-measured room temperature values. Figure 2 shows the alloy susceptibility plotted against reciprocal temperature in the region between room temperature and liquid nitrogen. In Fig. 3 the inverse of the manganese component of susceptibility (ΔX^{-1}) is shown as a function of absolute temperature in the temperature range between liquid nitrogen and liquid helium. An insert shows the behavior of the most concentrated alloy in the vicinity of the Néel point. If one

[a] The effective magneton number for this sample is also determined from the zero susceptibility value as shown in Fig. 2.

considers that $(dX^{-1}/dT)_{T_N}=0$ defines the Néel temperature, a value for T_N of 6±1°K is obtained for sample II. From the linear portions of Figs. 2 and 3, Curie constants were calculated and using concentrations obtained from Fig. 1(b) these were converted into effective magneton numbers. The desired results are shown in Table I from which it can be seen that the spin state of the manganese ion in zinc corresponds to a value of $\frac{3}{2}$ which would give an effective magneton number of 3.9.[11]

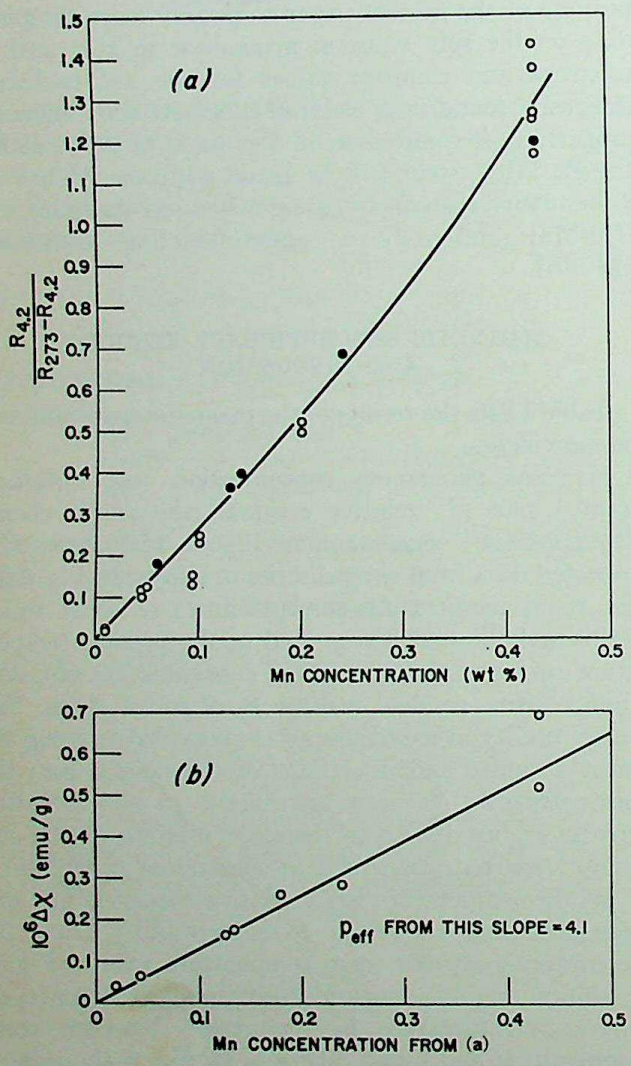

FIG. 1. (a) Resistance ratio as a function of weight percent manganese determined from spectroscopic analysis or quantity of manganese added to the melt. The solid circles represent data from the thesis of W. B. Muir, University of Ottawa. (b) The increase in susceptibility of pure zinc as a function of manganese concentration as determined from the resistance ratio of the alloys measured.

ANALYSIS OF THE MAGNETORESISTIVITY DATA FOR Zn-Mn SYSTEM

In an earlier publication[12] it was shown that the magnetoresistivity of dilute Cu-Fe alloys can be expressed as the sum of a normal magnetoresistive term ρ_n which is temperature-independent and obeys Kohlers' rule and an anomalous term ρ_s which is negative and decreases with decreasing temperature. The anomalous term ρ_s can be theoretically accounted for semiquantitatively for these alloys although the theory itself does not contain an explanation of the resistive minimum.[13,14] The magnetoresistive behavior for an alloy containing 0.11-at.% Mn is shown in Fig. 4 where it can be seen that the magnetoresistance is negative in sign and saturates at a field value of approximately 32 kOe. Shown in the insert of Fig. 4 is the magnetoresistance plotted as a function of H^2 where it can be seen that the magnetoresistance beyond the saturation value is a function of H^2. This we attribute to the normal magnetoresistive component, ρ_n. Using this device we can then separate ρ_n from ρ_{total} and obtain ρ_s as shown in Fig. 4.

Using Kasuya's expression for the term ρ_s and neglecting small terms, we can write:

$$\frac{\rho_{H\infty}}{\rho_{H_0}}=\frac{(b+C)_{H_0}}{(b+\langle j_z^2\rangle_{\text{av}})_{H_0}^2}\Big/\frac{(b+C)_{H\infty}}{(b+\langle j_z^2\rangle_{\text{av}})_{H\infty}^2}, \tag{1}$$

and

$$\rho_{H_0}=\frac{3\pi m^* c}{2h\zeta Ne^2}J^2\frac{(b+\langle j_z^2\rangle_{\text{av}})^2}{b+C}, \tag{2}$$

where

$$C=\langle j_z^2\rangle_{\text{av}}-\langle j_z\rangle_{\text{av}}\frac{2xe^x}{(e^x-1)^2},$$

[11] It should be pointed out that the earlier reported (Ref. 10) spin value of 2 for a concentrated Zn-Mn alloy resulted from a determination of the Curie constant too near the Néel temperature.

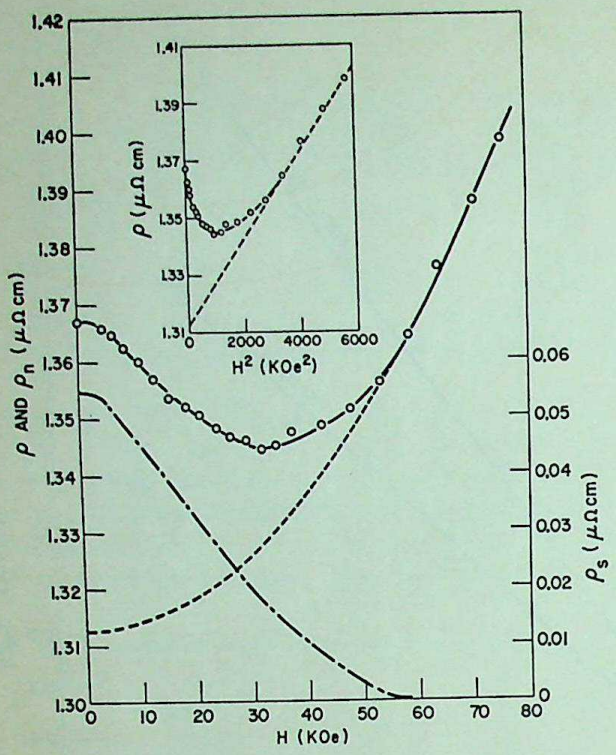

FIG. 4. Resistivity as a function of magnetic field strength for a Zn-Mn alloy containing 0.11 at.% Mn as determined from Fig. 1(a). The inset is the resistivity as a function of H^2 showing the normal magnetoresistivity component ρ_n as a dashed line. This normal component is also shown as a dashed line in the resistivity versus H plot and the dotted line is the difference $(\rho-\rho_n)$ and hence represents ρ_s.

and $b=(A/J)^2$; J is the s-d exchange integral; A is the Coulomb interaction constant; m^*, e is the effective mass and charge of the electron, respectively; ζ is the Fermi energy of the solvent; c is the concentration of paramagnetic ions per unit volume; N is the total number of atoms per unit volume; x is $g\mu_B H/kT$; $\langle j_z\rangle_{\rm av}$ is the average of the Z component of the paramagnetic ion angular moment vector j; $\langle j_z^2\rangle_{\rm av}$ is the average of the square of the Z component of the paramagnetic ion angular momentum. From Fig. 4 the saturation value of the magnetoresistance normalized to the zero-field resistivity value is

$$\rho_{H_{\rm sat}}/\rho_{H_0}\equiv\rho_{H_\infty}/\rho_{H_0}=0.960.$$

Then from Eq. (1) and using the value of $j=s=\frac{3}{2}$ from the susceptibility data a value of b can be found and, hence from Eq. (2), A and J calculated. The values of A and J are found to be 8.7×10^{-12} and 1.4×10^{-12} erg, respectively.

ESTIMATES OF J FROM THE NÉEL TEMPERATURE

Owen *et al.*[15] have given a molecular field derivation of the Curie point in terms of the s-d exchange integral J.[16] By writing the conduction electron and paramagnetic ion magnetization in terms of an s-d exchange interaction constant they find a nonzero magnetization when the temperature is equal to $S(S+1)J^2C/2k\zeta$. If we identify this temperature with the experimentally observed Néel point[17] we may then estimate a value of J. Using the most concentrated alloy which shows a Néel point of 6°K and using the Fermi energy of 1.64×10^{-11} erg for zinc yields a value of J equal to $(1.5\pm0.2)\times10^{-12}$ erg which is in good agreement with the value derived from the magnetoresistivity data.

SUPPRESSION OF THE CRITICAL TEMPERATURE IN DILUTE ALLOYS

The experimental situation at the present time indicates that if a transition metal impurity possesses a localized moment which corresponds closely to the free-ion value, then a suppression of the superconducting critical temperature will result. Baltenperger[1] has considered the influence of an s-d exchange interaction on the superconducting properties of a dilute paramagnetic alloy. The expression derived by him is

$$dT_c/dc=-2.49J^2s(s+1)\nu_0/kN, \qquad (3)$$

where ν_0 is the density of states at the Fermi level and the other symbols have the same meaning as before. The above expression is only valid if there is no spin ordering of the conduction electrons due to a cooperative magnetic interaction of the paramagnetic ions. Whether this condition is satisfied for the Zn-Mn system can be investigated by requiring that the field θ^n seen by the nonsuperconducting electrons is smaller than the thermal energy corresponding to the superconducting transition temperature. Baltensperger has, in fact, shown that

$$d\theta^n/dc=\nu_0H^2s(s+1)/6kN.$$

The inequality to be satisfied is then that

$$\partial\theta^n/\partial c<\partial T_c/dc.$$

Using a value of J found from the previous analysis and assuming ν_0 to be concentration-independent, yields a value of approximately 10°K/at.%. This value is certainly less than the value of 170°K/at.% reported for the Zn-Mn system in studies of the suppression of the critical temperature by Boato *et al.*[3] Having shown that this inequality is satisfied we can then use Eq. (3) derived by Baltensperger to calculate a value of the exchange integral J from the suppression of the critical temperature. This equation yields a value of 1.6×10^{-12} erg, which is in good agreement with the previously derived values.

RESISTANCE ANOMALY AND THE s-d EXCHANGE INTEGRAL

According to Yosida[13] and Kasuya[14] it should be possible to obtain a value for the s-d exchange integral in a dilute alloy exhibiting an antiferromagnetic ordering from the change in resistance above and below the Néel temperature

$$\Delta\rho \equiv \rho_N - \rho_0 = \frac{3\pi msc}{2e^2\hbar\zeta N} J^2. \qquad (4)$$

This graphical method for evaluating $\Delta\rho$ is shown in Fig. 5(a) and in applying this method Yosida has assumed that the resistivity in the absence of a cooperative interaction would be temperature-independent. If the resistivity below the Néel temperature is the resultant of two opposing effects, viz., the resistance minimum mechanism and the cooperative interaction, the true $\Delta\rho$ would be $(\rho_1-\rho_0)$ of Fig. 5(a). (For the Cu-Mn alloy referred to in Yosida's theoretical paper, application of this idea would lead to more than twice his value of $\Delta\rho$ and consequently a 50% increase in the calculated value of J to 3.0×10^{-12} erg resulting in better agreement with the theoretically free manganese ion value of 3.5×10^{-12} erg.) The true situation for this model, however, is not clear when the region over which the cooperative interaction sets in severely overlaps the region in which one would otherwise expect a resistance minimum resulting in the resistivity characteristic of Fig. 5(b). In estimating $\Delta\rho$ for a Zn-Mn alloy it is better to select an alloy sufficiently dilute that the antiferromagnetic transition is more clearly separated from the minimum. As indicated earlier we are proposing that in the Zn-Mn system the influence of the cooperative magnetic interaction exactly compensates the increase in resistance with lowering temperature characteristic of the resistivity minimum alone, resulting in a flattening-off of the resistivity curve below T_N [Fig. 5(b)]. In order to obtain $\Delta\rho$ we produce the resistivity curve as a circular arc having the same radius as the solid curve above T_N resulting in a value of ρ_1 from which $\Delta\rho=\rho_1-\rho_0$ can be obtained. Applying this

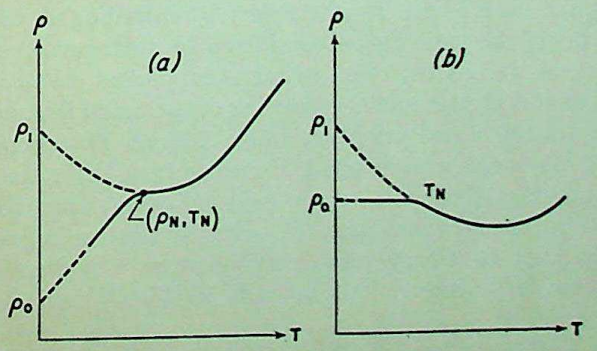

FIG. 5. (a) The resistivity as a function of temperature for a typical high concentration Cu-Mn alloy. (b) The resistivity as a function of temperature for a typical high concentration Zn-Mn alloy. The dashed lines represent the extrapolated curves.

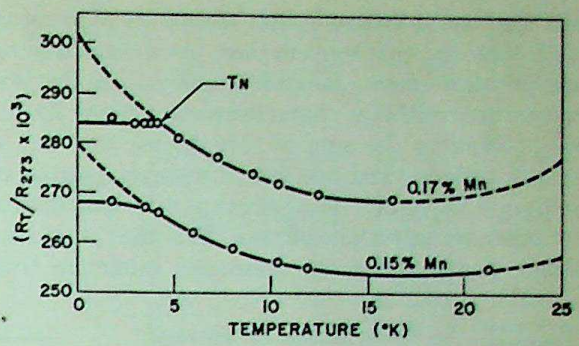

FIG. 6. The resistance ratio as a function of temperature of a 0.15 and 0.17-at.% Zn-Mn alloy. The resistivities of these two alloys is 6.7 and 6.9 $\mu\Omega$-cm, respectively. T_N is the corresponding temperature indicated in Fig. 5.

method to the Zn-Mn alloys of concentration 0.15-at.% Mn and 0.17-at.% Mn (Fig. 6) yields an average value for J of 1.5×10^{-12} erg.

There is good agreement between the value of J so calculated and that calculated from the magnetoresistance and the Néel temperature. This can be taken as evidence that the extrapolation procedure and its implications are valid, particularly since a direct application of the unmodified Yosida method would yield a $\Delta\rho$ of 0 for Zn-Mn alloys.

CONCLUSION

An estimate of J from the decrease in spin scattering on magnetic ordering in the Cu-Mn system has been estimated by Yosida to be 2.1×10^{-12} erg for a manganese ion of spin $\frac{5}{2}$. This value of J is higher but of the same order of magnitude as the value of 1.5×10^{-12} found for the zinc-manganese alloys reported in the present paper. An estimate for J from the suppression of the superconducting critical temperature for the Al-Mn system[3] yields a value of 0.23×10^{-12} erg for an estimated spin value for manganese of $\frac{1}{2}$. The fact that manganese possesses a very small moment, if any, when dissolved in aluminum[15] would indicate that the mechanism responsible for the suppression of T_c in the Al-Mn system is due to a cause other than that responsible for the observed effects in the Zn-Mn system.

Calculations of the exchange integral from the magnetic properties of dilute zinc alloys containing small concentrations of manganese have been made from the Néel temperature, the magnetoresistivity as a function of field strength and the suppression of the superconducting critical temperature. The theoretical equations used for these exchange integral determinations are all based on a conduction electron-paramagnetic ion exchange interaction of the form $2J$ S.s. The analysis of the experimental results based on this interaction all yield the same value for the exchange integral which

[15] E. W. Collings and F. T. Hedgcock, Phys. Rev. 126, 1654 (1962).

could lead one to conclude that the nature of the magnetic interaction that leads to these phenomena is of the same physical origin. Graphical analysis of the low-temperature resistance characteristics of dilute Zn-Mn alloys, assuming the sum of two terms; one due to magnetic ordering and one due to resonance scattering results in a value of J in agreement with that derived from other transport phenomena. This then suggests a method of separating the resistance minimum from total resistivity in the presence of a resistance maximum produced by magnetic ordering.

Covalency in Crystal Field Theory: $KNiF_3$

R. E. WATSON

Bell Telephone Laboratories, Murray Hill, New Jersey

AND

A. J. FREEMAN

National Magnet Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts*

(Received 13 November 1963; revised manuscript received 13 December 1963)

The theory of covalency in crystal field phenomena is examined, using, as example, the Ni-F_6 complex in $KNiF_3$. The Hund-Mulliken-Van Vleck molecular orbital-linear combination of atomic orbitals treatment is followed. The role of the antibonding *and* bonding electrons in the complex is discussed from a multielectron point of view. The exact self-consistent one-electron Hamiltonian is discussed in some detail. Emphasis is placed on elucidating the source and nature of the covalent effects appropriate to the various physical phenomena. We find that it is the covalent mixing of those *bonding* electrons having no antibonding partners which contribute to all experimental observables (including the crystal field splitting 10 Dq, transferred hyperfine interactions, neutron magnetic form factors, and superexchange interactions). This view of covalency differs markedly from the one followed by Sugano and Shulman, in that the covalency of the *antibonding* electrons, which are assigned the sole role in their approach, is totally irrelevant. Quantitative numerical estimates (using approximations to the exact Hamiltonian) are given for the two models of the covalent effects in $KNiF_3$, i.e., "unpaired" bonding and antibonding; they are shown to differ strongly. The relative roles of overlap and covalency are discussed; covalency is found to play an important but by no means dominant role. Numerical agreement between the present inexact cluster theory and experiment is found to be poor. The various sources of this disagreement are reviewed.

I. INTRODUCTION

CRYSTAL field theory[1,2] has had a long and varied history: when treated as a semiempirical theory, with the crystal field splitting 10 Dq considered as an adjustable parameter, it has been highly successful in fitting experimental data; when considered as a fundamental theory for the behavior of transition metal ions in crystalline fields, it has been strikingly unsuccessful in predicting, from first principles, the fundamental parameter 10 Dq. Following the pioneering computations of Van Vleck[3] and Polder,[4] a series of theoretical investigations[5–9] succeeded in pinpointing the basic shortcomings of the theory, and indicated the need for a multielectron many-center molecular approach.

The recent work of Sugano and Shulman[10] (henceforth denoted as S&S III), representing the most detailed computations undertaken to date, attempted to obtain a quantitative basis for the theory by including all the terms in the ionic model considered by their predecessors, as well as the effect of metal ion-ligand covalent mixing. A cluster model consisting of the metal ion and its nearest ligand neighbors in an external Madelung-like potential was invoked. Considering $KNiF_3$, they obtained a theoretical cubic field splitting parameter (10 Dq) for Ni which gave the first quantitative indication that covalency plays an important role in the crystal field interactions of salts as highly ionic as

$KNiF_3$. In addition, they considered the role of the computed covalent mixing in the F^{19} transferred hyperfine interactions.[11]

While the role of covalency in superexchange,[12] and transferred hyperfine effects[11,13–17] have been particular objects of study, overlap and covalent mixing significantly affect almost every observable in an iron series salt. Covalent behavior must be understood in detail before matters such as the theory of superexchange can be put on any sort of quantitative basis.

Sugano and Shulman's modification of crystal field theory to include covalency in the cluster model may be viewed as an extension of the traditional approach to crystal field effects in ionic salts. In $KNiF_3$, the familiar triply (t_{2g}) and doubly (e_g) degenerate $3d$ orbitals, describing the Ni^{2+} ion in its ground-state configuration ($t_\uparrow^3 t_\downarrow^3 e_\uparrow^2$), in the ionic model, become antibonding orbitals in covalent theory. These orbitals are shown schematically in Fig. 1. Also included are the bonding orbitals, which are formed predominantly from ligand $2s$ and $2p$ functions. Since their energy is lower than that of the antibonding orbitals, they are completely occupied. According to S&S, it is the covalency of the antibonding electrons which must be considered in order for the experimental observables to be reproduced. Thus, in the theory of the transferred hyperfine effects only the covalency of (spin) unpaired antibonding $3d$ electrons of majority spin contribute, while the crystal field splitting is associated with the $3d$ antibonding electrons of minority spin. Sugano and Shulman utilized the conventional approach of treating electrons of either spin identically and therefore obtained a common estimate of this covalent mixing for the two phenomena. In this approach, the bonding electrons are considered to play no role (other than to provide orthogonal partners for the antibonding electrons).

In this paper, the theory of covalency in crystal field phenomena is examined using the cluster model for $KNiF_3$ as example. We find the covalent mixing of those *bonding* electrons which have no antibonding partners, to be the appropriate manifestation of covalency in experiment. Unlike the antibonding version described above, it is the covalent mixing of the same (unpaired bonding) electrons (of minority spin in $KNiF_3$) which contributes to both $10\,Dq$ and the transferred hyperfine interactions and, in fact, to all experimental observables. The covalency (but not the overlap) of the antibonding electrons is entirely irrelevant because it is exactly compensated by the covalency of their bonding partners. This agrees with several features of the role of bonding electrons in transferred hyperfine theory which have been described in the context of the Heitler-London method by Keffer *et al.*[13] and for the molecular orbital (MO) method by Clogston *et al.*[15] These matters are important for if we solve the Hartree-Fock equations for the two types of covalent mixing we find them to differ markedly. This difference does not imply different orbitals for different spin in the sense of unrestricted Hartree-Fock (UHF) theory, because the antibonding covalency (which has *no* physical or variational meaning) may have any value—including that appropriate to the unpaired bonding electrons. (We briefly discuss, for the case of Cr^{3+}, the implications of "UHF covalent mixing.")

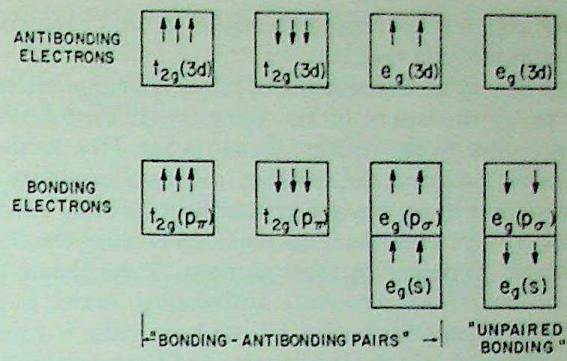

FIG. 1. A schematic representation of the antibonding and bonding electrons grouped into bonding-antibonding pairs and unpaired bonding electrons. For each, the predominant atomic orbital, from which the molecular orbital is formed, is indicated in parentheses; the F^- ligand $2s$, $2p_\sigma$, and $2p_\pi$ orbitals are denoted simply by s, p_σ, and p_π.

Two basic aspects of this crystal field theory are considered in what follows: (1) the quantitative implications of the approximations made in the treatment of a Hamiltonian, its matrix elements and related matters; (2) the source and nature of the covalent and overlap effects appropriate to the various physical phenomena. We concentrate on the latter in some detail in the present investigation and leave some aspects of the quantitative calculations to a future paper. Our studies of covalency are described in terms of the occupied one-electron orbitals of the cluster. An alternate approach to crystal field problems consists of dealing with the unoccupied antibonding orbitals, i.e., the antibonding holes (which are associated with the unpaired bonding electrons). Such a treatment of covalent mixing, and the resulting estimates of $10\,Dq$ and other experimental parameters, is exactly equivalent to that associated with the unpaired bonding orbital treatment provided that certain restrictions (to be discussed later) are maintained. For this reason, we will consider only one approach in detail but will make

brief contact with the unoccupied orbital prediction when describing results.

In Sec. II we describe the covalent mixing of interest to us. A discussion of the one-electron Hamiltonian appropriate to the system follows (in Sec. III). Sections IV and V discuss the covalent mixing appropriate to transferred hyperfine and crystal field splitting effects, respectively. The role of the unpaired bonding electrons becomes apparent in these sections. Throughout, the traditional (and incorrect) antibonding model is examined in parallel. In Sec. VI, we have cause to return to the matter of our Hamiltonian and the crucial role it plays in causing the two types of computed covalent mixing to differ. Since we use an approximate Hamiltonian, as in Ref. 10, certain "self-energy" problems arise which lead to serious internal inconsistencies in the results. The nature of these inconsistencies are explored. Their resolution requires the use of a better approximation to the true one-electron Hamiltonian, a matter reserved for the future. The various matrix elements appearing in our calculations are discussed, and their numerical values are reported, in Sec. VIII. Results, a discussion of their implications for other physical parameters, and conclusions follow.

II. THE MOLECULAR ORBITAL APPROACH

The molecular orbital approach is by now well known; hence, we will but briefly recapitulate some of the definitions and ideas required by us here. The antibonding molecular orbitals are defined by

$$\begin{aligned}\Psi_e{}^A &\equiv N_e(\varphi_e-\lambda_s\chi_{2s}-\lambda_\sigma\chi_{2p\sigma}),\\ \Psi_t{}^A &= N_t(\varphi_t-\lambda_\pi\chi_{2p\pi}),\end{aligned} \tag{1}$$

where the N_i are normalization constants, the φ's are $Ni^{2+}3d$ orbitals of t (xy, yz, and zx) and e (x^2-y^2 and $3z^2-r^2$) symmetry, and the χ's are appropriate linear combinations[11] of $2s$, $2p\sigma$, or $2p\pi$ atomic orbitals (ψ_i's) associated with the six nearest-neighbor F^- ions. The λ_i's are the covalent mixing parameters. The normalization constants are given by

$$\begin{aligned}N_e &= [1-2\lambda_s S_s-2\lambda_\sigma S_\sigma+\lambda_s{}^2+\lambda_\sigma{}^2+2\lambda_s\lambda_\sigma S_{s\sigma}]^{-1/2};\\ N_t &= [1-2\lambda_\pi S_\pi+\lambda_\pi{}^2]^{-1/2},\end{aligned} \tag{2}$$

where an S_i is the overlap integral between χ_i and the φ_{3d} orbital with which it is being combined, and $S_{s\sigma}$ is the overlap integral between χ_s and χ_σ; it need not be zero valued, as is often assumed.

One can alternatively speak of the covalent mixing associated with the bonding molecular orbitals,

$$\begin{aligned}\Psi_{es}{}^B &= N_{es}'(\chi_{2s}+\gamma_s\varphi_e+\gamma_{s\sigma}\chi_{2p\sigma}),\\ \Psi_{e\sigma}{}^B &= N_{e\sigma}'(\chi_{2p\sigma}+\gamma_\sigma\varphi_e+\gamma_{\sigma s}\chi_{2s}),\\ \Psi_t{}^B &= N_t'(\chi_{2p\pi}+\gamma_\pi\varphi_t),\end{aligned} \tag{3}$$

where

$$\begin{aligned}N_{es}' &= [1+2\gamma_s S_s+2\lambda_{s\sigma}S_{s\sigma}+2\gamma_s\gamma_{s\sigma}S_\sigma+\gamma_s{}^2+\gamma_{s\sigma}{}^2]^{-1/2},\\ N_{e\sigma}' &= [1+2\gamma_\sigma S_\sigma+2\lambda_{\sigma s}S_{s\sigma}+2\gamma_\sigma\gamma_{\sigma s}S_s\\ &\qquad +\gamma_\sigma{}^2+\gamma_{\sigma s}{}^2]^{-1/2},\\ N_t' &= [1+2\gamma_\pi S_\pi+\gamma_\pi{}^2]^{-1/2}.\end{aligned} \tag{4}$$

The bonding and antibonding orbitals are to be orthonormal, so to lowest order

$$\begin{aligned}\lambda_s &= \gamma_s+S_s,\\ \lambda_\sigma &= \gamma_\sigma+S_\sigma,\\ \lambda_\pi &= \gamma_\pi+S_\pi,\\ \gamma_{s\sigma} &= -\gamma_{\sigma s}-S_{\sigma s}.\end{aligned} \tag{5}$$

The bonding and antibonding orbitals are to be eigenfunctions of the Hartree-Fock (H-F) equations for a ($Ni-F_6$) cluster in $KNiF_3$, i.e., they are to satisfy

$$h\Psi_i = \epsilon_i\Psi_i, \tag{6}$$

where h is the one-electron self-consistent H-F Hamiltonian. In the present paper, we will follow Sugano and Shulman and approximate the effects of the crystal external to the cluster by an electrostatic Madelung-like potential V_{ext}, i.e., we assume that there are no covalent or overlap effects, between the cluster and its environment, which significantly affect the metal-ligand covalency of interest here. This approximation is necessary in order to make the problem tractable. (One can improve on the approximation by making V_{ext} the most accurate description of environmental effects obtainable with a local *effective* potential, but it is well to note that there are shortcomings in such an approach—shortcomings which are particularly significant when one considers superexchange or any other interaction between ions in different clusters.) The use of such a V_{ext} is compatible with a self-consistent H-F treatment for the cluster itself.

One automatic result of a self-consistent H-F treatment is that a set of orthonormal one-electron eigenfunctions is obtained. We are thus supplied with a test of the seriousness of any approximation we make in our Hamiltonian (or in evaluating matrix elements) which causes us to fail to have a proper self-consistent theory. The test consists of independently obtaining an antibonding orbital, Ψ^A, and its bonding partner, Ψ^B, and checking their orthogonality. We will see that the present approximate cluster theory does not always meet this orthogonality requirement.

We will solve Eq. (6) for Ψ within a very limited function space, namely, one spanned by the molecular orbitals constructed from Ni^{2+} and ligand-free ion orbitals. (One well might wish to allow greater variational freedom in a future calculation.) However, what is important to us here, is that the limited nature of this space in no way effects eigenfunction orthogonality or the self-energy problem to be discussed in Sec. VI. Let us

now consider, in detail, the nature of the one-electron Hamiltonian.

III. THE ONE-ELECTRON HAMILTONIAN

We are interested in obtaining the exact one-electron H-F Hamiltonian, appropriate to Eq. (6), derived from a many-electron Hamiltonian consisting of kinetic and electrostatic terms, where the environment external to the $(Ni-F_6)$ cluster is approximated by a Madelung-like one-electron electrostatic potential $V_{ext}(r_i)$. The process is made trivial by the fact that the two H-F many-electron states of interest to us are single determinants constructed from orthonormal one-electron orbitals (Ψ^A's and Ψ^B's). For such states the one-electron Hamiltonian h_i, for electron orbital i, is simply

$$h_i(r_1)=\tfrac{1}{2}\nabla_1^2+\sum_\alpha\left(-\frac{Z_\alpha}{r_{\alpha 1}}\right)+V_{ext}(r_1)+\sum\int\Psi_j^*(r_2)\frac{1-P_{12}}{r_{12}}\Psi_j(r_2)d\tau_2 \quad (7)$$

in atomic units. The α summation (over nuclear potential contributions) is limited to the one Ni and six F nuclei for we have already introduced the potential accounting for all electrons and nuclei (presumed) external to the cluster. The P_{12} operator permutes coordinates r_1 and r_2 giving us the interelectronic exchange terms, which occur only between electrons of common spin. The sum over interelectronic terms is limited to the cluster and consists of contributions from all electrons in the cluster including the ith electron itself. This is allowed in a self-consistent H-F theory because the ith electron Coulomb contribution is exactly canceled by its exchange term. We will have occasion to return to the matter of including or excluding an electron's self-energy contribution to Eq. (7) later.

We now with to re-express the interelectronic potential of h in terms of one-electron functions localized on the seven nuclei in the cluster, for it is in terms of these that the potential, of Eq. (7), can be evaluated. In this simple procedure the Ψ's are expressed as linear combinations of the local atomic orbitals (LCAO's), i.e., Ψ is broken up into Ni φ and ligand χ_i orbitals [with the χ_i's themselves expressed in terms of local orbitals (ψ_i's) at the various fluorine sites], whereupon Eq. (7) may be written as

$$h_i(r_1)=-\tfrac{1}{2}\nabla_1^2+V_{ext}(r_1)+V_m(r_1)+V_L(r_1)+V_S^{(1)}(r_1)+V_\gamma^{(1)}(r_1)+V_S^{(2)}(r_1)+V_\gamma^{(2)}(r_1)+V_{SL}(r_1). \quad (8)$$

As we shall see, the terms of the second line account for the important fact that the local one-electron functions of one center are nonorthogonal with those of another (i.e., $S\neq 0$) and that there is covalent mixing.

Let us now consider the individual terms separately. V_m: This term is simply the H-F nuclear and interelectronic Coulomb plus exchange potential for an isolated Ni^{2+} ion;

$$V_m(r_1)=-\frac{Z_{Ni}}{r_1}+\sum_{\substack{j=\text{all Ni}^{2+}\\ \text{electrons}}}\int\varphi_j^*(r_2)\frac{1-P_{12}}{r_{12}}\varphi_j(r_2)d\tau_2. \quad (9)$$

V_L: These are similar contributions from the ligand ions;

$$V_L(r_1)=\sum_{\alpha=1}^{6}\left\{\frac{-Z_\alpha}{r_{1\alpha}}+\sum_{\substack{j=\text{all electrons}\\ \text{on ion }\alpha}}\int\psi_{j,\alpha}^*(r_2)\frac{1-P_{12}}{r_{12}}\times\psi_{j,\alpha}(r_2)d\tau_2\right\}. \quad (10)$$

The above terms would make up the interelectronic contributions coming from the cluster if there were neither covalent mixing *nor* any overlap between orbitals on different sites. The omission of overlap terms may be thought of as yielding a potential of the form one would have when the ions of the cluster are infinitely separated. It is important to note that such a potential [actually the full first line of Eq. (8)] was used by Sugano and Shulman in their work. The consequences of this approximation will be discussed later.

Next we consider the overlap contributions to the potential. $V_S^{(1)}(r_1)$ and $V_S^{(2)}(r_1)$: The most obvious overlap effects are associated with metal-ligand nonorthogonality. In the case of zero covalency, this nonorthogonality is resolved by having $\lambda_i=S_i$ while $\gamma_i=0$ for the bonding-antibonding pairs. Setting λ_i and γ_i to these values, we can inspect the overlap terms arising in Eq. (8). There are terms linear in S, i.e.,

$$V_S^{(1)}(r_1)=-\sum_j 2S_j\int\varphi_j^*(r_2)\frac{1-P_{12}}{r_{12}}\chi_j(r_2)d\tau_2, \quad (11)$$

where the sum is over all bonding-antibonding pairs. Note that Eq. (11) is written in terms of the multicenter ligand molecular orbitals, χ_j. There are also higher order overlap terms in S_j, i.e.,

$$V_S^{(2)}(r_1)=+\sum_j S_j^2\left\{\int\varphi_j^*(r_2)\frac{1-P_{12}}{r_{12}}\varphi_j(r_2)d\tau_2+\int\chi_j^*(r_2)\frac{1-P_{12}}{r_{12}}\chi_j(r_2)d\tau_2\right\}+O(S^3). \quad (12)$$

These second-order terms are of the same order of importance as $V_S^{(1)}$ which involves an S_j times an overlap charge density. Note that a φ_s appears twice in the summations in these equations to account for its two partners, χ_s and $\chi_{s'}$. Third and higher order terms are, of course, less important.

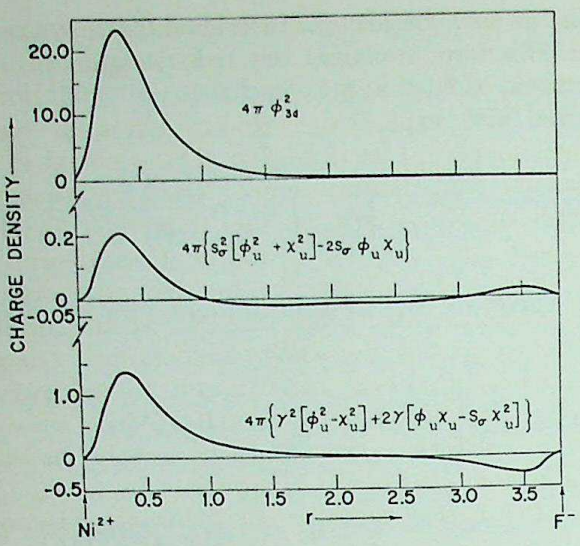

FIG. 2. The charge density of $4\pi\varphi_u^2$ of the $u(=3z^2-r^2)$ orbital compared with the p electron overlap charge density $4\pi\{S_\sigma^2[\varphi_u^2+\chi_\sigma^2]-2S_\sigma\varphi_u\chi_\sigma\}$ and covalent charge density $4\pi\{\gamma^2[\varphi_u^2-\chi_\sigma^2]+2[\varphi_u\chi_\sigma-S_\sigma\chi_\sigma^2]\}$ plotted along the z axis from Ni^{2+} to F^-. Densities are all in the same units, normalized such that $\int\varphi_{3d}^2(\mathbf{r})d\tau=1$; the free ion S value was used (see Table VII) and $S+\gamma$ was chosen so as to reproduce the experimental (Ref. 11) anisotropic F^- hyperfine term.

In Fig. 2 we plot the overlap charge density, giving rise to the sum of the $V_S^{(1)}$ and $V_S^{(2)}$ terms, along a metal-ligand axis, and for comparison, the charge density associated with an antibonding electron prior to the introduction of overlap and covalency [i.e., just $|\varphi_4(\mathbf{r})|^2$]. We see that the antibonding charge density has been delocalized, by the addition of the overlap terms, in the sense that there has been a buildup of charge on the ligand (which is one of six so affected), but, there has also been an increase of charge on the metal as well. These increases have been compensated for by a decrease of charge due to the $-2S_i[\varphi_i^*(\mathbf{r})\chi_i(\mathbf{r})]$ term, in the region between the ions. In other words, one is not dealing with a shift in charge (or spin) simply from one ion to another but onto the ions from the region between. The often cited picture of overlap (and covalent) effects delocalizing charge and spin off the metal ion is, therefore, not valid, for we are dealing with a process which is more complicated. Whether the overlap effect *acts as if* there is a shift onto, or off, the metal ion, depends strongly on the nature of the operator whose expectation value is in question.

V_{SL}: These are additional overlap potential contributions due to the nonorthogonality between ligand orbitals. First, ligand-ligand ($\psi-\psi$) overlap enters into the evaluation of the second line of Eq. (12) (where we have χ^2), and elsewhere. We will include the latter terms as part of V_{SL} but will not write them out explicitly. It should be noted that the normalization of the χ_i's as defined in S&S I [Eq. (2.4)], is affected by this nonorthogonality; however, for the purposes of this paper, we assume their normalization covention. Secondly, $\chi_s-\chi_\sigma$ nonorthogonality leads to additional potential terms, the lowest order ones being of the form

$$S_{s\sigma}{}^2\left[\int\chi_\sigma^*(r_2)\frac{1-P_{12}}{r_{12}}\chi_\sigma(r_2)d\tau_2+\int\chi_s^*(r_2)\frac{1-P_{12}}{r_{12}}\chi_s(r_2)\right]$$
$$-2S_{s\sigma}\int\chi_\sigma^*(r_2)\frac{1-P_{12}}{r_{12}}\chi_s(r_2)d\tau_2 \quad (13)$$

similar to what we have seen in Eqs. (11) and (12). Finally, the simultaneous nonorthogonality of φ_e with χ_s and χ_σ, which leads to terms involving the $\chi_\sigma\chi_s$ charge density, have been arbitrarily included in V_{SL}. The lowest order term is of the form

$$2S_sS_\sigma\int\chi_s^*(r_2)\frac{1-P_{12}}{r_{12}}\chi_\sigma(r_2)d\tau_2 \quad (14)$$

and is of higher order than the contributions written out explicitly in Eqs. (11), (12), and (13), i.e., it is the product of two overlap integrals times an overlap charge density potential. Finally we come to covalent contributions. $V_\gamma^{(1)}(r_1)$, $V_\gamma^{(2)}(r_2)$: These are most simply obtained by evaluating the interelectronic term Eq. (8) for nonzero γ_j (with $\lambda_j=\gamma_j+S_j$), and subtracting off the overlap terms already accounted for in $V_S^{(1)}$ and $V_S^{(2)}$. One obtains linear terms of the form

$$V_\gamma^{(1)}(r_1)=-\sum_{\substack{j=\text{antibonding}\\ \text{orbitals}}}2\gamma_j\int\varphi_j^*(r_2)\frac{1-P_{12}}{r_{12}}\chi_j(r_2)d\tau_2$$
$$+\sum_{\substack{j=\text{bonding}\\ \text{orbitals}}}2\gamma_j\int\varphi_j^*(r_2)\frac{1-P_{12}}{r_{12}}\chi_j(r_2)d\tau_2. \quad (15)$$

It is immediately apparent that contributions from members of an occupied bonding-antibonding pair cancel one another, leaving us *only* with contributions coming from *unpaired bonding orbitals*, i.e.,

$$V_\gamma^{(1)}(r_1)=+\sum_{\substack{j=\text{unpaired bonding}\\ \text{orbitals}}}2\gamma_j\int\varphi_j^*(r_2)\frac{1-P_{12}}{r_{12}}\times\chi_j(r_2)d\tau_2. \quad (16)$$

Such cancellations also occur for the covalent mixing involving (a nonzero) $\gamma_{\sigma s}$ in a $\Psi_s{}^B-\Psi_\sigma{}^B$ pair. A similar cancellation occurs in second order giving us

$$V_\gamma^{(2)}(r_1)=+\sum_{\substack{j=\text{unpaired}\\ \text{bonding}}}\left\{\gamma_j{}^2\left[\int\varphi_j^*(r_2)\frac{1-P_{12}}{r_{12}}\varphi_j(r_2)d\tau\right.\right.$$
$$\left.-\int\chi_j^*(r_2)\frac{1-P_{12}}{r_{12}}\chi_j(r_2)d\tau_2\right]$$
$$\left.-2\gamma_jS_j\int\chi_j^*(r_2)\frac{1-P_{12}}{r_{12}}\chi_j(r_2)d\tau_2\right\}$$
$$+\text{higher order terms.} \quad (17)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The cancellation illustrated in detail above follows simply from a well-known property of determinantal functions: Any linear combination of occupied orbitals in a Slater determinant leaves unchanged the expectation value of an operator—and hence does not affect the prediction of any physical observable.

The first line of Eq. (17) is associated with an obvious physical effect, namely, the transfer of charge from ligand to metal ions due to covalent mixing. The number of electrons so transferred is simply

$$N = \sum_{i=\text{unpaired bonding orbitals}} \gamma_i^2. \tag{18}$$

Antibonding-bonding pairs do not contribute to this transfer because the covalency of one is compensated for by that of the other, as is required, to second order, by the orthogonality conditions [Eqs. (5)]. The third line of Eq. (17) is coupled with $V_\gamma^{(1)}$ which is $2\gamma_j$ times an overlap potential. The two terms represent a first-order (in γ_j) shift of charge off the ligands into the space between ligands and the Ni^{2+} ion. It should be noted that as the unpaired bonding orbitals are of minority spin, the covalent terms involve a shift of minority spin onto the metal ion, effectively reducing the net spin localized at the Ni^{2+} site. These covalent charge density terms are plotted for a bonding $2p\sigma$ electron in Fig. 2 (their negative should be taken when considering spin effects) where γ was chosen so as to reproduce the experimental[11] anisotropic transferred hyperfine interaction. This choice causes these covalent effects to be greater than the overlap terms for the same e_g electrons. Such a dominance need not always occur. Note that there are also t_{2g} and Ni closed shell overlap charge, but *not* spin, density effects. The overlap and covalent e_g terms act cooperatively in their contributions to the Ni^{2+} charge and F^- spin densities while making opposing contributions to the Ni^{2+} spin and F^- charge behaviors.

We have seen a covalent shift of charge associated with unpaired bonding electrons and no such shift for bonding-antibonding pairs. This fact is of great interest to us for reasons beyond the mere matter of estimating a potential, for it indicates the profoundly different nature of the two types of covalent mixing. The mixing of a bonding-antibonding pair conserves the charge on the metal ion while that of an unpaired bonding electron involves the shift of charge from ligands to metal. This observation suggests that the computed covalent mixing, i.e., the γ_i, differs for the two cases and is the reason for our preoccupation with bonding electron behavior in this paper.

In the above discussion of the overlap and covalent contributions to the Hamiltonian, h, we deliberately neglected to specify exactly which orbitals were so involved. As covalent terms only occur in low order for unpaired bonding orbitals we need only consider those electrons which can enter into bonding with the open $3d$ shell; i.e., the $2s$, $2p$, and $1s$ shells of the ligands. The $2s$ and $2p$ electrons are expected to make small contributions, and the $1s$ electrons insignificant contributions, to $V_\gamma^{(1)}$ and $V_\gamma^{(2)}$.

We also expect the overlap terms to make a more significant contribution to the potential terms than do the covalent terms. Now, any shell which significantly overlaps another ion shell should be included in $V_S^{(1)}$, $V_S^{(2)}$, and/or V_{SL}. Hence, when including overlap terms in the potential one must inspect terms other than the Ni $3d$ and ligand $2s$ and $2p$ electrons, to which consideration is normally limited. In particular, one should, at the minimum, explore the role of the Ni $3s$ and $3p$ shells since their overlap with the ligand electrons is only moderately smaller than that of the $3d$ orbitals.

In the present paper we will follow the Sugano and Shulman treatment and mostly limit ourselves to a Hamiltonian (denoted by h_0) consisting of the first line of Eq. (8) alone for two reasons. First, we believe it imperative to fully explore the implications of their approximations, approximations which at first glance seem to yield excellent agreement with experiment, before going on to a more complete (and more complicated) treatment. Secondly, a more complete treatment appears to require far greater care in the numerical evaluation of matrix elements than does a treatment based on h_0 alone. Greater care is not only necessary in the handling of overlap and covalent terms but also in the evaluation of the h_0 matrix elements. Approximations which were apparently adequate for the simple case must be re-examined before one attempts the more detailed treatment; this is due, in part, to the severe numerical differencing which occurs in the course of evaluating matrix elements. Our reasons for being cautious on this matter will become obvious when we inspect the results of the present paper.

As Sugano and Shulman have emphasized, the use of h_0 can be viewed as the first iteration of a self-consistent theory for the $(Ni-F_6)$ covalent mixing problem. This is so, providing that overlap as well as covalent terms are included in a later iteration. As we shall see, the results of Sec. VIII suggest that a proper evaluation of covalent effects cannot be had without the inclusion of the overlap and covalent terms in the Hamiltonian [i.e., the second line of Eq. (8)]. It is our intention to investigate the effect of such terms in a future paper.

In going beyond the use of h_0, one is involved in an ever increasing commitment to details of the cluster model, details which do not reflect the situation in the actual crystal. The use of h_0 and the MO's as defined earlier for the cluster already imply a strong commitment.

IV. UNPAIRED SPIN COVALENCY AND TRANSFERRED HYPERFINE EFFECTS

We now consider the role of covalent mixing in transferred hyperfine effects. In doing this, we assume that the orthogonality relations of Eq. (5) hold and

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

that orbitals differing in spin may have different covalent parameters.

The isotropic F^{19} hyperfine parameter is considered to be primarily associated[14,11] with the unpaired $2s$ spin induced by nonorthogonality and covalency on the F^- site. After a variety of other contributions[16,17,11] are accounted for, the parameter is written as the product of the hyperfine constant associated with a single F^- $2s$ orbital times the fraction, f_s, of induced unpaired $2s$ spin character at the F^- site. Making the standard assumption of constant covalency for electrons of either spin, the value of f_s in $KNiF_3$ is

$$f_s=\lambda_s^2 N_s^2/3 \tag{19}$$

and arises from the antibonding electrons alone. The $\frac{1}{3}$ accounts for the fact that λ is defined in terms of molecular orbitals and that we are interested in the $2s$ character induced on a single F^- site (via both antibonding $e_\uparrow$ orbitals). The anisotropic hyperfine interaction is complicated by the presence of (1) both p_σ and p_π conbributions and (2) a substantial correction for classical spin dipolar effects (which must be made prior to estimating covalency from experiment). The p-electron interaction is entirely spin dipolar (i.e., not orbital) and given the experimental covalent hyperfine parameter, the fractional difference $(f_\sigma-f_\pi)$between induced p_σ and p_π behavior can be inferred.

The coventional assumption of common covalency for either spin leads to $f_\pi=0$ for $KNiF_3$ since all t orbitals are occupied in the ground state. Experiment, therefore, would seem to yield information concerning the $2s$ and $2p_\sigma$ covalent mixing in the antibonding $e_\uparrow$ orbitals from the observed isotropic and antisotropic interactions.

The above discussion assumes that the transferred hyperfine interaction is entirely due to the spin density associated with a ligand's ψ orbitals. However, the tails of the free ion Ni φ_{3d} (and neighboring ligand) orbitals overlap into the region of a F nucleus and contribute[16,17] to the spin density and hyperfine interaction via the φ^2 and $\varphi\chi$ terms. These terms are not negligible.[16] Unfortunately the use of free ion orbitals is inappropriate for this evaluation since these orbitals do not take account of the presence of neighboring ion nuclei. We will encounter similar problems, introduced by inappropriate orbital tail behavior, when discussing orbital reduction effects in Sec. IX. These matters will be ignored in the remainder of this section.

Let us now consider how the picture changes when one accounts for all covalent mixing while maintaining the necessary orthogonality of bonding and antibonding orbitals to second order in S_i, χ_i, and γ_i. We will again consider the $2s$ effects as they are the least complicated. The implications for anisotropic effects will then be immediately apparent.

Consider the contributions to f_s from the bonding $e_\uparrow$ and $e_\downarrow$, and antibonding $e_\uparrow$ electrons. Writing out the normalization constant in Eq. (17) and making use of Eq. (5), the antibonding contribution becomes

$$f_{s\uparrow}{}^A=\tfrac{1}{3}\{S_s{}^2+2S_s\gamma_{s\uparrow}+\gamma_{s\uparrow}{}^2\}+0(S^3). \tag{20}$$

(We will henceforth use superscripts A and B to denote antibonding and bonding, respectively, whenever appropriate for clarity.) In the absence of covalent bonding and $\chi_s-\chi_\sigma$ overlap, the f_s contributions are $+1$ for spin $\uparrow$ and -1 for spin $\downarrow$, and hence cancel. Covalency affects these f_s contributions via (1) the normalization of the $\Psi_{es}{}^B$ orbitals [cf. Eq. (4)] and (2) the χ_{2s} term of $\Psi_{e\sigma}{}^B$. With differing covalency, these contributions need no longer cancel. The individual spin contributions are

$$f_{s\uparrow}{}^B=\tfrac{1}{3}N_{s\uparrow}{}^2+\tfrac{1}{3}N_{\sigma\uparrow}{}^2\gamma_{\sigma s\uparrow}{}^2$$
$$=\tfrac{1}{3}\{1-2\gamma_{s\uparrow}S_s-\gamma_{s\uparrow}{}^2+S_{s\sigma}{}^2\}+0(S^3)+\cdots, \tag{21}$$
$$f_{s\downarrow}{}^B=-\tfrac{1}{3}\{1-2\gamma_{s\downarrow}S_s-\gamma_{s\downarrow}{}^2+S_{s\sigma}{}^2\}+0(S^3)+\cdots. \tag{22}$$

Combining all these contributions results in

$$f_s=\tfrac{1}{3}\{S_s{}^2+2\gamma_{s\downarrow}S_s+\gamma_{s\downarrow}{}^2\}+0(S^3). \tag{23}$$

Similarly, one obtains

$$f_\sigma=\tfrac{1}{3}\{S_\sigma{}^2+2S_\sigma\gamma_{\sigma\downarrow}+\gamma_{\sigma\downarrow}{}^2\}+0(S^3). \tag{24}$$

In other words, if bonding and antibonding orbitals of one spin are simultaneously occupied, there will be an $S_i{}^2$ overlap contribution, but their covalent terms cancel exactly. Hence, it is the covalency of the *bonding* $e_{s\downarrow}{}^B$ electrons which contribute to the isotropic transferred hyperfine interaction in $KNiF_3$, and if there is any question as to the constancy of $2s$ covalent mixing within the set of e orbitals, it is the mixing estimated for the $e_\downarrow{}^B$ electrons which must be compared with experiment.

The coventional cancellation associated with spin pairing has been lost, but the more fundamental pairing cancellation between bonding and antibonding orbitals has been seen. The immediate effects of this for the anisotropic F^- hyperfine interaction are (1) that $t_\uparrow$ and $t_\downarrow$ electrons cannot contribute, no matter what their respective covalencies, since antibonding-bonding pairs of both spins are occupied; (2) that there will be S^2, but no γ contributions from the majority spin $e_\uparrow{}^B$ and $e_\uparrow{}^A$ electrons; and (3) that covalent contributions come solely from unpaired $e_\downarrow{}^B$ electrons of minority spin. It is clear from the identical form of Eqs. (20) and (23) that the usual phenomenological approach, which uses the antibonding expression [Eq. (20)], actually determines[15] the unpaired bonding covalent mixing parameter.

Complications occur for almost empty d shell ions such as $Cr^{3+}(t_\uparrow{}^A)^3$ which has but three antibonding d-like electrons. There are no e^A electrons in the ground state and differences in $e_\uparrow{}^B$ and $e_\downarrow{}^B$ covalent mixing can lead, for example, to an isotropic F^- hyperfine term which would be zero in the traditional analysis.

Transferred hyperfine effects have been observed[18] in K_2NaCrF_6; the isotropic term is almost zero valued. This either implies that the e^B covalency differences are very small here or that an accidental near cancellation of a number of contributions has occurred. Neutron diffraction experiments on such a system could test for e electron character in the cluster's spin density.

It must be stressed that any computed differences in $e_\uparrow{}^B - e_\downarrow{}^B$ covalency, for this case, come from a different source than do the differences between the covalency of an occupied Ni^{2+} bonding-antibonding pair of one spin and that of an unpaired bonding orbital of the other. The covalent "unpairing" of the Cr^{3+} orbitals has its source in the unbalanced exchange terms of the open $3d$ shell. By this we do not mean the HF exchange polarization of the F^- ion by the $3d$ shell, a matter discussed elsewhere.[19] Instead, we mean the imbalance in covalent mixing caused by the imbalance in $3d$ exchange contributions to h_0 and, in turn, the various matrix elements appropriate to the determination of the covalent mixing. Although these exchange terms also contribute to the Ni^{2+} case, a more fundamental role is played by the intrinsic differences in the character of the antibonding-bonding pair covalency, on the one hand, and that of the unpaired bonding electrons on the other. Note that the unbalanced exchange terms cause the single determinant description of the Cr^{3+} cluster to be an improper eigenfunction, and of the Ni^{2+} cluster, to be a proper eigenfunction, of the spin operator (S^2). The Ni^{2+} description preserves its symmetry because of the presence of unpaired bonding orbitals of but one spin.[20]

V. THE CRYSTAL FIELD SPLITTING

We use the conventional definition of the crystal field splitting, namely,

$$10\,Dq \equiv \mathcal{E}[(t^{EA})^5(e^{EA})^3] - \mathcal{E}[(t^A)^6(e^A)^2], \quad (25)$$

where the latter is the energy of the ground state and the former is the energy of the excited state (hence the superscript E to designate this state) obtained by replacing the $t(xy)_\downarrow{}^A$ electron of the ground state by an $e(x^2-y^2)_\downarrow{}^A$ electron. If we make the common, but often unjustified,[21] assumption that all electrons but the promoted one maintain constant orbital behavior in the cluster states, we have

$$10\,Dq = \epsilon[e(x^2-y^2)_\downarrow{}^{EA}] - \epsilon[t(xy)_\downarrow{}^A], \quad (26)$$

where the ϵ's are the eigenvalues obtained with Eq. (6) for the one-electron Hamiltonian appropriate to the particular cluster state involved. To second order,

$$\epsilon_t{}^A = \langle\varphi_t|h|\varphi_t\rangle - 2S_t\langle\varphi_t|h|\chi_t\rangle - 2\gamma_t\langle\varphi_t|h|\chi_t\rangle + \{[S_t+\gamma_t]^2\langle\chi_t|h|\chi_t\rangle + [S_t{}^2-\gamma_t{}^2]\langle\varphi_t|h|\varphi_t\rangle\}, \quad (27)$$

which is obtained by multiplying Eq. (6) from the left by Ψ, reexpressing the Ψ's in terms of φ's and χ's, integrating and keeping all terms to second order. The first term of ϵ is simply the diagonal energy and includes the classic point charge crystal potential, Kleiner's correction[5] to such a potential, and ligand exchange terms; the second term is the first-order contribution to the overlap energy of the sort investigated by Tanabe and Sugano[7]; we then have the first-order term of the covalent contribution, which Sugano and Shulman concluded was important; and lastly, the second-order terms in overlap and covalency. The expression for $\epsilon_e{}^A$ is of the form of Eq. (27) except that there are first- and second-order overlap and covalent contributions from both the χ_s and χ_σ mixing, i.e.,

$$\epsilon_e{}^A = \langle\varphi_e|h|\varphi_e\rangle - \sum_{i=s,\sigma}\{2(S_i+\gamma_i)\langle\varphi_e|h|\chi_i\rangle + [S_i+\gamma_i]^2 \times\langle\chi_i|h|\chi_i\rangle + [S_i{}^2-\gamma_i{}^2]\langle\varphi_e|h|\varphi_e\rangle\}. \quad (28)$$

One may obtain alternative expressions[10] for the ϵ's, for example, by multiplying Eq. (16) by χ instead of Ψ, in which case ϵ^A is given by

$$\epsilon_t{}^A = \langle\varphi_t|h|\varphi_t\rangle - (S_t+\gamma_t)\langle\varphi_t|h|\chi_t\rangle + S_t(S_t+\gamma_t)\langle\varphi_t|h|\varphi_t\rangle. \quad (29)$$

Note the omission of the two multiplying the linear term.[22] Unlike Eq. (27), this relation only holds if Ψ is an eigenfunction of Eq. (6) (within our φ, χ subspace), in which case Eqs. (27) and (29) differ from one another in third and higher order in S and γ. This point is of some importance for we shall be evaluating Eq. (25) [and thus Eq. (27)] using noncovalent orbitals ($\gamma=0$).

We have already seen indications that the computed covalent mixing appropriate to a bonding-antibonding pair differs from that of an unpaired bonding electron. This suggests that the covalent mixing of the paired $t(xy)_\downarrow{}^B$ [and unpaired $e(x^2-y^2)_\downarrow{}^B$] orbital [$s$], appearing in the ground state, might very well undergo substantial changes on becoming an unpaired (and paired) electron in the excited state. We must then inspect the role of bonding orbital crystal field energies. The one-electron energy of a bonding t electron is, for example,

$$\epsilon_t{}^B = \langle\chi_t|h|\chi_t\rangle + 2\gamma_t\langle\varphi|h|\chi_t\rangle + \{\gamma_t{}^2\langle\varphi|h|\varphi\rangle - (2\gamma_tS_t+\gamma^2)\langle\chi_t|h|\chi_t\rangle\}. \quad (30)$$

[18] R. G. Shulman and K. Knox, Phys. Rev. Letters 4, 603 (1960).

[19] A. J. Freeman and R. E. Watson, J. Appl. Phys. 34, 1032S (1963); and (to be published).

[20] This observation is subject to the restriction that the Ψ's be constructed from a set of free ion φ's and ψ's having a single radial function per shell (although different φ_e and φ_t radial behavior is allowed).

[21] For example see, R. E. Watson, Phys. Rev. 118, 1036 (1960); in particular Tables V–VIII and related text.

[22] Their counterpart of the second line [e.g., in S&S III, Eq. (2.11)] shows a $(\varphi_e|h_0|\varphi_e)$ matrix element but we find $(\varphi_t|h_0|\varphi_t)$ more appropriate for this case.

The energy of a bonding-antibonding t orbital pair, Ω_t, in a crystal field is then

$$\begin{aligned}\Omega_t &= \epsilon_t{}^B+\epsilon_t{}^A-\langle\Psi_t{}^A\Psi_t{}^A|\Psi_t{}^B\Psi_t{}^B\rangle+\langle\Psi_t{}^A\Psi_t{}^B|\Psi_t{}^A\Psi_t{}^B\rangle\\ &= -S_t\langle\chi_t|h|\varphi_t\rangle+(1+S^2)\{\langle\varphi_t|h|\varphi_t\rangle+\langle\chi_t|h|\chi_t\rangle\\ &\qquad -\langle\varphi_t\varphi_t|\chi_t\chi_t\rangle+\langle\varphi_t\chi_t|\varphi_t\chi_t\rangle\}, \quad (31)\end{aligned}$$

where

$$\langle\Psi_A\Psi_B|\Psi_C\Psi_D\rangle \equiv \int\int d\tau_1 d\tau_2 \Psi_A{}^*(\mathbf{r}_1)\Psi_B(\mathbf{r}_1)\frac{1}{r_{12}}\Psi_C(\mathbf{r}_2)\Psi_D{}^*(\mathbf{r}_2). \quad (32)$$

The two-electron terms of the first line of (31) account for the fact that the interelectronic interaction between the pair of electrons has been counted twice when summing ϵ^B plus ϵ^A. An equivalent expression is obtainable for the e bonding electron; its derivation is but slightly complicated by the simultaneous presence of s and σ mixing.

In Eq. (31) as in Eqs. (16) and (17) we see the effect of the antibonding-bonding cancellation. The covalency of a bonding-antibonding pair plays no role in the cluster's energy[15] and hence in the crystal field splitting. Of course these pairs still make diagonal and overlap contributions to both the crystal field energy and to the Hamiltonian.

It is clear that only the unpaired bonding electrons make covalent contributions to the energies of Eq. (25). These total energies ($\mathcal{E}$) can be evaluated by a simple summation over one-electron ϵ's, providing that we account for the fact that this procedure introduces each interelectronic interaction twice by subtracting interelectronic Coulomb and exchange terms [as we did in Eq. (31)]. Here, we wish to concentrate on those ϵ's which contribute to a nonzero 10 Dq, namely all unpaired bonding electrons (which contribute covalent terms) and the bonding-antibonding pairs involved in the transition (which make diagonal and overlap contributions). The resulting $\mathcal{E}$'s are

$$\mathcal{E}[(t^A)^6(e^A)^2]=\epsilon_{xy\downarrow}{}^A+\epsilon_{xy\downarrow}{}^B+\epsilon_{s,v\downarrow}{}^B+\epsilon_{s,u\downarrow}{}^B+\epsilon_{\sigma,v\downarrow}{}^B+\epsilon_{\sigma,u\downarrow}{}^B+\sum_{i>j}[\langle\Psi_i\Psi_i|\Psi_j\Psi_j\rangle-\langle\Psi_i\Psi_j|\Psi_i\Psi_j\rangle]+\mathcal{E}_c \quad (33)$$

and

$$\mathcal{E}[(t^{EA})^5(e^{EA})^3]=\epsilon_{v\downarrow}{}^{EA}+\epsilon_{s,v\downarrow}{}^{EB}+\epsilon_{\sigma,v\downarrow}{}^{EB}+\epsilon_{xy\downarrow}{}^{EB}+\epsilon_{s,u\downarrow}{}^{EB}+\epsilon_{\sigma,u\downarrow}{}^{EB}+\sum_{i>j}[\langle\Psi_i\Psi_j|\Psi_j\Psi_j\rangle-\langle\Psi_i\Psi_j|\Psi_i\Psi_j\rangle]+\mathcal{E}_c, \quad (34)$$

where $\mathcal{E}_c$ is common to both energies and the sums go over all pairs of orbitals represented by the ϵ's. The subscripts v and u designate the (x^2-y^2) and $(3z^2-r^2)$ orbitals of e symmetry, respectively. The v orbital is involved in the crystal field transition ($t_{xy}{}^A \rightarrow e_{x^2-y^2}{}^A$) and the u orbitals are the "odd" unpaired bonding orbitals common to both crystal field states. Evaluating Eq. (25), rearranging terms and affecting appropriate cancellations, we have,

$$\begin{aligned}10Dq=&\{\langle\phi_e|h^E-V_{xy}{}^{\gamma E}-V_{s,u}{}^{\gamma E}-V_{\sigma,u}{}^{\gamma E}|\phi_e\rangle-\langle\phi_t|h-V_{s,v}{}^{\gamma}-V_{\sigma,v}{}^{\gamma}-V_{s,u}{}^{\gamma}-V_{\sigma,u}{}^{\gamma}|\phi_t\rangle\}\\ &+\sum_{\substack{i=s,j=\sigma\\ i=\sigma,j=s}}\{S_i{}^2[\langle\chi_{i,v}|h^E-V_{xy}{}^{\gamma E}-V_{s,u}{}^{\gamma E}-V_{\sigma,u}{}^{\gamma E}-\tfrac{1}{2}V_{j,v}{}^S|\chi_{i,v}\rangle+\langle\phi_v|h^E-V_{xy}{}^{\gamma E}-V_{s,u}{}^{\gamma E}-V_{\sigma,u}{}^{\gamma E}-\tfrac{1}{2}V_{j,v}{}^S|\phi_v\rangle]\\ &-2S_i\langle\chi_{i,v}|h^E-V_{xy}{}^{\gamma E}-V_{s,u}{}^{\gamma E}-V_{\sigma,u}{}^{\gamma E}-\tfrac{1}{2}V_{j,v}{}^S|\phi_v\rangle\}-\{S_\pi{}^2[\langle\chi_\pi|h-V_{s,v}{}^{\gamma}-V_{\sigma,v}{}^{\gamma}-V_{s,u}{}^{\gamma}-V_{\sigma,u}{}^{\gamma}|\chi_\pi\rangle\\ &+\langle\phi_{xy}|h-V_{s,v}{}^{\gamma}-V_{\sigma,v}{}^{\gamma}-V_{s,u}{}^{\gamma}-V_{\sigma,u}{}^{\gamma}|\phi_{xy}\rangle]-2S_\pi\langle\chi_\pi|h-V_{s,v}{}^{\gamma}-V_{\sigma,v}{}^{\gamma}-V_{s,u}{}^{\gamma}-V_{\sigma,u}{}^{\gamma}|\phi_{xy}\rangle\}\\ &-\{(\gamma_{xy\downarrow}{}^{EB})^2[\langle\chi_\pi|h^E-V_{s,u}{}^{\gamma E}-V_{\sigma,u}{}^{\gamma E}|\chi_\pi\rangle-\langle\phi_{xy}|h^E-V_{s,u}{}^{\gamma E}-V_{\sigma,u}{}^{\gamma E}|\phi_{xy}\rangle]\\ &-2\gamma_{xy\downarrow}{}^{EB}[\langle\chi_\pi|h^E-V_{s,u}{}^{\gamma E}-V_{\sigma,u}{}^{\gamma E}|\phi_{xy}\rangle-S_\pi\langle\chi_\pi|h^E-V_{s,u}{}^{\gamma E}-V_{\sigma,u}{}^{\gamma E}|\chi_\pi\rangle]\}\\ &+\sum_{\substack{i=s,j=\sigma\\ i=\sigma,j=s}}\{(\gamma_{i,v\downarrow}{}^B)[\langle\chi_{i,v}|h-V_{s,u}{}^{\gamma}-V_{\sigma,u}{}^{\gamma}-\tfrac{1}{2}V_{j,v}{}^{\gamma}|\chi_{i,v}\rangle-\langle\phi_v|h-V_{s,u}{}^{\gamma}-V_{\sigma,u}{}^{\gamma}-\tfrac{1}{2}V_{j,v}{}^{\gamma}|\phi_v\rangle]\\ &-2\gamma_{i,v\downarrow}{}^B[\langle\chi_{i,v}|h-V_{s,u}{}^{\gamma}-V_{\sigma,u}{}^{\gamma}-\tfrac{1}{2}V_{j,v}{}^{\gamma}|\phi_v\rangle-S_i\langle\chi_{i,v}|h-V_{s,u}{}^{\gamma}-V_{\sigma,u}{}^{\gamma}-\tfrac{1}{2}V_{j,v}|\chi_{i,v}\rangle]\}\\ &+\sum_{\substack{i=s,j=\sigma\\ i=\sigma,j=s}}\{(\gamma_{i,u\downarrow}{}^B)^2[\langle\chi_{i,u}|h-\tfrac{1}{2}V_{j,u}{}^{\gamma}|\chi_{i,u}\rangle-\langle\phi_u|h-\tfrac{1}{2}V_{j,u}{}^{\gamma}|\phi_u\rangle]-2\gamma_{i,u\downarrow}{}^B[\langle\chi_{i,u}|h-\tfrac{1}{2}V_{j,u}{}^{\gamma}|\chi_{i,u}\rangle\\ &-S_i\langle\chi_{i,u}|h-\tfrac{1}{2}V_{j,u}{}^{\gamma}|\phi_u\rangle]\}-\sum_{\substack{i=s,j=\sigma\\ i=\sigma,j=s}}\{(\gamma_{i,u\downarrow}{}^{EB})[\langle\chi_{i,u}|h^E-\tfrac{1}{2}V_{j,u}{}^{\gamma E}|\chi_{i,u}\rangle-\langle\phi_u|h^E-\tfrac{1}{2}V_{j,u}{}^{\gamma E}|\phi_u\rangle]\\ &-2\gamma_{i,u\downarrow}{}^{EB}[\langle\chi_{i,u}|h^E-\tfrac{1}{2}V_{j,u}{}^{\gamma E}|\chi_{i,u}\rangle-S_i\langle\chi_{i,u}|h^E-\tfrac{1}{2}V_{j,u}{}^{\gamma E}|\phi_u\rangle]\}, \quad (35)\end{aligned}$$

where each sum has but two terms ($i=s$ and $j=\sigma$ and vice versa) and where

$$V_i{}^S=S_i{}^2\left[\int\varphi_i{}^*(r_2)\frac{1-P_{12}}{r_{12}}\varphi_i(r_2)d\tau_2+\int\chi_i{}^*(r_2)\frac{1-P_{12}}{r_{12}}\chi_i(r_2)d\tau_2\right]-2S_i\int\varphi_i{}^*(r_2)\frac{1-P_{12}}{r_{12}}\chi_i(r_2)d\tau_2, \tag{36}$$

$$V_i{}^\gamma=+2\gamma_i\left[\int\varphi_i{}^*(r_2)\frac{1-P_{12}}{r_{12}}\chi_i(r_2)d\tau_2-S_i\int\chi_i(r_2)\frac{1-P_{12}}{r_{12}}\chi_i(r_2)d\tau_2\right]$$
$$+\gamma^2\left[\int\varphi_i{}^*(r_2)\frac{1-P_{12}}{r_{12}}\varphi_i(r_2)d\tau_2-\int\chi_i{}^*(r_2)\frac{1-P_{12}}{r_{12}}\chi_i(r_2)d\tau_2\right], \tag{37}$$

and h^E is the one-electron Hamiltonian defined for the excited state. The $\langle|V|\rangle$ integrals in Eq. (35) are the sole remaining interelectronic contributions from Eqs. (33) and (34), all others have cancelled. The first line of Eq. (35) consists of the diagonal crystal field terms; the next two lines are antibonding orbital overlap contributions; lines 4 and 5 are covalent contributions from the unpaired bonding t and e_v orbitals involved in the transition[23]; and the last two summations are covalent terms associated with the odd unpaired e_u bonding electrons. Within the cluster approximation Eq. (35) is an exact expression, to second order, for 10 Dq subject to the following three conditions:

(1) The Hamiltonian must be self-consistently defined for the set of Ψ's actually used, in which case Eq. (35) is correct independent of whether the Ψ's are, or are not, eigenfunctions of Eq. (6).

(2) The radial behavior of the φ and ψ atomic orbitals (not necessarily equal to that of free ion H-F functions), must be the same for the two crystal field states, otherwise there are additional contributions to 10 Dq.

(3) It is assumed that the ligand 1s shells do not enter into the bonding. Otherwise, there are additional covalent contributions from unpaired bonding $\Psi_{1s}{}^B$ orbitals. Such contributions are straightforwardly added to Eq. (35).

As already noted, the last four lines of Eq. (35) arise from the odd unpaired $\Psi_{i,u}$ bonding orbitals common to both crystal field states. These and the $V_{i,u}{}^\gamma$ contributions to the other lines sum to zero if an excited state parameter $\gamma_{i,u}{}^{EB}$ (and its associated matrix elements), equals its ground state, $\gamma_{i,u}{}^B$, counterparts. Assuming this equality to hold, Eq. (35) becomes more simply,

$$\begin{aligned}10\,Dq=&\{\langle\varphi_e|h^E|\varphi_e\rangle-\langle\varphi_t|h|\varphi_t\rangle\}+\{S_s{}^2[\langle\chi_s|h^E|\chi_s\rangle+\langle\varphi_e|h^E|\varphi_e\rangle]-2S_s\langle\chi_s|h^E|\varphi_e\rangle\}\\&+\{S_\sigma{}^2[\langle\chi_\sigma|h^E|\chi_\sigma\rangle+\langle\varphi_e|h^E|\varphi_e\rangle]-2S_\sigma\langle\chi_\sigma|h^E|\varphi_e\rangle\}-\{S_\pi{}^2[\langle\chi_\pi|h|\chi_\pi\rangle+\langle\varphi_t|h|\varphi_t\rangle]-2S_\pi\langle\chi_\pi|h|\varphi_t\rangle\}\\&-\{(\gamma_{\pi\downarrow}{}^{EB})^2[\langle\chi_\pi|h^E|\chi_\pi\rangle-\langle\varphi_t|h^E|\varphi_t\rangle]-2\gamma_{\pi\downarrow}{}^{EB}\langle\chi_\pi|h^E|\varphi_t\rangle+2\gamma_{\pi\downarrow}{}^{EB}S_\pi\langle\chi_\pi|h^E|\chi_\pi\rangle\}\\&+\{(\gamma_{s\downarrow}{}^B)^2[\langle\chi_s|h|\chi_s\rangle-\langle\varphi_e|h|\varphi_e\rangle]-2\gamma_{s\downarrow}{}^B\langle\chi_s|h|\varphi_e\rangle+2\gamma_{s\downarrow}{}^BS_s\langle\chi_s|h|\chi_s\rangle\}\\&+\{(\gamma_{\sigma\downarrow}{}^B)^2[\langle\chi_\sigma|h|\chi_\sigma\rangle-\langle\varphi_e|h|\varphi_e\rangle]-2\gamma_{\sigma\downarrow}{}^B\langle\chi_\sigma|h|\varphi_e\rangle+2\gamma_{\sigma\downarrow}{}^BS_\sigma\langle\chi_\sigma|h|\chi_\sigma\rangle\}\\&+\langle|V_{xy}{}^{\gamma E}|\rangle+\langle|V_e{}^\gamma|\rangle+\langle|V_{i,v}{}^S|\rangle.\end{aligned} \tag{38}$$

The three $\langle|V|\rangle$ terms have not been written out explicitly, in anticipation of the fact that we will evaluate this equation in terms of the approximate Hamiltonian, h_0, which does not contain V_s and V_γ terms. Hence, the $\langle|V|\rangle$ corrections of Eqs. (35) and (38) need not be made since these interelectronic effects were not counted twice in our sum over ϵ's. We will thus omit the last line when evaluating Eq. (38) with h_0. Without these terms, Eq. (38) would be identical with the traditional one given in terms of antibonding covalency, provided that (1) the ground-state unpaired $\gamma_{s\downarrow}{}^B$ and $\gamma_{\sigma\downarrow}{}^B$ values and their associated matrix elements are identical with those of the excited state $e_{s\downarrow}{}^{EA}$ and $e_{\sigma\downarrow}{}^{EA}$ electrons and (2) a similar equality holds for the unpaired $p_{\pi\downarrow}{}^{EB}$ and $p_{\pi\downarrow}{}^A$ contribitions. The present calculations indicate that these requirements are not met.

Before closing this section, we should note that, subject to two requirements, the unpaired bonding e electron covalent mixing contributing to 10 Dq is exactly that which is appropriate to the transferred hyperfine interactions. This differs with the antibonding orbital picture where ground-state antibonding spin ↑ covalency contributes to the hyperfine interaction and excited state antibonding spin ↓ covalency contributes to 10 Dq. The two requirements are: (1) that the covalent mixing of the two ground-state unpaired e^B orbitals be identical, a requirement fulfilled by symmetry considerations alone; and (2) that the "odd" e^B orbitals maintain constant covalency in the two cluster states, for

[23] When treating the covalent mixing of three orbitals (e.g., the $e_\downarrow{}^A$, $e_{s\downarrow}{}^B$, $e_{\sigma\downarrow}{}^B$) only two of which (the $e_{s\downarrow}{}^B$ and $e_{\sigma\downarrow}{}^B$) are occupied, there are covalent contributions to a quantity such as 10Dq. These include, first, the γ_s and γ_σ terms of Eq. (35) and second, nonzero $\gamma_{\sigma s}$ terms [see Eqs. (3)–(5) and related text] caused by nonzero $s-\sigma$ mixing. The $\gamma_{\sigma s}$ contributions enter in the third and higher orders in γ and S and were therefore not listed in Eq. (35). In addition, there are contributions arising from any nonzero overlap of closed Ni^{2+} shells with ligands, but these appear in third (and higher) order in 10 Dq.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

otherwise we have Eq. (35). It is reasonable to assume that this last requirement holds in a lower order theory but that, at some point, we must revert to using Eq. (35) where these orbitals contribute to 10 Dq.

VI. THE EVALUATION OF THE COVALENT MIXING AND THE ROLE OF SELF-ENERGY TERMS

We are interested in obtaining the unpaired bonding orbital covalency which contributes to 10 Dq and to transferred hyperfine effects. Also, as noted in Sec. II, independent estimates of the mixing occurring for the members of an antibonding-bonding pair supply us with a test of the internal consistency of our theory. With this factor in mind, we will estimate the covalency of all the occupied bonding and antibonding orbitals in the ground cluster state and of selected ones in the excited state. Let us now consider the process of estimating γ.

As already discussed, we wish to solve the H-F equations [Eq. (6)] defined[24] for the cluster, in a two-function space consisting of φ_t and χ_t for the t mixing, and a three-function space, made up of φ_e, χ_s and χ_σ for the e mixing, i.e., we solve 2×2 and 3×3 secular equations, respectively, for our Hamiltonian h. For the 3×3 solution, we need the matrix elements $\langle\chi_s|h|\chi_\sigma\rangle$ which were not considered by Sugano and Shulman. As these are intimately associated with the cluster approximation and also include important three- (and four-) center integrals and thereby divert us from the purpose of this paper, we shall not obtain these in the present treatment, deferring this matter, along with others which have been brought up, for a future effort involving the proper Hamiltonian, h, not h_0. We will instead explore the consequences of following the traditional view of assuming $\chi_s-\chi_\sigma$ mixing and overlap to be zero valued (i.e., $\gamma_{s\sigma}=\gamma_{\sigma s}=0$). In this approximation we obtain the following relation for any one of the γ values appropriate to Eq. (3):

$$S_i\langle\chi_i|h|\chi_i\rangle-\langle\varphi_1|h|\chi_i\rangle+\gamma_i[\langle\chi_i|h|\chi_i\rangle-\langle\varphi_i|h|\varphi_i\rangle]+\gamma_i^2[\langle\chi_i|h|\varphi_i\rangle-S_i\langle\varphi_i|h|\varphi_i\rangle]=0. \quad (39)$$

There are two roots to this equation: The $|\gamma|<1$ root is appropriate to the bonding orbital; the other, with $|\gamma|>1$, is appropriate to its orthogonal antibonding partner. Upon dropping the quadratic term, we obtain the Sugano-Shulman relation for γ_i, namely[25] [S&S III, Eq. (2.13)],

$$\gamma_i=\frac{\langle\varphi_i|h|\chi_i\rangle-S_i\langle\chi_i|h|\chi_i\rangle}{\langle\chi_i|h|\chi_i\rangle-\langle\varphi_i|h|\varphi_i\rangle}. \quad (40)$$

They also give a relation for λ_π [S&S III, Eq. (2.12)]

$$\lambda_\pi=\frac{\langle\varphi_t|h|\chi_\pi\rangle-S_\pi\langle\varphi_t|h|\varphi_t\rangle}{\langle\chi_\pi|h|\chi_\pi\rangle-\langle\varphi_\pi|h|\varphi_\pi\rangle}, \quad (41)$$

which we find is closely associated with the inverse of the second root of Eq. (39). We will obtain γ values appropriate to both bonding or antibonding mixing. We expect the smaller root of Eq. (39) and the result obtained from Eq. (40) to differ negligibly since the γ's are small; this will prove to be the case.

As discussed in Sec. III, in computing the matrix elements appearing in Eqs. (38)–(40), our H-F one-electron Hamiltonian, h, will be replaced by the approximate Hamiltonian h_0. Now, when evaluating the matrix element of a one-electron H-F Hamiltonian, one often may or may not, as one wishes, include the interelectronic Coulomb and exchange potential terms due to the electron for which the matrix element is being evaluated (in this case Ψ_i) because these terms, being equal, cancel one another. The inclusion of such self-energy terms leads to a common Hamiltonian for all electrons in the system, an important and often exploited feature of self-consistent H-F theory.[26,27] If by any chance the cancellation does not occur, these terms *must* be omitted from the Hamiltonian. Such a cancellation does not occur for h_0, since it is not a self-consistently defined Hamiltonian, and some ambiguity arises concerning the appropriate form of the self-energy term to be subtracted. Consider the evaluation of a matrix element appropriate to an antibonding orbital $\Psi_i{}^A$. The exact self-energy contribution to the potential is

$$\int\Psi_i{}^{A*}(r_2)\frac{1-P_{12}}{r_{12}}\Psi_i{}^A(r_2)d\tau_2, \quad (42)$$

but in view of the fact that h_0 is defined in terms of the (zero overlap) ionic ($Ni-F_6$) cluster [i.e., the first line of Eq. (8)], one would be subtracting out terms which did not appear in our Hamiltonian if we subtracted out Eq. (42). A possible choice, *consistent* with using the interelectronic potential of h_0, is to omit the Coulomb and exchange potential terms associated with the parent $3d\varphi_i$ (i.e., the overlap ionic counterpart of $\Psi_i{}^A$), as was done by Sugano and Shulman in the course of estimating antibonding covalency. Likewise, the equivalent χ_i contributions would then be omitted when estimating bonding covalency. The use of an approximate Hamiltonian has led to this choice of an approximate self-energy term. We will consider the effect of going to the more exact term after

[24] Since the antibonding-bonding pair mixing does not contribute to the cluster's total energy, we cannot properly derive the H-F equation appropriate to that mixing for such a derivation must follow from application of the variation principle to the total energy. One can write a one-electron H-F Hamiltonian [Eq. (7)] by inspection and solve for the pair mixing. This we will do but we must remember that the solution has a mathematical but not a physical meaning.

[25] Note the typographical error in the sign of the $S\langle\chi|h|\chi\rangle$ term in Eq. (2.13) of S&S III.

[26] For example, see A. J. Freeman and R. E. Watson, *Treatise on Magnetism*, edited by G. Rado and H. Suhl (Academic Press Inc., New York, to be published).

[27] Providing that we do not constrain spin pairs of bonding or antibonding orbitals to have the same covalent mixing. Such a requirement would involve us with the nonorthogonality associated with the conventional Hartree-Fock theory (Ref. 26).

first considering the implications of this (zero-overlap) ionic approximation.

The question arises, as to whether the p_π bonding and antibonding matrix elements, for example, evaluated with different self-energy terms will, on insertion into Eqs. (40) and (41), yield $\lambda_\pi{}^A$ and $\gamma_\pi{}^B$ values which satisfy the orthogonality relation [cf. Eq. (5)]. A failure to satisfy Eq. (5) may arise from approximations in our Hamiltonian, in the treatment of the self-energy terms or in evaluating matrix elements; but, whatever its source, this failure implies a breakdown of theory. The matrix elements, for bonding and antibonding orbitals, are best compared by writing them for the proper ionic Hamiltonian, h_0 [the first line of Eq. (8) minus the appropriate φ or χ self-energy terms] and for a Hamiltonian, h_0', without the self-energy subtraction [literally the first line of Eq. (8)]. (Up to this point, we have not considered the role of self-energy terms in discussing the h_0 Hamiltonian. We here redefine h_0 to include the above self-energy term so as to conform to existing usage.) Upon doing this, we have the relations

$$\begin{aligned}
&\langle\varphi_i|h_0'|\chi_i\rangle^A-\langle\varphi_i|h_0|\chi_i\rangle^A=\langle\varphi_i\varphi_i|\varphi_i\chi_i\rangle-\langle\varphi_i\varphi_i|\varphi_i\chi_i\rangle,\\
&\langle\varphi_i|h_0'|\chi_i\rangle^B-\langle\varphi_i|h_0|\chi_i\rangle^B=\langle\chi_i\chi_i|\chi_i\varphi_i\rangle-\langle\chi_i\chi_i|\chi_i\varphi_i\rangle,\\
&\langle\varphi_i|h_0'|\varphi_i\rangle^A-\langle\varphi_i|h_0|\varphi_i\rangle^A=\langle\varphi_i\varphi_i|\varphi_i\varphi_i\rangle-\langle\varphi_i\varphi_i|\varphi_i\varphi_i\rangle,\\
&\langle\chi_i|h_0'|\chi_i\rangle^B-\langle\chi_i|h_0|\chi_i\rangle^B=\langle\chi_i\chi_i|\chi_i\chi_i\rangle-\langle\chi_i\chi_i|\chi_i\chi_i\rangle.
\end{aligned}\tag{43}$$

The integrals on the right-hand side of Eq. (43), coming from the Coulomb and exchange self-energy terms, obviously cancel, indicating that these matrix elements are independent of whether such terms are included in the Hamiltonian. However, we also have

$$\begin{aligned}
&\langle\varphi_i|h_0'|\varphi_i\rangle^B-\langle\varphi_i|h_0|\varphi_i\rangle^B=\langle\varphi_i\varphi_i|\chi_i\chi_i\rangle-\langle\varphi_i\chi_i|\varphi_i\chi_i\rangle,\\
&\langle\chi_i|h_0'|\chi_i\rangle^A-\langle\chi_i|h_0|\chi_i\rangle^A=\langle\varphi_i\varphi_i|\chi_i\chi_i\rangle-\langle\varphi_i\chi_i|\varphi_i\chi_i\rangle,
\end{aligned}\tag{44}$$

and here the cancellation of terms does not occur. Noting that the bonding and antibonding matrix elements of h_0' are, by definition, identical, gives us the following relationships between bonding and antibonding h_0 behavior for a bonding-antibonding pair:

$$\begin{aligned}
&\langle\varphi_i|h_0|\chi_i\rangle^A=\langle\varphi_i|h_0|\chi_i\rangle^B,\\
&\langle\varphi_i|h_0|\varphi_i\rangle^A=\langle\varphi_i|h_0|\varphi_i\rangle^B+\langle\varphi_i\varphi_i|\chi_i\chi_i\rangle-\langle\varphi_i\chi_i|\varphi_i\chi_i\rangle,\\
&\langle\chi_i|h_0|\chi_i\rangle^A=\langle\chi_i|h_0|\chi_i\rangle^B-\langle\varphi_i\varphi_i|\chi_i\chi_i\rangle+\langle\varphi_i\chi_i|\varphi_i\chi_i\rangle.
\end{aligned}\tag{45}$$

The two-electron integrals are most definitely nonzero.[28] But, what is more important, we will see that the $\langle|h_0|\rangle^A$'s, on insertion into, say, Eq. (39) yield a different γ than do the $\langle|h_0|\rangle^B$'s. This means that the theory, with its present approximations, fails to yield the required bonding-antibonding pair orthogonality. We will see this failure to be severe.

Not only does the theory suffer this internal inconsistency but it is difficult to ascertain which of the approximations is most at fault. Use of the full Hamiltonian of Eq. (8), the exact self-energy term [Eq. (42)], and extreme care in the evaluation of matrix elements would resolve this problem but would also be beyond the scope of this paper. We do wish to inspect one feature of the theory here, namely, given a Hamiltonian (in this case h_0'), what part do the self-energy terms play in the behavior of individual matrix elements and, in turn, on the resulting estimates of covalency. Such an investigation will further indicate the nature of the computed covalency and its sensitivity to computational details (including assumed covalency) while enabling us to avoid the serious numerical problems associated with a proper treatment with the proper covalent Hamiltonian. We believe this to justify a partial handling of the problem.

Let us define a Hamiltonian, H, which is equal to h_0' minus self-energy terms defined for the covalent Ψ_i's in Eq. (42). One may then obtain equations similar to (43) or (44) such as

$$\begin{aligned}
&\langle\varphi_i|h_0'|\chi_i{}^A\rangle-\langle\varphi_i|H|\chi\rangle^A\\
&\quad=N_i\{\langle\varphi_i\varphi_i|\varphi_i\chi_i\rangle-\langle\varphi_i\varphi_i|\varphi_i\chi_i\rangle-2\lambda_i\langle\varphi\chi|\varphi\chi\rangle\\
&\qquad+\lambda_i\langle\varphi\chi|\varphi\chi\rangle+\lambda_i\langle\varphi\varphi|\chi\chi\rangle+\lambda_i{}^2\langle\chi\chi|\varphi\chi\rangle\\
&\qquad\qquad-\lambda_i{}^2\langle\chi\varphi|\chi\chi\rangle\}\\
&\quad=-\lambda_i\{\langle\varphi\chi|\varphi\chi\rangle-\langle\varphi\varphi|\chi\chi\rangle\}+0(\lambda^3)
\end{aligned}\tag{46}$$

or

$$\begin{aligned}
\langle\varphi_i|H|\chi_i\rangle^A=\langle\varphi_i|h_0|\chi_i\rangle^A-\lambda_i\{&\langle\varphi_i\varphi_i|\chi_i\chi_i\rangle\\
&-\langle\varphi_i\chi_i|\varphi_i\chi_i\rangle\}.
\end{aligned}\tag{47}$$

For the other matrix elements we obtain

$$\begin{aligned}
&\langle\varphi_i|H|\chi_i\rangle^B=\langle\varphi_i|h_0|\chi_i\rangle^B+\gamma_i\{\langle\varphi_i\varphi_i|\chi_i\chi_i\rangle\\
&\qquad\qquad-\langle\varphi_i\chi_i|\varphi_i\chi_i\rangle\},\\
&\langle\varphi_i|H|\varphi_i\rangle^A=\langle\varphi_i|h_0|\varphi_i\rangle^A-\lambda^2\{\langle\varphi_i\varphi_i|\chi_i\chi_i\rangle\\
&\qquad\qquad-\langle\varphi_i\chi_i|\varphi_i\chi_i\rangle\},\\
&\langle\chi_i|H|\chi_i\rangle^A=\langle\chi_i|h_0|\chi_i\rangle^A+[1-N_i{}^2]\\
&\qquad\qquad\times\{\langle\varphi_i\varphi_i|\chi_i\chi_i\rangle-\langle\varphi_i\chi_i|\varphi_i\chi_i\rangle\},\\
&\langle\varphi_i|H|\varphi_i\rangle^B=\langle\varphi_i|h_0|\varphi_i\rangle^B+[1-(N_i')^2]\\
&\qquad\qquad\times\{\langle\varphi_i\varphi_i|\chi_i\chi_i\rangle-\langle\varphi_i\chi_i|\varphi_i\chi_i\rangle\},\\
&\langle\chi_i|H|\chi_i\rangle^B=\langle\chi_i|h_0|\chi_i\rangle^B-\gamma^2\{\langle\varphi_i\varphi_i|\chi_i\chi_i\rangle\\
&\qquad\qquad-\langle\varphi_i\chi_i|\varphi_i\chi_i\rangle\},
\end{aligned}\tag{48}$$

where terms of order λ^3, γ^3, or higher have been dropped. We will report solutions of Eq. (39) utilizing the linear covalent contributions to the off-diagonal $\langle\varphi|H|\chi\rangle^A$ and $\langle\varphi|H|\chi\rangle^B$ matrix elements (omitting second and

[28] The fact that self-energy terms cause $\langle|h|\rangle^B$ matrix elements to differ from their $\langle|h|\rangle^A$ counterparts is, in itself, a necessary but not sufficient condition for a computed γ^A to differ from γ^B. A computation with the exact one-electron Hamiltonian and with the exact self-energy terms [Eq. (42)] will have $\langle|h|\rangle^B\neq\langle|h|\rangle^A$ for the $\langle\chi|h|\chi\rangle$, $\langle\chi|h|\varphi\rangle$ and $\langle\varphi|h|\varphi\rangle$ matrix elements, one will obtain identical γ values. In the present case, the differences, in $\langle\varphi|h_0|\chi\rangle$ matrix elements will be seen to cause severe differences between a γ^A and its partner γ^B.

higher order corrections). We will see the computed covalency to be sensitive to the estimates of covalency used in evaluating these matrix elements.

We have so far considered the differences which do, but should not, occur in the estimates appropriate to members of a bonding-antibonding pair. Let us now consider how these do (and should) differ with that appropriate to an unpaired bonding orbital. When obtaining the $\langle\varphi_i|h|\varphi_i\rangle$ and $\langle\varphi_i|h|\chi_i\rangle$ matrix elements for *either* member of a bonding-antibonding pair, the Coulomb and exchange contributions of φ_i to V_m [see Eq. (9)] cancel after the manner of the right-hand sides of Eqs. (43). The Coulomb repulsions of the *seven* other Ni $3d$ electrons remain, and the potential contributed by the Ni ion to these matrix elements is that characteristic of Ni^{2+}. However, no such cancellation occurs when evaluating the same matrix elements for an unpaired bonding orbital because the φ_i involved in the bonding is not one of the *eight* contributing to the Ni potential. Eight $3d$ electrons make Coulomb contributions in this case, causing the potential to be characteristic of Ni^{+}, not of Ni^{2+}. [Such a $3d$ electron Coulomb contribution to $\langle\varphi|h|\varphi\rangle$ which is $\sim$1 a.u., is to be compared with (1) the denominators of Eq. (40) which are as small as 0.25 a.u., (2) the $\langle\varphi\varphi|\chi\chi\rangle$ Coulomb self-energy terms of Eqs. (44) and (45), which are $\sim$0.3 a.u. and (3) $3d-3d$ exchange interactions, which are the order of 0.1 a.u.] It must be emphasized that this difference occurs whether we evaluate matrix elements with h_0 or with the exact self-consistent Hamiltonian h. In other words, such an effect on the current results involving h_0, is indicative of what actually occurs for the exact self-consistent LCAO treatment of the cluster.

From our experience with the potential terms of Sec. III, we should have anticipated the differences in the Ni potentials appropriate to the various $\langle\varphi|h|\varphi\rangle$ and $\langle\varphi|h|\chi\rangle$ matrix elements. The fact that these differences occur is a key to the intrinsically different nature of the covalency of a bonding-antibonding pair on one hand and an unpaired bonding orbital on the other. The magnitude (1 a.u.) of the difference in the $\langle\varphi|h|\varphi\rangle$ matrix elements has observable quantitive repercussions on one's theoretical estimates and makes it imperative that the pertinent covalent mixing be investigated.

VII. THE MATRIX ELEMENTS

In this section we evaluate the h_0 matrix elements appropriate to the various bonding and antibonding cases of interest, and examine the effects due to the net $3d$ spin on the Ni^{2+} ion. Wherever possible, we will rely on the one- and two-electron integrals already obtained in S&S III and the same approximations have been made when evaluating the V_L matrix elements. The additional required integrals have been evaluated with conventional (or restricted) analytic H-F (hence-forth denoted as RHF) functions for[29] Ni^{2+} and[30] F^{-}. However, no additional three- and four-center integrals were obtained for this work although they are required in a proper treatment of the theory. The Switendick-Corbato IBM 7090 program[31] was used for such two-center integrals as arose.

TABLE I. The one-electron energies (Ref. 32) of the RHF $3d$ orbitals, for the $^3F(M_L=L,\ M_s=S)$ state of Ni^{2+}, as defined by Eq. (52). In these tables, the appropriate m_s value is denoted by the arrow (↑ and ↓ denote $m_s=\frac{1}{2}$ and $-\frac{1}{2}$, respectively). Also included is the ϵ_{RHF} value. All quantities are in atomic units.

ϵ_{3d}	$m_s=$	↑	↓	
$m_l=2$		−1.46199	−1.39472	
1		−1.44377	−1.34007	
0		−1.41399	−1.34007	
−1		−1.44377	−0.38057	unoccupied
−2		−1.46199	−0.38057	orbitals
$\epsilon_{RHF}=-1.41254$				

A. $\langle\varphi_i|h_0|\varphi_i\rangle$

It is in this matrix element that $3d$ shell exchange and Ni^{+} versus Ni^{2+} potential repercussions are most important. We are constructing our molecular orbitals from free ion H-F orbitals and this suggests that we make use of the familiar[25] one-electron Hartree-Fock equation,

$$\mathcal{H}_{Ni}\varphi_i(\mathbf{r},\boldsymbol{\sigma})=\epsilon_i\varphi_i(\mathbf{r},\boldsymbol{\sigma}), \tag{49}$$

when evaluating $\langle\varphi_i|h_0|\varphi_i\rangle$. Here φ_i is a one-electron spin orbital (i.e., a function of space and spin), ϵ_i is its H-F energy eigenvalue, and $\mathcal{H}_{Ni}$ is the one-electron H-F Hamiltonian for Ni^{2+}, consisting of kinetic, nuclear potential, and interelectronic Coulomb and exchange terms. With the self-energy terms included, $\mathcal{H}_{Ni}$ is independent[26] of which Ni^{2+} orbital it operates on and is related to h_0' by

$$h_0'=\mathcal{H}_{Ni}+V_L(r). \tag{50}$$

Since our $3d\varphi_i$'s are RHF functions this suggests that we simply have

$$\langle\varphi_i|h_0'|\varphi_i\rangle=\epsilon_{RHF}+\langle\varphi_i|V_L|\varphi_i\rangle, \tag{51}$$

where ϵ_{RHF} is the $3d$ eigenvalue. Unfortunately, this equation does not hold, for the RHF $Ni^{2+}\varphi$'s are not exact eigenfunctions of Eq. (49). RHF theory requires[26] a single radial function per shell. For an open-shell ion this is only obtained by constraints, for there exists no single radial function which, when inserted into the occupied φ_i's, will satisfy Eq. (49) for all electrons in a shell. The immediate implications of this can be seen by first inspecting Table I where the values[32] of

$$\epsilon_i\equiv\langle\varphi_i|\mathcal{H}_{Ni}|\varphi_i\rangle \tag{52}$$

TABLE II. One-electron energies for the cubic $3d$ orbitals of Ni^{2+} as defined by Eq. (52) for the configurations indicated in the text. All quantities are in atomic units.

$\epsilon_{t\uparrow}=-1.42742$	$\epsilon_{e\downarrow}=-0.38057$
$\epsilon_{t\downarrow}=-1.35829$	$\epsilon_{e\downarrow}{}^{E}=-1.35829$
$\epsilon_{e\uparrow}=-1.47226$	$\epsilon_{t\downarrow}{}^{E}=-0.38057$
$\epsilon_{\mathrm{RHF}}=-1.41254$	

for the various occupied and unoccupied $3d$ orbitals of the RHF Ni^{2+} ion are listed. Also included is ϵ_{RHF}, which was used in S&S III when evaluating Eq. (51) for $\langle\varphi_i|h_0|\varphi_i\rangle$. We see that the occupied orbital ϵ_i's vary by as much as 0.12 a.u. Energy denominators as small as 0.22 a.u. occur in Eqs. (40) and (41), suggesting that these variations can observably affect the evaluation of these equations. One notes that the smaller ϵ_i's occur for occupied $3d$ orbitals of minority spin as one would expect since exchange lowers an electron's energy. The unoccupied orbital ϵ's lie approximately 1 a.u. higher than the others and show (cf. the discussion in the preceding section) the Coulomb energy penalty of attempting to place a ninth $3d$ electron on the ion. This penalty, which the unpaired bonding orbital covalency must pay, greatly influences results.

One may rigorously use Eq. (51) providing one inserts the ϵ_i, defined by Eq. (52) for the orbital *and* multielectron Ni state of interest. The ϵ_i's of interest are readily obtained with the available[29] integrals and are listed in Table II. The resulting $\langle\varphi_i|h_0|\varphi_i\rangle$'s evaluated using Eq. (51), with self-energy terms properly accounted for and utilizing the S&S III approximate values for the $\langle\varphi_i|V_L|\varphi_i\rangle$'s are given in Table III. Also listed for comparison are the matrix elements as obtained by Sugano and Shulman; these are $\langle\varphi_i|h_0|\varphi_i\rangle^A$ values.

B. $\langle\chi_i|h_0|\varphi_i\rangle$

If one assumes Eq. (49) to hold, then these matrix elements are obtained by first evaluating

$$\langle\chi_i|h_0'|\varphi_i\rangle=\langle\chi_i|\mathcal{H}_{\mathrm{Ni}}|\varphi_i\rangle+\langle\chi_i|V_L|\varphi_i\rangle$$
$$=\epsilon_{\mathrm{RHF}}S_i+\langle\chi_i|V_L|\varphi_i\rangle. \quad (53)$$

TABLE III. The matrix elements $\langle\varphi|h_0|\varphi\rangle$ for bonding (B), antibonding (A), and excited configuration (E) covalent mixing. All quantities are in atomic units.

		S&S III values			
$t_{\uparrow}{}^{A}$		0.1216	(0.1365)	$t_{\uparrow}{}^{B}$	−0.1358
$t_{\downarrow}{}^{A}$		0.1907	(0.1365)	$t_{\downarrow}{}^{B}$	−0.0667
$e_{\uparrow}{}^{A}$	(s or p_σ)	0.0604	(0.1202)	$e_{\uparrow}{}^{B}(s)$	−0.2058
				$e_{\uparrow}{}^{B}(p_\sigma)$	−0.2178
$e_{\downarrow}{}^{EA}$		0.1744	(0.1202)	$e_{\downarrow}{}^{EB}(s)$	−0.0918
				$e_{\downarrow}{}^{EB}(p_\sigma)$	−0.1038
				$e_{\downarrow}{}^{B}(s)$	0.8859
				$e_{\downarrow}{}^{B}(p_\sigma)$	0.8739
				$t_{\downarrow}{}^{EB}$	0.9110

But since the φ_i's are not exact eigenfunctions of that equation, the $\langle\chi_i|\mathcal{H}_{\mathrm{Ni}}|\varphi_i\rangle$ contribution should not be estimated in this way. This contribution has, with one approximation, been evaluated explicitly and the results appear in Table IV. The one approximation, necessitated by numerical inaccuracies in the $1s$ integral, consists of omitting the Coulomb potential term due to the $1s^2$ shell, and compensating for this with a nuclear potential term for a nuclear charge two less than that of Ni. Otherwise, the Switendick-Corbato program was used to obtain all integrals occurring in the $\langle\chi_i|\mathcal{H}_{\mathrm{Ni}}|\varphi_i\rangle$'s. The $\epsilon_{\mathrm{RHF}}S_i$ products are included in Table IV and we see that these differ but slightly from the exact values, indicating that assuming Eq. (42) has less significant repercussions here than it does for $\langle\varphi|h|\varphi\rangle$ matrix elements.

TABLE IV. Values of $\langle\chi_i|\mathcal{H}_{\mathrm{Ni}}|\varphi_i\rangle$ and $\epsilon_{\mathrm{RHF}}S_i$ (with S_i taken from S&S III) for ground and excited (E) configuration covalent mixing. All quantities are in atomic units.

	$\langle\chi_i\|\mathcal{H}_{\mathrm{Ni}}\|\varphi_i\rangle$	$\epsilon_{\mathrm{RHF}}S_i$
$t_{\uparrow}$	−0.10528	−0.1067
$t_{\downarrow}$	−0.10406	−0.1067
$e_{\uparrow}(s)$	−0.11751	−0.1150
$e_{\uparrow}(p_\sigma)$	−0.15150	−0.1564
$e_{\downarrow}{}^{E}(s)$	−0.11751	−0.1150
$e_{\downarrow}{}^{E}(p_\sigma)$	−0.14695	−0.1564
$e_{\downarrow}(s)$	−0.08478	...
$e_{\downarrow}(p_\sigma)$	−0.09572	...
$t_{\downarrow}{}^{E}$	−0.0739	

Using the S&S III estimates of the $\langle\chi_i|V_L|\varphi_i\rangle$ contributions, the $\langle\chi_i|h_0|\varphi_i\rangle$ matrix elements are given in Table V. As we see from Eqs. (45), these matrix elements, unlike $\langle\chi|h_0|\chi\rangle$ and $\langle\varphi|h_0|\varphi\rangle$, are independent of whether we are dealing with bonding or antibonding orbitals. The matrix elements are sensitive to whether they are for an antibonding-bonding pair or for an unpaired bonding orbital [$e(s)_{\downarrow}$, $e(p\sigma)_{\downarrow}$, and $t_{\downarrow}{}^{E}$]. We see values for the latter to be appreciably smaller in magnitude.

TABLE V. The matrix elements $\langle\chi_i|h_0|\varphi_i\rangle$ for ground and excited (E) configuration covalent mixing.[a] All quantities are in atomic units.

	Present calculation	S&S III
$t_{\uparrow}$	−0.0428	(−0.0443)
$t_{\downarrow}$	−0.0416	
$e_{\uparrow}(s)$	−0.1185	(−0.1160)
$e_{\uparrow}(p_\sigma)$	−0.0937	(−0.0986)
$e_{\downarrow}{}^{E}(s)$	−0.1185	
$e_{\downarrow}{}^{E}(p_\sigma)$	−0.0891	
$e_{\downarrow}(s)$	−0.0858	
$e_{\downarrow}(p_\sigma)$	−0.0379	
$t_{\downarrow}{}^{E}$	−0.0115	

[a] These matrix elements are independent of whether we are dealing with bonding or antibonding effects (see text).

C. $\langle \chi_i | h_0 | \chi_i \rangle$

The various values of this matrix element are readily obtained using the integrals appearing[33] in Table II of S&S III. The results appear in Table VI. Two features of the matrix element behavior should be noted. First, as expected, unlike the cases of $\langle \chi | h_0 | \varphi \rangle$ and $\langle \varphi | h_0 | \varphi \rangle$ matrix elements, the $\langle \chi | h_0 | \chi \rangle$ matrix elements appropriate to the unpaired bonding orbitals differ but trivially from the paired bonding orbital values. This small difference indicates that these matrix elements cannot compensate for the shifts, appearing in the unpaired bonding $\langle \varphi | h_0 | \chi \rangle$ and $\langle \varphi | h_0 | \varphi \rangle$ values, due to

TABLE VI. The matrix elements $\langle \chi_i | h_0 | \chi_i \rangle$ for bonding (B), antibonding (A) and excited configuration (E) covalent mixing. All quantities are in atomic units.

the Ni^+ potential. Secondly, we see a sign reversal, similar to the one in Table II, on going from the antibonding to the bonding member of a p_π or p_σ pair, which is again due to the self-energy terms of Eqs. (45). Their effect is to reverse the sign of the denominator of Eq. (40) and of the linear term of Eq. (39), a feature which will be of great importance to us when discussing results.

D. The Overlap Integrals, S_i

As already noted, the present investigation has utilized analytic HF functions in its evaluation of integrals. Sugano and Shulman used the same Ni $3d$, but different F^-, orbitals. They used simple two-exponential analytic approximations to the F^- functions of Froese,[34] a choice which was necessitated by the extensive nature of the computations. S_i values which were obtained for the current set of functions, along with their S&S III counterparts, are listed in Table VII; the differences serve as a measure of the error, due to wave function uncertainty, that should be attached to such integrals as these. The S_i obtained with Sonnenschein's F^- orbitals will be used in the following section.

TABLE VII. Comparison of overlap integrals obtained by S&S III and in this calculation.

	This calculation	S&S III
S_t	0.07077	0.07557
$S_e(s)$	0.07977	0.08143
$S_e(p_\sigma)$	0.10499	0.11071

[33] Two additional integrals are needed. Their values, in the notation of the S&S III Appendix, are: $(d\sigma, p\pi^+ \| d\delta^+, p\pi^-) = -0.000255$ a.u. $(d\sigma, p\pi^+ \| p\pi^-, d\delta^+) = 0.000039$ a.u. The $\langle \chi | h_0 | \chi \rangle$ integrals are the most seriously affected by the (almost) complete omission (Ref. 10) of three and four-center integrals.

[34] C. Froese, Proc. Cambridge Phil. Soc. 53, 206 (1957).

E. $\langle | H | \rangle$

From the definitions of Eqs. (47) and (48), we see that these matrix elements are functions of covalency and as we will want them for varying γ and λ values, we list in Table VIII the terms

$$[\langle \varphi_i \varphi_i | \chi_i \chi_i \rangle - \langle \varphi_i \chi_i | \varphi_i \chi_i \rangle],$$

which are necessary for evaluating these equations and the corresponding terms of Eq. (45) (used in the evaluation of Tables III and VI). These were obtained from integrals appearing in S&S III, which only include two-center integral contributions. It should be noted that by basing these terms on two-center integrals alone, we are making ligand χ self-energy corrections [the first equation of (44)] which are strictly compatible with the V_L in our h_0 Hamiltonian. Here too, the inclusion of three-center contributions to these integrals may have appreciable quantitative effects on these terms. In the calculations which follow, we will keep only the linear covalent contributions occurring in the $\langle \varphi_i | H | \chi_i \rangle$ matrix elements; the other elements will then keep their h_0 values. In view of our decision not to use a proper covalent Hamiltonian in this paper, a more detailed treatment seems unjustified.

VIII. RESULTS

Equations (39) and (40) have been evaluated with the h_0 matrix elements of the preceding section for the various bonding and antibonding γ's. The results appear in Table IX. Only the γ's, which are less than 1 in magnitude, have been reported for Eq. (39); as stated earlier, the larger roots are redundant.

An important feature of the results in Table IX concerns the internal consistency of a theory relying on h_0. We see that the $\gamma_i{}^A$ and $\gamma_i{}^B$, of a p_σ or p_π antibonding-bonding pair, differ in sign while those for s bonding differ in magnitude. As we have already stressed, a $\gamma_i{}^A$ must equal its partner $\gamma_i{}^B$ if the orthogonality requirements of Eqs. (5) are to be realized. Any failure to meet these requirements implies a

TABLE VIII. The $[\langle \varphi_i \varphi_i | \chi_i \chi_i \rangle - \langle \varphi_i \chi_i | \varphi_i \chi_i \rangle]$ values necessary for obtaining the covalent contributions to the $\langle | H | \rangle$ matrix elements. All quantities are in atomic units.

breakdown of the theory. The deviations seen in Table IX lead to antibonding-bonding orthogonality integrals as large as 0.6 instead of the required zero. Thus, the severity of this orthogonality breakdown renders any quantity estimated with these γ's at best suspect.

The γ_p sign reversals of Table IX have been caused by the reversal in sign of the $[\langle\chi|h_0|\chi\rangle-\langle\varphi|h_0|\varphi\rangle]$ term of Eqs. (39)–(41), due to self-energy effects. We expect a similar sign reversal in this term if we go to a theory utilizing the exact self-consistent Hamiltonian (and the exact self-energy expressions). The only way in which this exact theory can then yield a common $\gamma_p{}^A$ and $\gamma_p{}^B$ will be if $\langle\varphi|h|\chi\rangle$ reverses sign as well (note that here we refer to a matrix element of h, not h_0). We will shortly see indications that this does indeed occur.

Three other features of the results of Table IX should be viewed before we leave them. First, Eq. (40) and the more exact (39) give results of similar character but occasionally differ by as much as 10%. Secondly, the difference in γ's, for pairs of orbitals differing only in spin, are not negligible. These do not affect our predictions for Ni^{2+} but such effects are of sufficient magnitude to observably affect the transferred hyperfine spectrum associated with an ion such as Cr^{3+} (cf. Sec. IV). Finally, we see the unpaired bonding orbital γ values to be appreciably smaller than their paired orbital antibonding counterparts, suggesting that one must not assume them equivalent and that one must utilize the unpaired bonding results when estimating 10 Dq or some other experimental parameter. The large uncertainty which one must attach to the antibonding γ's (due to the antibonding-bonding pair breakdown) makes this comparison tenuous. The results which we will now inspect, also indicate substantial differences between the γ^A and unpaired γ^B behavior.

We are not prepared in the present paper to attempt a calculation involving the full Hamiltonian, h, of Eq. (8), but we do wish to gain some idea of the sensitivity of the predictions to covalency. To do this we will go over to the covalent treatment of the self-energy correction, utilizing the H matrix elements of Eqs. (47) and (48) (actually we will only consider the linear contributions to the $\langle\varphi|H|\chi\rangle$'s). Computing γ_i's as a function of assumed γ^0 values (appearing in $\langle\varphi|H|\chi\rangle$), we obtain the results of Table X. We see that the bonding-antibonding pair results are quite sensitive to this covalent contribution and that the negative γ's turn positive with increasing covalency because of a sign reversal in the $\langle\varphi|H|\chi\rangle$ elements. Since we have not used the proper Hamiltonian, we cannot expect complete convergence of the p electron bonding-antibonding γ_i pairs. The table also suggests that, given the Hamiltonian, we have underestimated the bonding-antibonding covalency if we use the antibonding results of Table IX.

In contrast with the paired bonding behavior, the unpaired bonding γ's of Table X show a tendency of $\langle\varphi|H|\chi\rangle$ to reverse sign. The $(\langle\chi|h_0|\chi\rangle-\langle\varphi|h_0|\varphi\rangle)$ term does not have a negative sign (as do the paired bonding elements), and this causes the trend toward negative γ's. The tendency towards increased paired orbital γ's and decreased unpaired bonding γ's serves to accentuate the different nature of the two types of covalent mixing.

TABLE X. The covalent mixing γ_i, as estimated using Eq. (39) with $\langle\varphi_i|H|\chi_i\rangle$ matrix elements for bonding (B), antibonding (A), and excited configuration (E) cases as a function of assumed covalency.

TABLE XI. The covalent mixing parameters, γ_i, as estimated using Eq. (39) with $\langle\varphi_i|H|X_i\rangle$ matrix elements for the unpaired $t_\downarrow^{EB}$, $e_\downarrow^B(s)$, and $e_\downarrow^B(\sigma)$ orbitals for assumed γ_i^0 values.

	Input γ_i^0	Computed γ_i
$e_\downarrow^B(s)$	0.01	0.015_4
$e_\downarrow^B(\sigma)$	0.05	0.047
$t_\downarrow^{EB}$	0.025	0.0236

In Table XI we have reevaluated the unpaired γ's with input $\langle\varphi|H|\chi\rangle$ covalent contributions suggested by Table X. The results show internal consistency and are in crude agreement with the noncovalent estimates of Table IX. This is largely due to the fact that the covalency is small and hence the covalent self-energy repercussions are small (but not insignificant).

So far we have only considered the occupied orbitals of the cluster and have not used the alternate approach of dealing with the antibonding holes. As stated earlier, such an approach is exactly equivalent to the unpaired bonding method provided that one maintains various restrictions of the present paper (e.g., common radial behavior for the φ's and χ's appropriate to an antibonding-bonding pair on the one hand and to the unpaired bonding orbitals and antibonding holes on the other). In a less restricted treatment, the two approaches need not be equivalent but one is then involved with an unrestricted H-F theory and its associated difficulties.[26] Estimates of antibonding hole γ values involve *no* self-energy corrections [e.g., in Eqs. (44), (47), and (48)], and the results must equal (to second order) their unpaired bonding counterparts in order to maintain orthogonality requirements. Using Eq. (40) and the matrix elements and integrals of Tables III–VIII, we obtain values of γ equal to 0.014_7, 0.048, and 0.024 for the $e(s)$, $e(\sigma)$, and t^E orbitals, respectively. These are in remarkable agreement with the values listed in Table XI.

While we seem to have converged on "self-consistent" unpaired bonding values in Table XI, this by no means implies that they are in detailed agreement with what will be yielded by the more exact theory. On the other hand, they differ strikingly with those bonding-antibonding results obtained either by Sugano and Shulman or in Tables IX and X. This is due to the Ni^+-Ni^{2+} Coulomb cancellation differences and will remain in the exact self-consistent field cluster theory.

In order to facilitate the discussion of 10 Dq and transferred hyperfine effects, the γ values, appropriate to the unpaired bonding and antibonding models, have been extracted from Tables IX to XI and listed together in Table XII. The S&S III antibonding results are included for comparison, as are the γ^A values suggested by Table X, since these would be appropriate to 10 Dq and the transferred hyperfine effects if we had adhered to the traditional (but incorrect) antibonding model. Different γ^A values are reported for 10 Dq and for the transferred hyperfine effects as spin $\downarrow$ parameters are appropriate to the former and spin $\uparrow$ to the latter in the antibonding model. Computed 10 Dq or f_i values based on these γ^A will not be reported since this would be incorrect. We merely note that the use of these γ^A's would predict even stronger covalent effects than those appearing in S&S III.

A. Transferred Hyperfine Effects

Values of f_i were determined by using Eqs. (23) and (24) for the various sets of unpaired bonding γ_i's reported (and defined) in Table XII. The separate spin $\uparrow$ and spin $\downarrow$ contributions to the f_i values are listed in Table XIII along with the experimental[11] values of f_i. The experimental f_s value includes the so-called $1s-2s$ cross-term correction.[16,17] Under the antibonding column, we list the S&S III predictions and give their pure overlap contribution separately from the covalent terms [cf. Eq. (20)].

The predicted f_s values are not in good agreement with experiment; the S&S III antibonding prediction is in somewhat better, but by no means good, agreement. What agreement there exists for the unpaired bonding results, arises largely from the spin $\uparrow$ electron overlap term rather than from the spin $\downarrow$ covalent terms.

The experimental f_σ value lies between the S&S III antibonding prediction and those of the present calculations. The theory is again seen to be in poor agreement with experiment. Quite aside from the fact that the S&S III predictions involve the inappropriate antibonding γ's, we do not find them in marked numerical agreement with experiment. The present results consistently and appreciably underestimate both f_s and f_σ. We will see a similar, and perhaps related, low value for 10 Dq. Let's consider that case now.

B. Crystal Field Splitting Parameter

Our expression for 10 Dq [Eq. (38)] was derived for the exact self-consistent Hamiltonian h, but, as discussed earlier, we shall use h_0 matrix elements to estimate the diagonal, overlap, and covalent contributions. Before proceeding to this task, it is instructive to

TABLE XII. The γ values appropriate to the unpaired bonding and the antibonding models for 10Dq and the transferred hyperfine effects as obtained from Tables IX–XI. Included are the S&S III antibonding estimates.

Experiment	=0.0378			

compare this estimate with the results appearing in S&S III. Such a comparison, however, cannot be done directly since their equation for 10 Dq [S&S III, Eq. (2.11)] differs with Eq. (38). For example, they have an e_s overlap term,

$$-S_s\langle\varphi_c|h|\chi_s\rangle+S_s^2\langle\varphi_c|h|\varphi_c\rangle \tag{54}$$

and a covalent contribution

$$-\gamma_s^{EA}\langle\varphi_c|h|\chi_c\rangle+S_s\gamma_s^{EA}\langle\varphi_c|h|\varphi_c\rangle. \tag{55}$$

Here, the second-order contributions appear in the "renormalization" term of their equation. Equations (54) and (55) obviously differ with lines 1 and 4 of Eq. (38) which are their counterparts here. Prior to comparing our results with S&S III, we must then ask whether the differing equations for 10 Dq in any way affect our observations. With this in mind, we will first evaluate Eq. (38) with the antibonding γ's and matrix elements of S&S III. [Equation (38) is readily converted for use in their antibonding model by replacing the values of γ and the matrix elements of the fifth line (for the t^{EB} electron) by the corresponding t^A values and similarly replacing the e_s^B and e_σ^B of the sixth and seventh lines by their counterparts e_s^{EA} and e_σ^{EA}, respectively.] The results of this calculation are given in Table XIV along with the values obtained by using Eq. (2.11) of S&S III, with and without second-order terms. Sugano and Shulman identified the linear terms, alone, as specific overlap or covalent contributions. With the inclusion of second-order terms, we see from Table XIV that the two equations yield the same *total* contribution from a particular electron but differ appreciably as to the relative roles of "covalent" and "overlap" effects. This implies that one equation or the other has incorrectly identified these contributions.

As already discussed, Eq. (38) was obtained from one-electron energy expressions [e.g., Eqs. (27), (28), and (30)] by the explicit evaluation of $\langle\Psi|h|\Psi\rangle$, a process which correctly yields the energy whether or not Ψ is an eigenfunction of h. The matrix elements of the resulting equations were then in no way manipulated. Equation (38) correctly yields a value of 10 Dq in the limit of zero covalency by the simple expedient of setting the γ values equal to zero: the terms which remain are considered to be diagonal or overlap contributions; those which are introduced in the process of allowing nonzero γ's are considered covalent effects. Thus, we conclude, Eq. (38) gives the proper breakdown of covalent and overlap effects.

Equation (2.11) of S&S III is based on one-electron energy expressions such as Eq. (29) which in turn was obtained from

$$\langle\varphi|h|\Psi\rangle/\langle\varphi|\Psi\rangle=\epsilon, \tag{56}$$

a relation which holds only if Ψ is an eigenfunction of the H-F equation [Eq. (6)], i.e., only for the *one* value of γ appropriate to that equation. One can alternatively obtain Eq. (29) by using Eq. (40) to remove a linear $-(\gamma+S)\langle\varphi|h|\chi\rangle$ term from Eq. (27). However, in doing this, one assumes a specific relation between γ, S, $\langle\varphi|h|\varphi\rangle$, $\langle\varphi|h|\chi\rangle$, and $\langle\chi|h|\chi\rangle$, namely, that γ be appropriate to the H-F solution. The resulting expression is simpler than Eq. (38), but it yields correct results only if the H-F γ value is inserted, and we can no longer correctly separate the covalent and overlap contributions by simple inspection, as we did for Eq. (38). From Table XIV we see that in S&S III the role of overlap effects was underestimated and that of covalency overestimated.

Computed unpaired bonding values for 10 Dq are listed in Table XV: Cases A and B (described earlier) have been merged since they yield identical results; the S&S III antibonding values[35] of Table XIV have again been included for comparison. All of these results have been obtained by using Eq. (38) and all indicate

TABLE XIV. The overlap and covalent contributions to 10 Dq obtained using Eq. (38) [modified as indicated in the text] and by using Eq. [S&S III, (2.11)] when evaluated with the matrix elements and γ^A's of S&S III. All quantities are in cm^{-1}.

		S&S III Eq. (2.11)	
	Eq. (38)	Linear terms only	Linear plus second-order terms
s contributions

that overlap effects dominate. The covalent contributions play a small role in the present calculations and the resulting 10 Dq values are observed to be substantially smaller than experiment.

Upon seeing such a disagreement with experiment, one might well inquire into the role played by uncertainties or errors in the γ values. From a given set of matrix elements (say, the unpaired bonding $\langle|h_0|\rangle$'s), an unpaired bonding γ, which is obtained variationally, gives the lowest one-electron (and in turn cluster) covalent crystal field energy obtainable for the orbital in question. Any deviation in the γ eigenvalues, for electrons appearing in the cluster ground state, will raise the ground-state energy, hence decreasing 10 Dq. Any similar deviation for a γ^E will raise the excited state energy, thereby increasing 10 Dq. If we utilize the unpaired bonding $\langle|h_0|\rangle$ integrals, any variation in the $\gamma_\sigma{}^B$ or $\gamma_s{}^B$, from the values of Table IX, will, therefore, decrease 10 Dq, while a variation in $\gamma_t{}^{EB}$ will increase it. Consider the effect of varying $\gamma_\sigma{}^B$, since it contributes the dominant covalent term in Table XV. If we assume Eq. (24) to be rigorously appropriate to the experimental f_σ value, we can obtain an experimental $\gamma_\sigma{}^B$ which is four times the value appearing in Tables IX and XI. Inserting this into Eq. (38) yields a e_σ covalent term of ~-1100 cm^{-1} which, holding all other contributions constant, leads to a 10 Dq of only $\sim$1000 cm^{-1}. Thus, a mismatch between a γ value and a set of matrix elements can severely affect a computed 10 Dq. The behavior of these matrix elements determines the result; they could be of sufficient accuracy to yield qualitatively correct γ values while being quite unsatisfactory for an estimate of 10 Dq.

As stated, Eq. (38) should be evaluated for the exact self-consistent Hamiltonian. In the absence of such computations, we can again gain some indication of the sensitivity of the results to matrix element behavior by evaluating Eq. (38) for 10 Dq with the bonding $\langle\varphi|H|\chi\rangle^B$ matrix elements of Eq. (48). Replacing a $\langle\varphi|h_0|\chi\rangle^B$ integral by $\langle\varphi|H|\chi\rangle^B$ affects both covalent and overlap contributions to 10 Dq. The results of Table X indicate that $\langle\varphi|H|\chi\rangle^B$ is smaller in magnitude than its partner $\langle\varphi|h_0|\chi\rangle^B$ for small covalent mixing (eventually reversing sign for greater covalency), and imply, in turn, a decrease in 10 Dq. Using $\langle\varphi|H|\chi\rangle^B$ values appropriate to the computed γ's, decreases the covalent and overlap contributions by $\sim$2000 cm^{-1} and yields a 10 Dq value $\approx$800 cm^{-1}, again increasing the numerical disagreement with experiment.

As was the case for the f_i's, the present calculations yield a 10 Dq which is appreciably less than experiment. These underestimates may be related; if so, more than a simple underestimate of γ values has occurred. We are involved with the more subtle, and more difficult, matter of matrix element behavior. Unfortunately, we have little evidence of whether a treatment involving the exact one-electron Hamiltonian, will or will not improve the numerical agreement with experiment. It is important to note that approximations were made[10] in estimating the V_L contributions to the $\langle\varphi|h_0|\chi\rangle$ and $\langle\chi|h_0|\chi\rangle$ matrix elements, but it is presently not obvious what repercussions, if any, these had on the results. This will be investigated in the future. Of greatest interest, of course, is the question of whether a treatment, such as the one outlined above, with the exact h, yields reasonable agreement with experiment. It need not.

IX. OTHER PARAMETERS AFFECTED BY COVALENCY

Other parameters are affected by covalency, including the orbital reduction factors appropriate to the interelectronic Slater F^k (or Racah B and C) integrals of multiplet theory[36] and to g shifts and spin-orbit coupling,[37] and the determination of superexchange[12] interactions and neutron form factors.[38]

In the antibonding approach to the expectation value of a one-electron operator, Op, one compares $\langle\Psi_i{}^A|\mathrm{Op}|\Psi_j{}^A\rangle$ with the free ion $\langle\varphi_i|\mathrm{Op}|\varphi_j\rangle$ value. Quite often, a reduction factor defined by

$$k=\langle\Psi_i{}^A|\mathrm{Op}|\Psi_j{}^A\rangle/\langle\varphi_i|\mathrm{Op}|\varphi_j\rangle \tag{57}$$

is introduced to account for observed differences. Such a factor is, in principle, straightforward to obtain but is, in practice, almost never evaluated because of difficulties associated with the $\langle\chi|\mathrm{Op}|\varphi\rangle$ and $\langle\chi|\mathrm{Op}|\chi\rangle$ matrix elements. The one case where Eq. (57) has been evaluated occurs for Stevens' orbital reduction factor, k,[37,14] appropriate to

$$\langle\Psi_i|l_m|\Psi_j\rangle=k_{i,j,m}\langle\varphi_{3di}|l_m|\varphi_{3dj}\rangle, \tag{58}$$

Digitized by Arya Samaj Foundation Chennai and eGangotri

where l_m is some component of the orbital angular momentum **l**. The $\varphi\chi$ and $\chi\chi$ contributions to k can be included and k tends to be less than one.

For other operators it is often assumed that the reduction effects are adequately predicted by the approximate relation

$$\langle \Psi_i^A | \mathrm{Op} | \Psi_j^A \rangle = N_i N_j \langle \varphi_{3di} | \mathrm{Op} | \varphi_{3dj} \rangle , \qquad (59)$$

where the N's are the normalization constants of Eq. (2). The $\langle \varphi | \mathrm{Op} | \chi \rangle$ and $\langle \chi | \mathrm{Op} | \chi \rangle$ terms are neglected, because they are inconvenient to evaluate and are, hopefully, negligible. Detailed inspection of the Stevens' orbital reduction factor suggests that this approximation is inadequate. Nevertheless, necessity led Tinkham to rely on such a normalization estimate when discussing spin-orbit effects.[14] Sugano and Shulman also used this approach when dealing[10] with the experimentally observed[11] reduction of the Racah B and C integrals from their free ion values (here, the normalization enters in the fourth power because two-electron terms are involved).

In the (multielectron) unpaired bonding approach, the simple one-electron picture of the traditional model is lost. As discussed earlier, the overlap effects arise from the bonding-antibonding pairs and covalent contributions come from the unpaired bonding electrons. Now, if one ignores the $[\varphi^*(\mathbf{r})\chi(\mathbf{r})]$ overlap density terms, overlap effects increase the charge and spin on the Ni^{2+} ion. Covalent mixing also increases the charge but decreases the spin (i.e., increases minority spin). Our picture of reduction effects therefore depends on whether we are dealing with a charge or a spin-dependent effect.

The complications introduced by the multielectron considerations increase the size of the computations, but introduce no formal difficulties. When dealing with a diagonal one-electron operator matrix element one need only sum over paired bonding-antibonding, and unpaired bonding contributions. The neutron magnetic form factor is an interesting example of this case. For an off-diagonal matrix element [e.g., between the ground and excited states of Eq. (25)] we must remember that as one changes the occupation of antibonding orbitals, the bonding orbitals are also changed by the change in covalency [it was this which invalidated Eq. (26) as an expression for $10\,Dq$]. Such variations cause the orbitals of one state to lose their orthonormality with respect to orbitals of the other. These complications are easily managed computationally by using a formalism such as Löwdin's[39] for dealing with nonorthogonal functions or by evaluating the matrix element in terms of the antibonding holes (s). The difficulties associated with $\langle \varphi | \mathrm{Op} | \chi \rangle$ and $\langle \chi | \mathrm{Op} | \chi \rangle$ matrix elements, mentioned above, also occur in the present approach. Detailed estimates of orbital reduction effects will not be attempted in this paper. Let us briefly consider an example using the incorrect normalization correction to make an estimate of a reduction effect. In Sugano and Shulman's calculations, the competition between the overlap and the (dominant) antibonding covalent contributions, led to reductions in the Racah B and C integrals equal to those actually observed. If one were to consider such simple normalization corrections for the unpaired bonding results, one finds that the antibonding overlap terms lead to a 3 and 4% *enhancement* of the Racah B and C integrals and a negligible covalent contribution from the unpaired bonding electrons.

Similarly, the small magnitude of the unpaired bonding covalent mixing leads to poor agreement [using, say, Eq. (59)] with the various experimental "k" values.

On several occasions in this section, we have cited difficulties associated with evaluating $\langle \chi | \mathrm{Op} | \varphi \rangle$ and $\langle \chi | \mathrm{Op} | \chi \rangle$ integrals. As this matter has implications for any more exact theory of crystal field effects, let us consider it briefly here. One is frequently interested in the highly singular r^{-3} operator appropriate to fine structure and hyperfine interactions. Matrix elements of this, and other, operators often nearly diverge because the LCAO wave functions were not required to have the proper singular behavior in the vicinity of each of the nuclei present (cf. the previous discussion of transferred hyperfine effects). Thus, even if the $\langle \varphi | \mathrm{Op} | \chi \rangle$ and $\langle \chi | \mathrm{Op} | \chi \rangle$ integrals are well behaved, their computed numerical values could be quite unrealistic. To our knowledge this matter has not been investigated and correcting for it promises to be a most interesting problem. Until this is done, one cannot claim complete quantitative understanding of the various orbital reduction effects.

X. CONCLUDING DISCUSSION

A large number of observations, some major and some minor, have been made, concerning the application of the LCAO molecular orbital method to crystal field theory, in this paper. Perhaps the most important of these is the fact that it is the *unpaired bonding* electrons and not the antibonding electrons, which make covalent contributions to physical observables. The importance of this observation is largely due to the *intrinsic* (hence, quantitative) difference in the nature of the two types of covalent mixing (based on diagonalizing the one-electron Hamiltonian). In addition, we saw indications that a theory based on the incomplete Hamiltonian h_0, is internally inconsistent, hence inadequate. The results, obtained with h_0, were also seen to be in poor agreement with experiment, the covalent contributions being significant but by no means dominant. We are not optimistic that the same theory, evaluated with the exact H-F Hamiltonian, will recapture good agreement with all experimental parameters. (These observations are, of course, made for the molecular orbital theory. The alternative Heitler-London approach to the crystal field prob-

lem[13] is being studied by Rimmer and Hubbard.[40] The Heitler-London method introduces covalency through configuration mixing and thereby loses the simplicity of the single determinant description of the MO theory.)

The fact that the unpaired bonding orbitals make the only covalent contributions to an observable, is not surprising. It has been recognized for some time that, when dealing with Hartree-Fock single determinants, any mixing between a pair of *occupied* orbitals in no way affects the expectation value of an operator.[36] This immediately implies that the covalency of the simultaneously occupied orbitals of a bonding-antibonding pair, cannot in any way, affect the prediction of any observable, for the (NiF_6) cluster states considered here.

Our understanding of orbital reduction effects and of the covalent "delocalization" of charge and spin differs in the two approaches. In particular, the covalency of a bonding-antibonding pair conserves charge on the metal ion while that of the unpaired bonding orbital involves a shift of charge from the ligands to the metal. Such differences in the *nature* of the two types of covalent mixing, have quantitative repercussions on the estimates of γ values (cf. Table XII). This is the most immediate quantitative reason for our preoccupation with unpaired bonding effects in this paper. As noted, the differences between computed paired and unpaired covalent mixing do not destroy the required spin symmetry of the cluster (i.e., it is an eigenfunction of S^2). The unpaired bonding approach may be viewed as the proper application of *restricted* H-F theory to the current cluster model for $KNiF_3$. Spin symmetry is maintained and what is more, if we apply the variation principle to the total energy of the cluster (with respect to the covalent mixing parameters), subject to the (RHF) requirement that the two types of covalent mixing be identical, one of necessity obtains the unpaired bonding (or antibonding hole) values. (The discussion for Cr^{3+} has, of course, encompassed UHF theory and the breakdown of spin symmetry.)

We also noted that a theory based on the mixing of free ion metal φ and ligand ψ orbitals and based on the approximate Hamiltonian, h_0, appeared unsatisfactory (quite aside from the fact that quantitative agreement with experiment was not obtained) for we saw serious internal inconsistencies in the covalent mixing estimated for bonding-antibonding pairs. The effects did not seem so severe for unpaired bonding γ values, an observation which is probably misleading.

[40] D. Rimmer and J. Hubbard (unpublished), who use the configuration interaction method of Keffer *et al.* (Ref. 13).

Having failed to produce even fair agreement with experiment, the question arises whether the same theory, evaluated for the exact self-consistent Hamiltonian h, will or will not produce agreement with experiment. We do not expect the current (free ion ψ and φ) cluster model to yield good agreement (say to 20%) for all the parameters considered in this paper. Should such a failure prove to be the case, there will again arise the old question of the variation of atomic orbital character away from the free ion behavior assumed in the present LCAO approach. Such a variation can take several forms: first, there is the matter of bulk expansion or contraction of the metal[17,41] ion (or ligands); secondly, there is the question of the extent to which $3d\varphi_t$ and φ_3 orbitals differ radially[42]; thirdly, there can be variation in orbital behavior from one multielectron state to the other; fourthly, one can allow different bonding and antibonding ψ's to have different radial parts for their φ and χ basis orbitals (involving us almost inevitably with a UHF theory); lastly, we have to consider the variation of orbitals centered on one nucleus when in the immediate vicinity of another, a matter important to orbital reduction and hyperfine effects. A bulk expansion of the metal φ orbitals may be expected with the covalent increase of charge occuring at the Ni site. This would improve numerical agreement with some experiments but it remains to be seen if this effect is fundamental to the current disagreement with experiment. Other questions which arise, include the role of correlation effects, one's ability to adequately define V_{ext} and the justification of the cluster model itself.

Finally, it is imperative that a proper crystal field cluster treatment, involving the exact Hamiltonian, be done. In this way, a number of the questions of the present paper would be resolved. We believe a calculation of this sort to currently be attainable with reasonable accuracy.

Note added in proof. In a recent publication, E. Šimánek and Z. Šroubek [Physica Status Solidi 4, 251 (1964)] have considered unpaired bonding effects for the same system.

Magnetic Moments and Unpaired Spin Densities in the Fe-Rh Alloys*

G. SHIRANE AND R. NATHANS
Brookhaven National Laboratory, Upton, New York

AND

C. W. CHEN
Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

(Received 22 January 1964)

The distribution of magnetic moments in the Fe-Rh system has been investigated by the neutron diffraction technique in the composition range between 35 and 50 at.%Rh. These alloys have chemical order of CsCl type; the body-corner positions are occupied by FeI atoms and the body centers by Rh and FeII atoms. The magnetic moments in ferromagnetic alloys containing 35, 40, and 48% Rh are $\mu_{FeI}=3.1\ \mu_B$, $\mu_{FeII}=2.5\ \mu_B$, and $\mu_{Rh}=1.0\ \mu_B$ at 25°C. The moment of the FeI atom in the 50% Rh alloy, which is antiferromagnetic at room temperature, increases to $3.3\ \mu_B$. A detailed study of the unpaired spin density distribution in the 48% Rh alloy was made by the polarized beam technique. While the FeI atom has a nearly spherical density distribution, that of the Rh atom shows a strong tendency towards e_g symmetry. The coherent nuclear scattering amplitude of Rh was determined to be $0.585\pm0.005\times10^{-12}$ cm.

I. INTRODUCTION

IN a previous paper[1] we have reported a systematic investigation of the Fe-Rh alloys by the Mössbauer technique. Up to 52% Rh these alloys possess a body-centered cubic lattice in which there is chemical order of CsCl type when the Rh concentration exceeds 20%. In the ordered alloys, iron atoms located at the body corners are labeled FeI and those in the Rh sites at the body centers FeII (see the insert to Fig. 1). The system exhibits two interesting magnetic properties. First, fairly large moments are observed over a wide concentration range,[1,2] as shown in Fig. 1. Second, a ferromagnetic-antiferromagnetic transition[3,4] occurs in alloys containing around 50% Rh. The transition temperature increases with increasing Rh concentration, and is observed to be 65°C in the 50% Rh alloy. The room temperature phase changes from ferromagnetic to antiferromagnetic between 49% and 50% Rh.

The Mössbauer measurements[1] revealed two distinct hyperfine fields in ordered alloys, corresponding to FeI and FeII. For example, H_i(I) and H_i(II) were found to be 277 and 384 kOe, respectively, in an alloy containing 48% Rh. It was suggested that FeII, which is surrounded by 8 Fe nearest neighbors, may have a smaller magnetic moment than FeI despite its higher hyperfine field. The main interest in this alloy system therefore lies in the composition dependence of both the moments and the hyperfine fields of FeI, FeII, and Rh.

A neutron diffraction study of the FeRh alloy was first carried out by Bertaut, de Bergevin, and Roult.[5] Using powder data, they reported $\mu_{Fe}=2.8\ \mu_B$ and $\mu_{Rh}=0.8\ \mu_B$ for the 53% Rh alloy in the ferromagnetic region above 60°C. The present work describes neutron diffraction measurements of the magnetic moments of FeI, FeII, and Rh in ordered alloys, and a detailed study of the spin density distribution of Fe and Rh in the 48% Rh alloy. A study of the 50% Rh alloy, which is antiferromagnetic at room temperature, was also made.

II. EXPERIMENTAL

A. Samples

The alloys used in this work are those previously investigated by the Mössbauer technique. All alloys

TABLE I. Physical properties of Fe-Rh alloys. The moment value of 50% Rh (*) is obtained by extrapolation from the ferromagnetic phase above 65°C.

Composition	48% Rh	50% Rh
Lattice constant	2.989 Å	2.986 Å
Curie temperature	500°C	405°C
Magnetic moment per atom, 300°K	2.07 μ_B	1.94 μ_B*
Néel temperature	...	65°C

were prepared from high-purity metals by levitation melting with subsequent heat treatments as described in the previous paper.[1] The chemical analysis agreed with the nominal composition within 0.5 at.%. Single crystals large enough for neutron diffraction study were obtained by levitation melting of the 48 and 50% Rh alloys. Efforts to grow single crystals of the 25% Rh alloy by the electron beam technique were not successful. This may be due to the existence of a γ phase at high temperatures. An attempt to obtain single crystals of the 35% Rh alloy by the stress annealing technique was also unsuccessful.

Thus polycrystalline samples containing 35 and 40% Rh were used to study the moments of FeI and FeII. Detailed studies of the ferromagnetic and antiferromagnetic phases were carried out on the 48% Rh and 50% Rh single crystals, respectively. The magnetic properties of these two alloys are listed in Table I.

Interpretation of the magnetic diffraction data requires a precise knowledge of the chemical order in these alloys. Previous Mössbauer measurements, coupled with x-ray powder patterns, had revealed pronounced order in all the alloys containing more than 20% Rh. A careful study of the 50% Rh alloy, to be described later, showed that ordering is complete. Somewhat less accurate measurements on the 35% and 48% alloys gave a similar result.

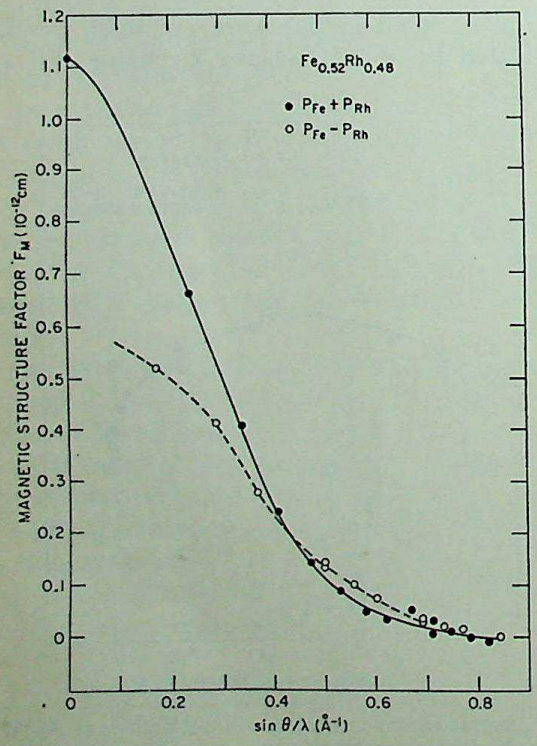

FIG. 2. The observed magnetic structure factors F_M, of $Fe_{0.52}Rh_{0.48}$. Reflections with $h+k+l=2n$ are shown by solid circles, those with $h+k+l=2n+1$ by open circles. The point at $\sin\theta/\lambda=0$ corresponds to the observed bulk moment of 4.14 μ_B.

B. Polarized Neutron Technique

Except for the study of the antiferromagnetic phase containing 50% Rh, all the measurements were made with the use of the polarized neutron technique, which has already been described in detail.[6–9] By reversing the incident neutron polarization, we measure the polarization ratio

$$I_{(+)}/I_{(-)}=(1+\gamma)^2/(1-\gamma)^2,$$

where γ is the ratio of the magnetic to the nuclear structure factor (F_M/F_N). The observed ratios were corrected for incomplete polarization of the incident beam (0.98) and for incomplete polarization reversal (0.98).

It is also necessary to make allowance for multiple scattering processes within the crystal. It has been shown[9] that multiple scattering can introduce serious errors in the measured polarization ratios. In order to detect and eliminate this effect, the crystals were mounted on a goniometer in a magnetizing field of 10 kOe, and the polarization ratio was studied as a function of the azimuthal angle around the scattering vector.

III. SPIN DENSITY IN FERROMAGNETIC $Fe_{0.52}Rh_{0.48}$

Single crystals were cut into the shape of pillars, roughly 2×3 mm in cross section and 15 mm in length, with their long axes along [110] and [100], respectively. In addition, a smaller cylindrical [110] crystal (1-mm diam), which was cold worked, was used to check for possible extinction effects in strong reflections. Extinction effects were also investigated by mis-setting the Bragg angle.[6] Even for undistorted crystals, extinction corrections were proved to be negligible except for the two strongest reflections.

Intensity measurements were made out to an angle corresponding to $\sin\theta/\lambda=0.85$ Å^{-1}, with a wavelength of 1.05 Å. The number of reflections totaled 26, and all except two, (321) and (421), are contained in the two zones. The results are shown in Fig. 2 and Table II. In calculating the magnetic structure factor F_M from the relationship $\gamma=F_M/F_N$ we used $b_{Fe}=0.951$[9] and $b_{Rh}=0.585\times10^{-12}$ cm, the latter value being determined from the 50% Rh alloy (see Sec. V). The errors quoted

in Table II are the standard deviations of repeated measurements.

In the CsCl type of structure, the structure factors F_M are divided into two kinds,

$$F_M = p_{Fe} + p_{Rh} \quad \text{for} \quad h+k+l=2n,$$
$$F_M = p_{Fe} - p_{Rh} \quad \text{for} \quad h+k+l=2n+1,$$

where p_{Fe} and p_{Rh} are the magnetic scattering amplitudes of Fe and Rh, respectively, and are equal to the product of the magnetic moment μ and the form factor f,

$$p_{Fe} = \mu_{Fe} f_{Fe}, \quad p_{Rh} = \mu_{Rh} f_{Rh}.$$

Figure 2 clearly shows that these two groups of reflections lie on two separate curves which cross each other around $\sin\theta/\lambda = 0.45$ Å^{-1}. This implies that the rhodium form factor f_{Rh} becomes negative at this point, in agreement with recent calculations by Watson and Freeman.[10] Thus it falls off much more rapidly as a function of the scattering angle than the form factor of Fe, which becomes negative only above $\sin\theta/\lambda = 0.80$ Å^{-1}.

TABLE II. Magnetic structure factors F_M, in units of 10^{-12} cm, per CsCl type unit cell of $Fe_{0.52}Rh_{0.48}$.

hkl	$F_M(\pm 0.001)$	hkl	$F_M(\pm 0.002)$
100	0.516	011	0.658
111	0.410	200	0.400
120	0.275	211	0.237
300	0.136	022	0.141
122	0.144	130	0.090
311	0.104	222	0.053
230	0.076	321	0.035
322	0.039	400	0.052
140	0.037	033	0.009
133	0.023	411	0.030
421	0.016	240	0.012
500	0.003	233	0.000
430	0.004	422	−0.010

These data were analyzed in two ways. The first is the direct comparison of observed and calculated structure factors, and the second involves the Fourier inversion of the data. We shall describe the second approach first, since it gives a more visible picture. This process of Fourier inversion was used by Pickart and Nathans[8] for Fe_3Al and Shull and Yamada[9] for Fe. Our preliminary analysis was made with a Fourier projection on the (110) plane, but a heavy overlap due to an extended wave function of Rh made the three-dimensional Fourier analysis desirable.

Following conventional crystallographic notation, we have

$$\rho(xyz) = (1/V) \sum F_{hkl} \cos 2\pi(hx+ky+lz),$$

where ρ is the magnetic spin density and V is the unit cell volume. The summation has been carried out on the computer. Figure 3 illustrates a portion of the (110) plane intersecting the two atoms in the unit cell. This Fourier map clearly illustrates the lobe along the [001] axis for Rh, the characteristic of e_g symmetry. On the other hand, the Fe density distribution corresponds more closely to spherical symmetry. Figure 4 illustrates the moment density along two principal directions, [001] and [111], the latter being directed towards the nearest neighbors. This figure shows that the Fe spin density also shows some deviation towards e_g symmetry, in that the density along [001] is slightly higher than that along [111] at the equivalent distance.

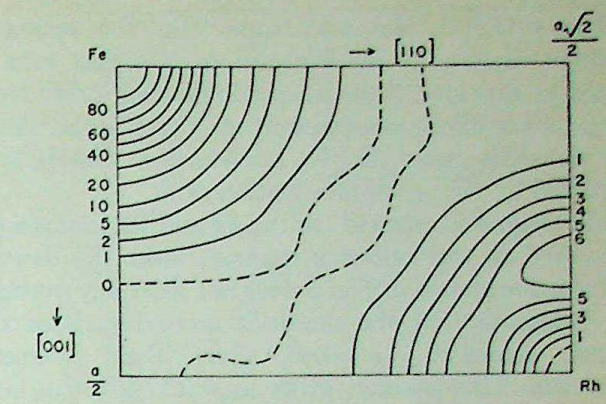

FIG. 3. Magnetic moment density distribution in the (110) plane. The scale is taken to give 100 at the Fe nucleus, which corresponds to 6.82 μ_B/Å^3.

It is emphasized that the large difference in the angular dependence of the form factors, f_{Fe} and f_{Rh}, has a significant effect on their Fourier contours. Available data within the given angle of $\sin\theta/\lambda = 0.85$ Å^{-1} allow an excellent resolution of the Rh spin density distribution to be made since its form factor crosses zero at

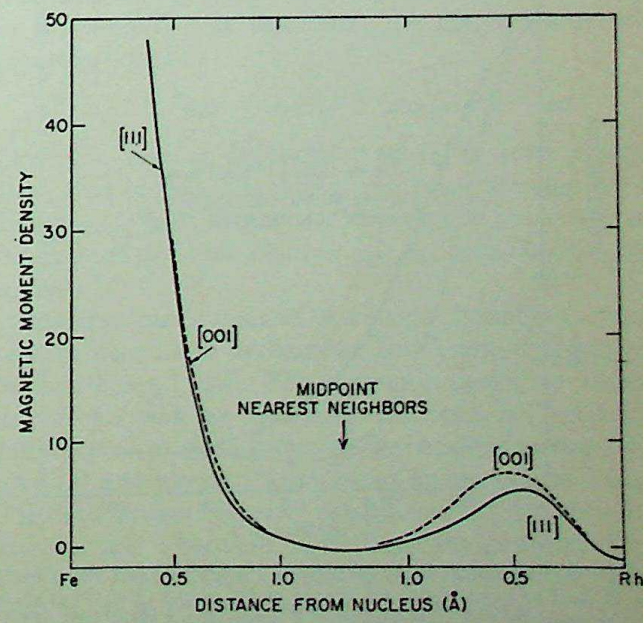

FIG. 4. Magnetic moment density distribution in the [001] and [111] directions as a function of distance from the nuclei. The scale 10 corresponds to 0.68 μ_B/Å^3. [111] corresponds to the nearest-neighbor direction.

$\sin\theta/\lambda = 0.45$ Å^{-1}. We may note that the magnetic moment density at the Rh nucleus is almost zero as would be expected if the magnetic moment arises from the presence of unpaired d electrons. On the other hand, the densities near the Fe nucleus are considerably distorted by the series termination error.

The magnetic moments of the Fe and Rh atoms were estimated in the following manner. Since the density distribution shown in Fig. 3 does not show any overlap, the integration of the densities around each of the atoms, namely $\sum \rho(r) 4\pi r^2$, gives their magnetic moments. This method gives $\mu_{Fe} = 3.17 \pm 0.10\ \mu_B$ and $\mu_{Rh} = 0.97 \pm 0.10\ \mu_B$. These values are subject to errors which result from the fact that only a finite number of reflections are used in the construction of a Fourier map. The effect of this series termination error on magnetic density was studied in detail by Pickart.[11] From this study we can estimate that in the present case the error is not more than a few percent for Fe. Another estimate was made directly from the data shown in Fig. 2. We draw a smooth curve through the observed points, taking into account the asphericity. Then for a given observed value of $p_{Fe} + p_{Rh}$, that of $p_{Fe} - p_{Rh}$ can be estimated with reasonable accuracy. In this way we can obtain p_{Fe} and p_{Rh} uniquely as a function of $\sin\theta/\lambda$. Then $p_{Fe} = \mu_{Fe} f_{Fe}$ were compared with the form factor of Fe metal.

If we now assign a value of 3.14 μ_B to the FeI moment, it may be seen from Fig. 5 that the form factor thus obtained is almost identical to that of Fe metal as

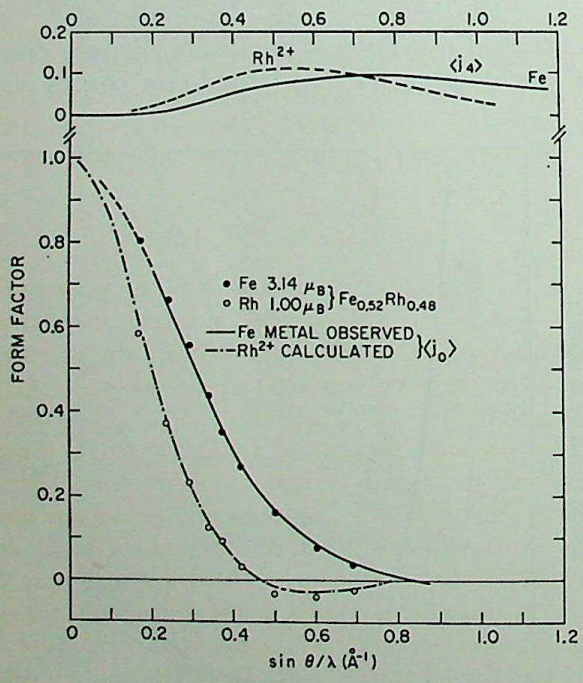

FIG. 5. Estimated form factors of Fe and Rh, as described in the text. The observed form factor of Fe metal (Ref. 9) is shown by the solid line and the calculated form factor (Ref. 10) of Rh^{2+} by the broken line. The calculated aspherical terms $\langle j_4 \rangle$ are shown at the top.

[11] S. J. Pickart, Acta Cryst. 16, 174 (1963).

determined by Shull and Yamada[9] over a quite wide angular range. This Fe moment, combined with the observed bulk moment of 4.14 μ_B, gives $\mu_{Fe} = 3.14\ \mu_B$, $\mu_{Rh} = 1.0\ \mu_B$.

At present, theoretical form factors[10] for Rh are available only for Rh^{2+} and Rh^{3+}. The observed form factor f_{Rh} turns out to be in excellent agreement with the calculated value for Rh^{2+}. The almost perfect agreement shown in Fig. 5 is probably fortuitous. In the above process, we have neglected the fact that a small fraction (4%) of the Rh sites are occupied by FeII atoms. If we assume the moment of FeII atoms is 2.5 μ_B, as will be shown in the next section, the true rhodium moment in $Fe_{0.52}Rh_{0.48}$ should be 0.94 μ_B, and the form factor should be slightly modified.

The aspherical moment distribution, particularly pronounced in Rh, was already apparent in the Fourier

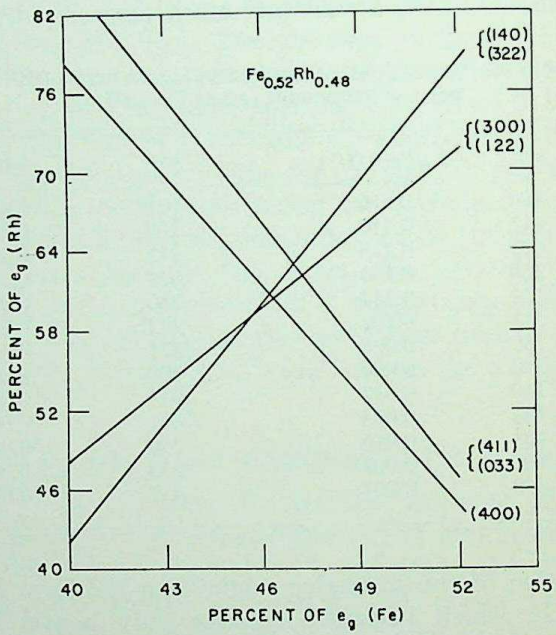

FIG. 6. Graphical determination of the fractions of e_g character for Fe and Rh in $Fe_{0.52}Rh_{0.48}$. 40% e_g corresponds to spherical symmetry.

densities shown in Figs. 3 and 4. A qualitative estimate was made by comparison of observed and calculated structure factors of three pairs of reflections, shown in Fig. 6, and (400) which shows the largest deviation from the spherical part. The form factor for e_g symmetry is given by

$$f(e_g) = \langle j_0 \rangle + \tfrac{3}{2} A \langle j_4 \rangle ,$$

$$A = \frac{h^4 + k^4 + l^4 - 3(h^2k^2 + k^2l^2 + l^2h^2)}{(h^2 + k^2 + l^2)^2} .$$

The calculated values[10,12] for $\langle j_4 \rangle$ are shown in the top part of Fig. 5. By a graphical method, the best solution for the percentage of e_g character in the spin density

distribution was found to be $e_g(\mathrm{Fe})=47\pm1\%$, $e_g(\mathrm{Rh})=62\pm3\%$.

Spherical symmetry corresponds to 40% e_g and 60% t_{2g} character.

IV. MOMENT DISTRIBUTION IN ALLOYS

Having established the values of the magnetic moments in the 48% Rh alloy, it is now of great interest to study the composition dependence of these moments, and in particular, that of FeII, namely Fe atoms on the Rh sites. These features were studied with polycrystalline samples of the 35 and 40% Rh alloys consisting of rectangular pillars 2×5×18 mm. Both the polarized and unpolarized beam techniques were employed in these experiments. In the case of the former, a correction for depolarization of the neutron beam within the polycrystalline samples is

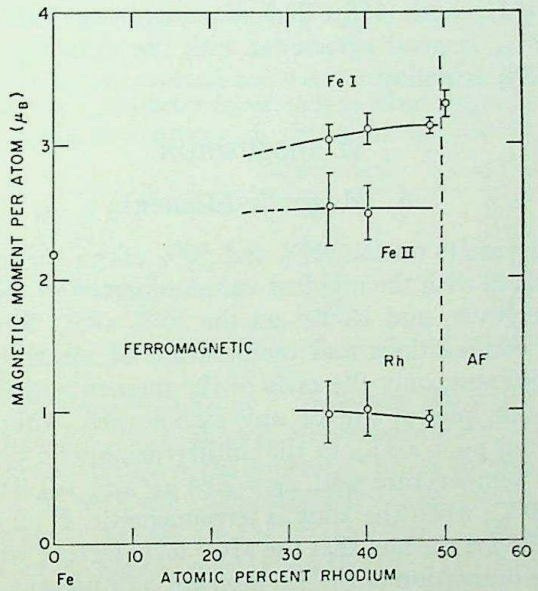

FIG. 7. Moment distributions in Fe-Rh alloys at room temperature.

required. With these in an applied field of 11 kOe, this correction turned out to be relatively small. The degree of chemical order in the 35% Rh sample was checked, and the order parameter was found to be at least 0.95.

The data were collected from a few reflections, (110), (200), (211), and (100). From these we can determine $F_M(+)=p_{\mathrm{FeI}}+p_{\mathrm{FeII}}+p_{\mathrm{Rh}}$ and $F_M(-)=p_{\mathrm{FeI}}-(p_{\mathrm{FeII}}+p_{\mathrm{Rh}})$. These, combined with the observed total moment by magnetic measurements, give the individual moments uniquely if we assume that the form factors of Fe and Rh determined for the 48% Rh alloy are unchanged in the other alloys.

The results are shown in Fig. 7. Large uncertainties, particularly in the moment of FeII, were introduced because of poor statistics in the powder diffraction data. It is quite clear, however, that μ_{FeII} is definitely smaller than μ_{FeI} despite its higher hyperfine field.

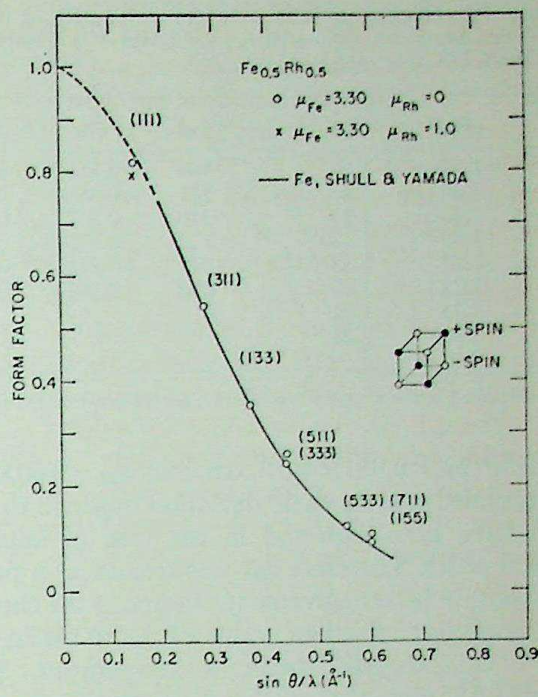

FIG. 8. Form factor of Fe in the antiferromagnetic phase of $Fe_{0.50}Rh_{0.50}$ at room temperature. The assumption that $\mu_{Rh}=1.0\,\mu_B$ does not introduce any noticeable change in the Fe form factors except for the (111) reflection.

V. ANTIFERROMAGNETIC PHASE IN $Fe_{0.5}Rh_{0.5}$

The basic magnetic structure of this phase was reported by Bertaut *et al.*[5] and is shown as an insert to Fig. 8. This is the so-called *G*-type structure,[13] in which every positive Fe spin is surrounded by six negative Fe spins. The magnetic unit cell edge is thus double that of the chemical cell. The Rh atom, which is located at the body-centered position, is now surrounded by four positive and four negative Fe spins. Thus the Rh moments may not be ordered. Even if they are ordered in the same *G*-type structure, the magnetic intensity is proportional to

$$F_M^2=(\mu_{\mathrm{Fe}}f_{\mathrm{Fe}})^2+(\mu_{\mathrm{Rh}}f_{\mathrm{Rh}})^2.$$

Since the angular dependence of f_{Fe} is quite different from that of f_{Rh}, it is possible in principle to solve for both μ_{Fe} and μ_{Rh}. In practice, however, F_M^2 is extremely insensitive to small changes of μ_{Rh} when $\mu_{\mathrm{Rh}}f_{\mathrm{Rh}}<0.1\,\mu_{\mathrm{Fe}}f_{\mathrm{Fe}}$.

The specimen consisted of a single crystal in the shape of a cylinder 1 mm in diameter and 5 mm in length with its axis along [110]. The magnetic peaks are indexed as *hkl* all odd by doubling the unit cell. Accurate intensity data were collected for both magnetic (*h*,*k*,*l* all odd) and nuclear peaks using an unpolarized beam. The absorption of the sample was relatively high ($\mu=4.2$ cm^{-1}) because of its large Rh content. A preliminary comparison of the observed structure factors with those calculated from the expressions

$$F_{\mathrm{cal}}=(b_{\mathrm{Fe}}\pm b_{\mathrm{Rh}})e^{-B(\sin\theta/\lambda)^2},$$

in which[9] $b_{Fe}=0.951\times10^{-12}$ cm and $b_{Rh}=0.60\times10^{-12}$ cm,[14] revealed a systematic deviation opposite to what would have been expected in the case of imperfect chemical order. Therefore b_{Rh} was treated as a parameter to obtain better agreement. Assuming the chemical order is perfect, the new value of $b_{Rh}=0.585\pm0.005\times10^{-12}$ cm, together with a temperature factor $B=0.433$ Å^2, give the excellent agreement shown in Table III.

If chemical order is not complete, or the Rh content not 50%, it is clear that b_{Rh} would become even smaller. The above value of the temperature factor B was used to correct the observed magnetic structure factors. Magnetic intensities were also corrected for $\lambda/2$ contamination ($\sim$0.2%). Intensity data given in Table IV are average values of equivalent reflections. In view of the nuclear intensity agreement, it was assumed that no extinction correction was needed.

The magnetic reflections were first analyzed on the assumption that $\mu_{Rh}=0$. The Fe moment was determined from the (311) and (133) reflections using the form factor of metallic Fe. This gave

$$\mu_{Fe}=3.30\,\mu_B.$$

The form factor f_{Fe} was then calculated for all the reflections using this moment value. There appears to be a slight systematic deviation of the observed form factor from the solid line representing that of metallic Fe as shown in Fig. 8. A part of this might be due to a systematic error introduced by an inaccurate temperature factor correction. (The polarized beam technique is free from this error since it is always the ratio, F_M/F_N, which is measured.)

Some estimate of the Rh moment can be made on the basis of the innermost magnetic peak. If we were to assume that the Rh moment remains 1.0 μ_B in the antiferromagnetic state, then we obtain the value of the Fe form factor indicated by the cross in Fig. 8, which falls definitely below the extrapolated curve. Hence, our data does suggest that if the aligned moment on the Rh atoms in this magnetic state is not zero, it is at least lowered. However, the determination of the Fe moment is almost unaffected by this uncertainty in the Rh moment.

The asphericity of the Fe density distribution was estimated from two pairs of reflections, (511) and (333), and (711) and (155). The amount of e_g character is 48±3%, in good agreement with the value for FeI in the 48% Rh alloy.

VI. DISCUSSION

A. Magnetic Moments

Our results on the 48% and 50% alloys can now be compared with the moment values reported by Bertaut, de Bergevin, and Roult[5] on the 53% alloy. Since the alloy compositions and temperature of measurements are different, only the ratio of the moments in the two magnetic phases are of any significance. They have reported $\mu_{Fe}=3.3\,\mu_B$ in the antiferromagnetic phase at room temperature and $\mu_{Fe}=2.84\,\mu_B$ and $\mu_{Rh}=0.80\,\mu_B$ at 100°C, when the alloy is ferromagnetic. If allowance is made for the fact that the Mo^{3+} form factor[15] was used in the derivation of the Rh moment, our present result. are seen to be in good agreement with these values The rhodium form factor determined in the present work drops off, as a function of scattering angle, somewhat more slowly than that of Mo^{3+}, as might be expected from their respective positions in the 4*d* series.

It is interesting to compare the magnetic moment of Fe in the antiferromagnetic phase with the Fe moment extrapolated from the ferromagnetic region. At room temperature, the extrapolated total moment is 3.88 μ_B per unit cell (Fig. 1). Assuming that the ratio of μ_{Fe} to μ_{Rh} retains the value found in 48% Rh, we obtain a value of 3.0 μ_B for the Fe moment. The observed moment is 10% higher than this value. This tendency may also be seen in Fig. 7, in which the moments were plotted as a function of composition.

At the transition from the ferromagnetic to the antiferromagnetic phase, the unit cell volume decreases[3] by

1% and the hyperfine field at Fe^{57} decreases by 6%.[1,16] This is another illustration of the fact that, in this system, the hyperfine field is not related in any simple manner to the magnetic moments. We have already shown that FeII in the ferromagnetic phase has a smaller moment, despite its considerably higher hyperfine field, than FeI. We believe this is due to a different degree of polarization of the conduction electrons, with respect to which the hyperfine field is quite sensitive. At present there is, however, no direct experimental evidence to verify this assumption.

B. Form Factors

The form factors of Fe in the rhodium alloys are shown in Fig. 9, together with the previous results given for metallic Fe by Shull and Yamada[9] and for Fe_3Al by Pickart and Nathans.[8] The first striking characteristic is that the spherical parts of the form factors are very similar to each other, although the magnetic moments of the Fe atoms in their various surroundings are quite different, as shown in Table V. However, the asphericity of the density distribution differs considerably.

TABLE V. Magnetic moments and their asphericities in several Fe alloys. 40% e_g character corresponds to spherical symmetry.

	Moment (μ_B)	e_g (%)
Fe Metal	2.18	0.53
Fe_3Al FeI	2.18	0.60
Fe_3Al FeII	1.50	0.48
$Fe_{0.52}Rh_{0.48}$ FeI	3.14	0.47
$Fe_{0.5}Rh_{0.5}$ FeI	3.30	0.48

Let us now compare the spherical part of the observed form factor with the calculated part. The most recent calculations available are the Hartree-Fock calculations with exact exchange polarization treatment by Freeman and Watson[17] for the two configurations $3d^8$ and $3d^64s^2$. Somewhat surprisingly, the form factors for these two configurations turn out to be almost identical.[18] This is in striking contrast to previous calculations by the same authors[12,19] in which they obtained practically identical results for $3d^64s^2$ and $3d^6(Fe^{2+})$, but considerably lower values for $3d^8$.

Shull and Yamada compared their observed form factors of Fe to the latest spin-polarized calculations and obtained a constant "ratio" between the two, namely, that the observed values were 10% higher than the calculated values. They attributed the difference to the polarization of 4s electrons assuming the calculated form factors were correct. Our data for the FeRh alloys as well as the previous results for Fe_3Al deviate from this constant ratio relation at the low-angle reflections with $\sin\theta/\lambda < 0.2$ Å^{-1}. If we include these points for comparison, better over-all agreement is obtained with the earlier calculations of Weiss and Freeman.[20] We believe that, at present, the proper procedure for obtaining information about the conduction electron polarization is to depend only on the experimental intensity observations and their Fourier transform. Our present data for the Fe-Rh alloys are not sufficient to draw significant conclusions concerning this point.

General Theory of Cross Relaxation. I. Fundamental Considerations*

W. J. C. GRANT
Bell Telephone Laboratories, Murray Hill, New Jersey

(Received 30 January 1964)

A statistical analysis is made of spin transitions induced by dipole interactions which change the total magnetization while exactly conserving energy. The first-order effect of the dipole operator can be described by a function $\Phi(\omega)$, which is related to the level broadening observed in resonance lines. The second-order effect leads to a function $\chi(\omega)$ which represents the power spectrum of the dipole operator. The cross-relaxation probability $W_{CR}(\omega)$ is given by the convolution of these two functions. W_{CR} is calculated explicitly in various approximations, without appeal to moments. For single-spin flips in magnetically dilute systems, the magnitude of W_{CR} depends linearly on the concentration n. There is a very sharp peak at $\omega=0$ with a width proportional to the geometric mean of the resonance width and of the nearest-neighbor dipole energy.

I. INTRODUCTION

SINCE cross relaxation was first proposed[1] as an explanation of intermediate relaxation times,[2] much theoretical and experimental work has amplified and confirmed the occurrence of such a relaxation process. As a starting point, we summarize the present state of the theory. One considers a Hamiltonian

$$\mathcal{H}=\mathcal{H}_0+\mathcal{H}_{dip}, \tag{1}$$

where $\mathcal{H}_0$ includes Zeeman and crystal energies, and $\mathcal{H}_{dip}$ is the dipole interaction energy. The cross-relaxation transition probability is given by

$$W(\omega)=(2\pi/\hbar)M^2g(\omega), \tag{2}$$

where M is the transition matrix element arising from $\mathcal{H}_{dip}$, $g(\omega)$ is a probability function peaked at $\omega=0$, and $\hbar\omega$ is the energy that is exchanged between $\mathcal{H}_0$ and $\mathcal{H}_{dip}$. In terms of a representation in which $\mathcal{H}_0$ is diagonal, the $g(\omega)$ embodies the effect of the diagonal and semidiagonal parts of $\mathcal{H}_{dip}$, which rearrange the entire dipole lattice in such a manner as to conserve over-all energy.

Two prescriptions have been used to calculate $g(\omega)$. The "exact" method evaluates moments of $g(\omega)$ by means of the usual trace formulas.[1,3] The "approximate" method considers $g(\omega)$ as the convolution of the resonance lines between which cross relaxation occurs. For instance, let $g_1(\omega)$ describe the line shape for absorption between states A and B, and let $g_2(\omega)$ describe the absorption line shape involving states C and D; then the $g(\omega)$, for a process in which one spin flips from A to B while another flips from D to C would be given by

$$g(\omega)=\int_{-\infty}^{\infty}g_1(\omega')g_2(\omega-\omega')d\omega', \tag{3}$$

where ω corresponds to the "leftover" energy, $\Delta E_{AB}-\Delta E_{CD}$. Since g_1 and g_2 are quite sharply peaked around $\omega=0$, g will also be peaked at $\omega=0$ in agreement with experiment.[4–8]

A number of difficulties have arisen, however, with the more detailed quantitative development of the theory. Among these we may mention the following:

(1) The "exact" moment calculations of Kopvillem,[9] Kiel,[10] and Hirono[11,12] indicate that the shape function which seems consistent with these calculations does not resemble the shape function which emerges from the "approximate" method. For 1- and 2-spin processes, Kopvillem predicts a square shape with a width of the same order as the resonant frequency, and essentially independent of concentration. Similarly, for a 3-spin process, Kiel and Hirono obtain leading terms for $g(\omega)$ which are in first-order concentration and frequency-independent. Equation (3), on the other hand, predicts a sharply peaked resonance function with a width and a concentration dependence similar to the absorption signal.

(2) The relationship of experimentally observed features to the predictions of either method seem somewhat unclear. For a concentrated system like LiF,[4] the convolution scheme provides a satisfactory interpretation for much, but not all, of the data. For dilute systems like ruby, the effects are also sharply resonant[6] and, at least for two-spin processes, appear to have a concentration-dependent width. On the other hand, this width seems to exceed considerably the absorption width expected from the convolution scheme. Furthermore, the intensity of the effect shows a concentration dependence unaccounted for by any calculation.

(3) There are also two conceptual difficulties. One

involves the sometimes ambiguous relationship of a function to its moments (to be more fully discussed in a future publication); the other concerns the precise origin and meaning of the shape function $g(\omega)$. Clarification of this latter question is one of the main objectives of the present work.

We shall re-examine the physical premises of the theory, construct a new mathematical formalism, and derive closed analytic expressions for the transition probability. While our theory is applicable to general cross-relaxation processes, we begin with the simplest possible process, in which a single spin flips.

II. ELEMENTARY PHYSICAL CONSIDERATIONS

We consider the Hamiltonian of Eq. (1).

$$\mathcal{H}=\mathcal{H}_0+\mathcal{H}_{\rm dip}.$$

Without the interaction $\mathcal{H}_{\rm dip}$, each particle is independent, and its energy has eigenvalues $E_A{}^0$, $E_B{}^0$, etc. The eigenvalues of $\mathcal{H}$ are then simply sums of the single-particle eigenvalues. Because the particles are coupled by $\mathcal{H}_{\rm dip}$, their individual energy is no longer a constant of the motion. Nevertheless, as long as $\mathcal{H}_{\rm dip}$ is small, it is still convenient to choose the eigenstates of $\mathcal{H}_0$ as the zeroth-order eigenstates of $\mathcal{H}$. The diagonal and off-diagonal elements of $\mathcal{H}_{\rm dip}$ are then defined with respect to a representation in which $\mathcal{H}_0$ is diagonal. In first order, the diagonal elements of $\mathcal{H}_{\rm dip}$ can be thought of as shifting the energy of each particle, by an amount $E^{\rm dip}$, from its unperturbed value E^0. The energy shift will be different for each ion, because each ion sees a different local field. The energies of all the particles in a given Zeeman state will form a distribution centered on the Zeeman energy. In this sense, one speaks of the dipole interaction as "smearing" the Zeeman levels. The energy shift of an individual ion will depend not only on the specific environment in which the ion finds itself, but also on the Zeeman state in which it happens to be, since the diagonal elements of $\mathcal{H}_{\rm dip}$ are not all equal.

In higher order, transitions between states can be considered as induced by the "rotating" off-diagonal dipole matrix elements. Just as each ion sees a different diagonal perturbation, so it sees a different transition operator. Both are effects of the same local field.

We wish to calculate the probability that a particle will make a nonradiative transition from Zeeman state A, with unperturbed energy $E_A{}^0$, to Zeeman state B, with unperturbed energy $E_B{}^0$. Such a transition is possible only for a spin which happens to see a dipolar configuration such that, by flipping, it automatically changes the dipolar energy by the right amount to compensate for the change in Zeeman energy. Energy conserving transitions between separated Zeeman states A and B are possible because (1) the actual energy of a spin in state A or B will, in general, deviate from $E_A{}^0$ or $E_B{}^0$; (2) the magnitude of this perturbation will be different when the spin finds itself in state A and when in state B.

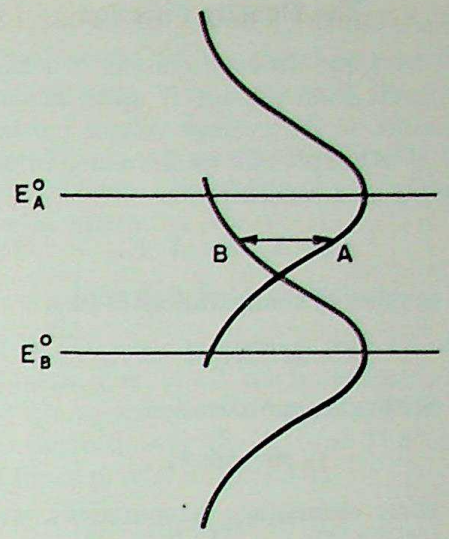

FIG. 1. Energy conserving transitions between different Zeeman states.

Figure 1 shows a distribution of states around Zeeman energies $E_A{}^0$ and $E_B{}^0$. We are interested in transitions between points like A and B. Such transitions are nonradiative, since they fulfill the requirement

$$E_A{}^{\rm total}=E_B{}^{\rm total}, \tag{4}$$

where

$$E^{\rm total}=E_0+E^{\rm dip}. \tag{5}$$

At the same time, such transitions change the relative populations of levels A and B, as well as the total magnetization of the system.

We do not require that each spin flip be accompanied by a dynamic rearrangement of the entire lattice to conserve energy, and in this respect our picture seems somewhat simpler than the one suggested by Bloembergen.

Stated in the present terms, the crux of the problem is to pick out those dipole configurations which meet the rather stringent requirement of Eq. (4). For each such configuration, we calculate the transition probability and then sum the result. The probability of finding a suitable dipole configuration can be considered as a density function. The total transition probability can then be interpreted as the average of the transition operator over this density function.

III. GENERAL EXPRESSION FOR CROSS-RELATION PROBABILITY

We now derive in integral form a general expression for the probability of a dipole-induced single-spin flip. For clarity's sake, we somewhat arbitrarily divide the discussion into three steps. First, we set up a formalism to project the suitable dipole configurations. Then we calculate the transition probability, summed over these configurations. Finally, we discuss the significance of the resulting formula from some alternate viewpoints.

The Density Function

We first calculate the total number of configurations that can result from putting N spins randomly into M lattice sites. If the average volume per lattice site is v, then M is simply the total volume in units of v. We define the spin concentration

$$n=N/M\equiv vN/V. \tag{6}$$

The total number of configurations is then

$$C=M!/N!(M-N)!. \tag{7}$$

By use of Stirling's approximation

$$x!=x^xe^{-x}, \tag{8}$$

and after some elementary computations, we obtain, for small n,

$$C=(1/N!)[M(1-n)]^N. \tag{9}$$

The factor $(1-n)$ accounts for the fact that we allow only one spin per lattice site rather than an arbitrary number. Stated in terms of the volume V

$$C=\frac{1}{N!}\left(\frac{1-n}{v}\right)^N V^N\equiv\frac{1}{N!}\left(\frac{1-n}{v}\right)^N\int d\mathbf{r}_1\cdots d\mathbf{r}_N. \tag{10}$$

Let us consider the simple question: What is the probability that a spin in state A will have some specified energy $E_A{}^{\text{total}}$? Now

$$E_A{}^{\text{total}}=E_A{}^0+E^{\text{dip}}. \tag{5}$$

$E_A{}^{\text{total}}$ and $E_A{}^0$ are numbers, but $E_A{}^{\text{dip}}$ is a function of the coordinates of every spin in the system. When we count the number of configurations, $C(E_A{}^{\text{total}})$, which fulfills the requirement (5), we proceed as before, except that we need to introduce the constraint [$\delta(x-x_0)$ is the Dirac delta function]

$$\delta[E_A{}^{\text{total}}-(E_A{}^0+E_A{}^{\text{dip}})]$$

into the volume integrals of Eq. (10):

$$C(E_A{}^{\text{total}})=\frac{1}{N!}\left(\frac{1-n}{v}\right)^N\int d\mathbf{r}_1\cdots d\mathbf{r}_N \times\delta[E_A{}^{\text{total}}-(E_A{}^0+E_A{}^{\text{dip}})]. \tag{11}$$

The fractional number of configurations that meet this constraint is evidently

$$f(E_A{}^{\text{total}})=C(E_A{}^{\text{total}})/C=\frac{1}{V^N}\int d\mathbf{r}_1\cdots d\mathbf{r}_N \times\delta[E_A{}^{\text{total}}-(E_A{}^0+E_A{}^{\text{dip}})]. \tag{12}$$

In similar fashion, the condition that a particle in state B has an energy $E_B{}^{\text{total}}$ is expressed by the constraint

$$\delta[E_B{}^{\text{total}}-(E_B{}^0+E_B{}^{\text{dip}})].$$

The condition, $E_A{}^{\text{total}}=E_B{}^{\text{total}}$, is expressed by the constraint

$$\delta[E_A{}^{\text{total}}-E_B{}^{\text{total}}].$$

Finally, to find the total number of "overlapping" states, one must integrate over-all values of $E_A{}^{\text{total}}$ and $E_B{}^{\text{total}}$. Thus, the fraction of configurations that satisfy our requirements is given by

$$f=\frac{1}{V^N}\int d\mathbf{r}_1\cdots d\mathbf{r}_N\delta[E_A{}^{\text{total}}-(E_A{}^0+E_A{}^{\text{dip}})] \times\delta[E_B{}^{\text{total}}-(E_B{}^0+E_B{}^{\text{dip}})] \times\delta[E_A{}^{\text{total}}-E_B{}^{\text{total}}]dE_A{}^{\text{total}}dE_B{}^{\text{total}}. \tag{13}$$

Using the elementary properties of δ functions,[13] and the notation

$$\hbar\omega=E_A{}^0-E_B{}^0, \tag{14}$$

$$\hbar\Delta\omega=E_B{}^{\text{dip}}-E_A{}^{\text{dip}}, \tag{15}$$

the expression (13) can be written more simply

$$f(\omega)=\frac{1}{V^N}\int d\mathbf{r}_1\cdots d\mathbf{r}_N\delta[\omega-\Delta\omega]. \tag{16}$$

Replacing the δ function by its Fourier transform, we have

$$f(\omega)=\frac{1}{V^N}\int d\mathbf{r}_1\cdots d\mathbf{r}_N\frac{1}{2\pi}\int_{-\infty}^{\infty}e^{-i\rho(\omega-\Delta\omega)}d\rho. \tag{17}$$

The $\Delta\omega$ in Eq. (17) is a function of all the $\mathbf{r}$'s. We assume that the contributions of all the particles to the energy shift $\Delta\omega$ are additive:

$$\Delta\omega=\sum_i\Delta\omega(\mathbf{r}_i) \tag{18}$$

$$\equiv\frac{1}{\hbar}\sum_i\mathfrak{IC}_{BB}{}^{\text{dip}}(\mathbf{r}_i)-\mathfrak{IC}_{AA}{}^{\text{dip}}(\mathbf{r}_i). \tag{19}$$

The approximation of additivity Eq. (18) involves an error of the order of the ratio of the dipolar energy to the Zeeman energy, which is small except for very low magnetic fields. With Eq. (18), the $\mathbf{r}$ integrals implied in Eq. (17) are now separable, and we may write

$$f(\omega)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\Phi(\rho)e^{-i\rho\omega}d\rho \tag{20}$$

with

$$\Phi(\rho)=\lim_{N\to\infty}\left[\frac{1}{V}\int d\mathbf{r}e^{i\rho\Delta\omega(\mathbf{r})}\right]^N. \tag{21}$$

The function $\Phi(\rho)$ and its Fourier transform $f(\omega)$ have been discussed by many authors.[14–17]

We are thus able to calculate, in terms of known functions, the fraction of configurations for which an *energy conserving* transition between two Zeeman states is possible. This fraction is a function of the energy separation $\hbar\omega$ of the Zeeman states. We have referred to it as a density function because it gives the density of available configurations as a function of ω.

The Transition Operator

The introduction of the transition operator is straightforward. This operator is $(\sum M_i)^2$, where M_i is the off-diagonal dipole matrix element connecting Zeeman states A and B, and involving the ith spin and the reference spin we are considering. The M_i are functions of the coordinate variables. Consequently, the transition matrix element is different for each allowed configuration of spins. This means that in the process of picking out suitable configurations from the ensemble, we weight each configuration separately with its own transition operator. In other words, the transition matrix element goes inside the coordinate integrals of Eq. (13). Analogous to Eq. (16), we now obtain for the actual transition probability

$$W(\omega)=\frac{2\pi}{\hbar}\frac{1}{V^N}\int d\mathbf{r}_1\cdots d\mathbf{r}_N[\sum_i M^2(\mathbf{r}_i)]\delta(\omega-\Delta\omega). \quad (22)$$

We note that

$$(\sum M_i)^2=\sum M_i^2. \quad (23)$$

The cross terms vanish in the understood integration over time because of the different time dependence of each M_i.

Each term in the sum over i gives an identical integral, so that

$$W(\omega)=\frac{2\pi}{\hbar}\frac{n}{v}\int_{-\infty}^{\infty}\chi(\rho)\Phi(\rho)e^{-i\rho\omega}d\rho, \quad (24)$$

where

$$\chi(\rho)=\frac{1}{2\pi}\int d\mathbf{r}M^2(\mathbf{r})e^{i\rho\Delta\omega(\mathbf{r})}, \quad (25)$$

and $\Phi(\rho)$ is defined in Eq. (21). Actually, the N in Eq. (21) is here replaced by $N-1$, but this makes no difference whatsoever since

$$\lim_{V\to\infty}\left[\frac{1}{V}\int d\mathbf{r}e^{i\rho\Delta\omega(\mathbf{r})}\right]=1. \quad (26)$$

We remark parenthetically that our discussion is applicable rather more simply to resonance lines. The differences are the following: Our constraint $\Delta E^{\text{total}}=0$ is replaced by the constraint $\Delta E^{\text{total}}=\Delta E^{\text{Zeeman}}$, which merely shifts the center frequency. The transition operator is changed to S_x^2, without any coordinate dependence, which eliminates $\chi(\rho)$ in Eq. (24). In particular, $\Phi(\rho)$ remains the same. Thus, $\Phi(\rho)$ is essentially the Fourier transform of the resonance line shape. The function $\Phi(\rho)$ is therefore accessible to us through experiment, even if we were not able to calculate it.

Equation (24) is our general formula for the single-spin cross-relaxation probability, as a function of the Zeeman level separation, $\hbar\omega$.

Alternate Interpretations

Equation (24) can be given a variety of physical interpretations. First of all, the function $\chi(\rho)$ is closely related to the autocorrelation function of the transition operator, summed over the lattice. The autocorrelation of a function $F(t)$ is defined as

$$C(\rho)=\langle F(t+\rho)F^*(t)\rangle_{\text{time average}}. \quad (27)$$

If F is an operator, then in the Heisenberg representation

$$F(t+\rho)=\exp(i\mathcal{H}\rho/\hbar)F(t)\exp(-i\mathcal{H}\rho/\hbar). \quad (28)$$

When F and $\mathcal{H}$ refer to the off-diagonal and diagonal parts of $\mathcal{H}^{\text{dip}}$, we obtain

$$M(t+\rho)=e^{i\rho\Delta\omega}M(t) \quad (29)$$

and

$$C(\rho)=\langle|M(t)|^2\rangle_{\text{time average}}e^{i\rho\Delta\omega}. \quad (30)$$

Summing $C(\rho)$ over the lattice yields our $\chi(\rho)$. We have defined, in Eq. (27), an unnormalized autocorrelation function, which is not usual. In point of fact, our $\chi(\rho)$ is unnormalized. It accounts for the magnitude of the transition matrix element as well. Indeed

$$\int_{-\infty}^{\infty}W(\omega)d\omega=\frac{2\pi}{\hbar}\frac{n}{v}\int d\mathbf{r}M^2. \quad (31)$$

This can be seen immediately by evaluating the Fourier transform of $W(\omega)$, that is, $\chi(\rho)\Phi(\rho)$, at $\rho=0$.

If $\chi(\rho)$ is the autocorrelation function of the transition operator, then its Fourier transform is the power spectrum of this operator. The Fourier transform of the function Φ, as we have seen, is essentially the resonance line shape. The transition probability is thus given by the scaled power spectrum of the transition operator convoluted with the spectrum of the broadened levels. If the transition operator were a δ function in ω space, then we would surely expect that energy could not be conserved in a single-spin flip unless the Zeeman level separation were of the order of the dipolar broadening. This assumption is implicit in the calculation of the cross-relaxation probability according to the scheme represented in Eq. (3). Conversely, if the levels were sharp, they would see a resonant component of the interaction mechanism only when the level separation fell within the Fourier spectrum of this mechanism. This latter consideration, in fact, provided the basis for the calculation of spin-lattice relaxation in Bloembergen, Purcell, and Pound's classic

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

nuclear relaxation paper.[18] In our case, the levels as well as the transition operator have a spectrum, and the resulting width is obtained by convolution.

Alternatively, one can interpret Eq. (24) simply as an application of the "Golden Rule":

$$W=(2\pi/\hbar)|\mathfrak{IC}_{\text{transition}}|^2\rho(E). \tag{32}$$

We must be somewhat careful in our interpretation of this formula. Any particular single spin, in flipping from Zeeman level A to level B, does not have available a continuum of states, but exactly one well-defined, albeit perturbed state. This state is either degenerate with the initial state or it is not; accordingly, $\rho(E)$ is either 1 or 0. We must then sum these Kronecker-δ probabilities over the discrete manifold of N spin states. If we replace the discrete manifold by a continuum of levels, and the Kronecker δ by a Dirac δ, we are immediately led to the equations that we have already derived.

In a third interpretation, we could regard $\rho(E)$ in Eq. (32) as referring to the lattice as a whole. It would then be a true density function. Given two Zeeman states separated in unperturbed energy by ΔE^0, and broadened into a continuous set of states by the dipole interaction, then ρ would represent the average occupancy of that subset of states for which $\Delta E^{\text{total}}=0$. Thus, $\rho(E)$ would correspond to our $f(\omega)$ in Eq. (21). When averaging the transition matrix element over the distribution ρ, one must evidently integrate over all the random variables involved. In the present case these include the space coordinates. This is precisely what we have done. This interpretation is implicit in the spin-spin line shape formula first given by Waller,[19] and quoted in Ref. 18. We note that in Ref. 1, however, the spatial average of the matrix element and the level density function are calculated separately.

We could indeed have written down Eqs. (24) and (25) almost immediately by invoking any of these three considerations. Our more pedestrian presentation, while perhaps less elegant, has been aimed at giving as clear a justification as possible for the mathematical expression of the theory.

Finally, we remark that the concentration dependence of the shape of $W(\omega)$ resides entirely in Φ, not in χ. The level broadening described by Φ depends linearly on the concentration for low concentrations and is proportional to the square root of the concentration for high concentrations, if the broadening is due to the dipole field. This, of course, is well known. The power spectrum of the transition operator, described by χ depends only upon the spatial integrals of the relevant coordinate functions. The *relative* occupation probabilities of the lattice sites are clearly not affected by the concentration; hence, the functional form of these integrals is not affected. Of course, the concentration enters also as a scale factor in Eq. (24) governing the absolute magnitude of $W(\omega)$.

IV. EVALUATION OF THE INTEGRALS

Our next task is to evaluate the function χ and its Fourier transform. The transition probability itself will be proportional to the convolution of this transform with the transform of Φ.

Definition of $\Delta\omega$ and M

As a preliminary, we must define the functions represented by $\Delta\omega(\mathbf{r})$ and $M(\mathbf{r})$ in Eqs. (24) and (25). In Bloembergen's tabulation of dipole matrix elements,[1] his A and B functions correspond to our $\Delta\omega(\mathbf{r})$ and his C, D, E, and F functions correspond to our $M(\mathbf{r})$. Abbreviating his notation, we write

$$\Delta\omega(\mathbf{r})=q(3\cos^2\theta-1)/r^3, \tag{33}$$

$$M(\mathbf{r})=g(\sin\theta\cos\theta)/r^3, \quad \text{if} \quad \Delta m=\pm1, \tag{34}$$

$$M(\mathbf{r})=g(\sin^2\theta)/r^3, \quad \text{if} \quad \Delta m=\pm2. \tag{35}$$

Here q and g contain appropriate diagonal and off-diagonal spin-matrix elements. These expressions are valid only for two special cases: (1) There is no crystal field, or, (2) if there is a crystal field, the magnetic axis coincides with the crystal axis. In the more general case, when the magnetic field makes an arbitrary angle with the crystal axis, the expressions are generalized as follows:

$$\Delta\omega(\mathbf{r})=\sum_{k=0}^{2} q_k P_{2k}\equiv\frac{1}{r^3}f(\theta), \tag{36}$$

$$M(\mathbf{r})=\frac{1}{r^3}\sum_{k=0}^{2} g_k P_{2k}\equiv\frac{1}{r^3}m(\theta). \tag{37}$$

Here P_{2k} are the Legendre polynomials P_{20}, P_{21}, P_{22}, and the q_k and g_k now represent exceedingly complicated functions of the spin-matrix elements, the magnetic field, and the crystal field parameters. But even in the most general case, $\Delta\omega$ and M resolve into a product of an angular function and r^{-3}.

Evaluation of χ

Instead of evaluating $\chi(\rho)$ directly, we consider first a slightly more general integral than the one in Eq. (25):

$$I(\rho,n)=\int_{-1}^{1} d\cos\theta\int_{r_0}^{\infty} r^2dr\frac{m^2(\theta)}{r^{3n}}e^{[i\rho f(\theta)/r^3]}, \tag{38}$$

so that

$$\chi(\rho)=I(\rho,2). \tag{39}$$

The lower limit of the r integral is the nearest-neighbor distance r_0. This distance can never be zero since two particles cannot occupy the same spot.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

To perform the integration over r, we put

$$a=\rho f(\theta), \tag{40}$$

$$t=-ia/r^3. \tag{41}$$

We obtain

$$I(\rho,n)=\int_{-1}^{1} d\cos\theta \frac{m^2(\theta)}{3(-ia)^{n-1}}\int_0^{-ia/r_0^3} e^{-t}t^{n-2}dt. \tag{42}$$

The t integral will be recognized as defining the incomplete γ function[20] so that

$$I(\rho,n)=\int_{-1}^{1} d\cos\theta\left(\frac{m^2(\theta)}{3r_0^{3(n-1)}}\right)\frac{\gamma(n-1,\ -ia/r_0^3)}{(-ia/r_0^3)^{n-1}}, \tag{43}$$

$$\chi(\rho)=\int_{-1}^{1} d\cos\theta\left(\frac{m^2(\theta)}{3r_0^3}\right)\frac{\gamma(1,\ -ia/r_0^3)}{-ia/r_0^3}. \tag{44}$$

After a slight manipulation of the expansion[20]

$$\gamma(a,x)=\sum_{n=2}^{\infty}\frac{(-)^n x^{a+n}}{n!(a+n)}, \tag{45}$$

the result of Eq. (44) may be written

$$\chi(\rho)=\int_{-1}^{1} d\cos\theta\left(\frac{m^2(\theta)}{3r_0^3}\right)\left(\frac{1-e^{i\rho f(\theta)/r_0^3}}{-i\rho f(\theta)/r_0^3}\right). \tag{46}$$

The result (46) could, of course, be obtained directly from (38), but we shall need the general expression (43) later on.

We must still do the angular integral and then take the Fourier transform. These operations cannot be performed analytically for the most general angular functions $m(\theta)$ and $f(\theta)$ defined in Eqs. (36) and (37). We shall, therefore, consider a number of special cases, amenable to calculation, from which the significant features of the result will become apparent.

Let us assume, as is invariably the case for a transition probability $W(\omega)$ that is symmetric in ω, that the diagonal perturbations $\Delta\omega$ and $-\Delta\omega$ occur in pairs, the perturbation of either sign being associated with the same off-diagonal M. Under this assumption, we shall make, in turn, a sequence of approximations:

Case a. We replace both angular functions in Eq. (46) by some constant average value, $\langle m^2\rangle$ and $\langle f\rangle$.

Case b. We replace $m^2(\theta)$ by some average value; replace $f(\theta)$ by a function defined only by the property that, as $\cos\theta$ goes from -1 to $+1$, the function assumes with equal likelihood all values from $-L$ to L.

Case c. We replace $m(\theta)$ by $g(\sin\theta\cos\theta)$ and $f(\theta)$ by $q(3\cos^2\theta-1)$. These functions can be considered as specializations of Eqs. (36) and (37) by setting $q_1=q_2=g_0=g_2=0$. They are the physically correct functions when the magnetic field is parallel to the c axis.

Case d. Finally, we consider the possibility that $\Delta\omega$ does not occur in pairs, so that $W(\omega)$ will not be symmetric. We shall evaluate the integrals with the physically exact functions $m(\theta)=g(\sin\theta\cos\theta)$ and $f(\theta)=q(3\cos^2\theta-1)$.

The actual computations are quite involved. They are outlined in the Appendix. Here we only present and discuss the results.

It is convenient to define the quantity

$$\epsilon=1/r_0^3. \tag{47}$$

Then expressions like $q\epsilon$, $L\epsilon$, $\langle f\rangle\epsilon$ all represent, at least to order of magnitude, the effective nearest-neighbor dipole energy.

Case a

$$\chi(\omega)=\frac{4\pi\langle m^2\rangle}{3r_0^3\epsilon\langle f\rangle}\left[u_1\left(\frac{\omega}{\epsilon\langle f\rangle}+1\right)-u_1\left(\frac{\omega}{\epsilon\langle f\rangle}-1\right)\right], \tag{48}$$

$$\begin{aligned} u_1(x)&=0, \quad x<0\\ &=1, \quad x>0. \end{aligned} \tag{49}$$

Equation (48) represents a square shape of range $-\epsilon\langle f\rangle<\omega<\langle f\rangle\epsilon$, and magnitude $4\pi\langle m^2\rangle/3r_0^3\epsilon\langle f\rangle$. The area is $8\pi\langle m^2\rangle/3r_0^3$. In ruby, the nearest-neighbor dipole energy in the absence of exchange would be about 2.3 kMc/sec, so that this result is rather reminiscent of Kopvillem's.[8]

What happens to this disconcerting square shape, once we assume almost any kind of nonconstant angular function $f(\theta)$, is intuitively apparent. As we integrate over θ we shall be summing different square waves corresponding to different values of f. These rectangles are all centered at the origin and their height is inversely proportional to their extent along the ω axis. The result must inevitably be a function with a maximum at the origin and a falling monotonically to zero in the wings. If the range of $f(\theta)$ includes the value zero, which it does in all practical cases, the resulting function must approach infinity at the origin. The area of $\chi(\omega)$ is always equal to $\chi(\rho)_{\rho=0}$, and inspection of Eq. (46) shows that this area still remains $8\pi m^2/3r_0^3$, regardless of any assumption about m and f. Consequently, the convolution of this singular function with the bell-shaped transform of $\Phi(\rho)$ will always give a finite, more or less bell-shaped result. We already know, then, from these very general considerations, that the cross-relaxation probability $W(\omega)$ must have a resonant shape.

Case b

$$\begin{aligned} \chi(\omega)&=\frac{8\pi\langle m^2\rangle}{3r_0^3}\frac{1}{2L\epsilon}\ln\frac{L\epsilon}{\omega}, \quad |\omega|<L\epsilon\\ &=0, \quad |\omega|>L\epsilon. \end{aligned} \tag{50}$$

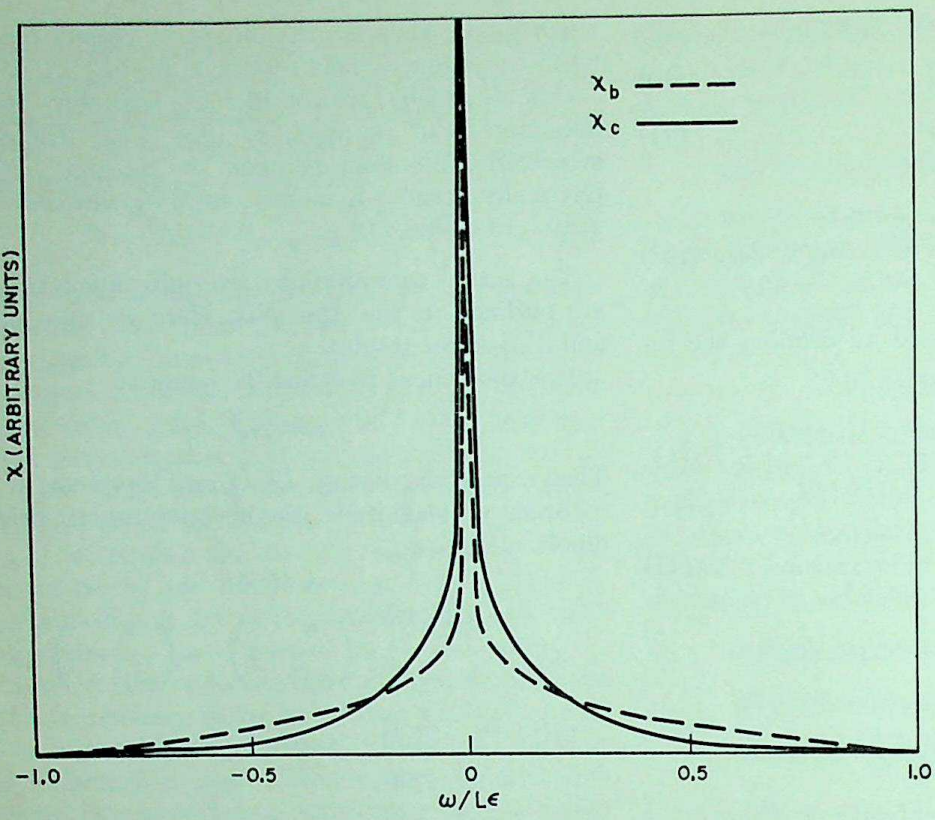

FIG. 2. χ_b [Eq. (50)] and χ_c [Eq. (53)].

This function has a logarithmic singularity at the origin and an area of $8\pi\langle m^2\rangle/3r_0^3$, as expected. The "half-power" width is, of course, undefined. If we define a half-width $\omega_{1/2}$ by the relation

$$\int_0^{\omega_{1/2}} \chi(\omega)d\omega = \tfrac{1}{2}\int_0^{\infty} \chi(\omega)d\omega, \tag{51}$$

then $\omega_{1/2}$ turns out to be

$$\omega_{1/2} = L\epsilon/5.4 \cong L\epsilon/2e. \tag{52}$$

Case c

If $|\omega| < q\epsilon$,

$$\chi(\omega) = \frac{4\pi g^2}{27\sqrt{3}r_0^3 q\epsilon}\left\{\sqrt{3}+\ln\frac{\sqrt{3}-1}{\sqrt{3}+1} -\tfrac{1}{3}\left[\left(1-\frac{\omega}{q\epsilon}\right)^{1/2}\left(5+\frac{\omega}{q\epsilon}\right)+\left(1+\frac{\omega}{q\epsilon}\right)^{1/2}\left(5-\frac{\omega}{q\epsilon}\right)\right] +\ln\left|\frac{[1-(\omega/q\epsilon)]^{1/2}+1}{[1-(\omega/q\epsilon)]^{1/2}-1}\right|+\ln\left|\frac{[1+(\omega/q\epsilon)]^{1/2}+1}{[1+(\omega/q\epsilon)]^{1/2}-1}\right|\right\}. \tag{53a}$$

If $q\epsilon < |\omega| < 2q\epsilon$,

$$\chi(\omega) = \frac{4\pi g^2}{27\sqrt{3}r_0^3 q\epsilon}\left\{\sqrt{3}+\ln\frac{\sqrt{3}-1}{\sqrt{3}+1} -\frac{1}{3}\left(1+\frac{|\omega|}{q\epsilon}\right)^{1/2} \times\left(5-\frac{|\omega|}{q\epsilon}\right)+\ln\left|\frac{[1+(|\omega|/q\epsilon)]^{1/2}+1}{[1-(|\omega|/q\epsilon)]^{1/2}-1}\right|\right\}. \tag{53b}$$

If $|\omega| > 2q\epsilon$,

$$\chi(\omega) = 0. \tag{53c}$$

In Fig. 2 we display this function, together with the simple logarithmic function of Eq. (50). In Eq. (50) we have chosen $L=2$ and $\langle m^2\rangle = \langle \sin^2\theta \cos^2\theta\rangle = 2/15$, and in Eq. (53) we have put $g=q=1$, so that the parameters match in both expressions. With this choice of numbers, the logarithmic function behaves like $\ln|\omega|^{-0.0444/\epsilon}$ near the origin, whereas the more complicated function behaves like $\ln|\omega|^{-0.0856/\epsilon}$. The exact function has the sharper singularity. The areas, as well as all qualitative features are the same.

Case d

If $\omega < -q\epsilon$,

$$\chi(\omega) = 0. \tag{54a}$$

If $-q\epsilon < \omega < 0$,

$$\chi(\omega) = \frac{4\pi g^2}{27\sqrt{3}r_0^3 q\epsilon}\left\{-\frac{1}{3}\left(\frac{\omega}{q\epsilon}+1\right)^{1/2}\left(\frac{\omega}{q\epsilon}-5\right) +\ln\left|\frac{[1+(\omega/q\epsilon)]^{1/2}+1}{[1+(\omega/q\epsilon)]^{1/2}-1}\right|\right\}. \tag{54b}$$

If $0 < \omega < 2q\epsilon$,

$$\chi(\omega) = \frac{4\pi g^2}{27\sqrt{3}r_0^3 q\epsilon}\left\{\sqrt{3}+\ln\frac{\sqrt{3}-1}{\sqrt{3}+1} -\frac{1}{3}\left(\frac{\omega}{q\epsilon}+1\right)^{1/2} \times\left(\frac{\omega}{q\epsilon}-5\right)+\ln\left|\frac{[1+(\omega/q\epsilon)]^{1/2}+1}{[1+(\omega/q\epsilon)]^{1/2}-1}\right|\right\}. \tag{54c}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

If $\omega > 2q\epsilon$,

$$\chi(\omega) = 0. \tag{54d}$$

We remark that this function is not symmetric in ω. The asymmetry is important primarily in the wings. $\chi(\omega)$ and $\chi(-\omega)$ assume identical form as ω approaches zero. The associated function $\Phi(\omega)$ behaves similarly. It seems likely, therefore, that any asymmetry arising from the present considerations would be accessible only to measurements made under conditions where large amounts of energy are transferred to or from the dipole system.

Qualitatively there is little difference between the symmetric case c and the nonsymmetric case d, just as little difference results from using the approximate f and m of case b instead of the f and m of case c, which represent the dipole interaction exactly provided the Zeeman and crystal field operators commute. In all cases there is a logarithmic singularity at the origin, and an over-all width determined by the effective nearest neighbor dipole energy. It is clear that these characteristics of χ can be expected to hold even when the most general form of f and m allowed by Eqs. (36) and (37) is physically appropriate.

Convolution

As indicated by Eq. (24), the function we seek, $W(\omega)$, is proportional to the convolution of $\Phi(\omega)$ and $\chi(\omega)$.

The widths of two convoluted functions, generally speaking, add in some fashion. Two Lorentz curves add width algebraically, two Gaussians add width rms wise. In particular, in the limit that the width of one function goes to zero, the resultant width approaches the width of the other function. A δ function simply leaves its partner intact. Our function $\chi(\omega)$ is an exception to this rule. Its peculiar properties under convolution are of considerable importance in determining the shape of $W(\omega)$.

As far as the effect on the resultant width is concerned, the exact shape of Φ does not make much difference, particularly when Φ is either very much broader or very much narrower than χ. If we use the simplified form of $\chi(\omega)$ given in Eq. (50), and simplify $\Phi(\omega)$ by a square shape of unit area and half-length a, we can do the convolution analytically.

If $a > L\epsilon$, it turns out that the resulting half-width is always identically a. Thus, when Φ is broader than χ, χ adds no width at all, but merely smoothes out the discontinuity of the square shape. In this case χ is practically equivalent to a δ function. The more interesting case is when $a < L\epsilon$. Then the convolution gives:

If $0 < |\omega| < (L\epsilon - a)$,

$$W(\omega) = \frac{C}{4}\left[\frac{2}{L\epsilon} + \frac{1}{L\epsilon}\left(\frac{\omega}{a}+1\right)\ln\left|\frac{L\epsilon}{\omega+a}\right| + \frac{1}{L\epsilon}\left(1-\frac{\omega}{a}\right)\ln\left|\frac{L\epsilon}{a-\omega}\right|\right]. \tag{55a}$$

If $(L\epsilon - a) < |\omega| < (L\epsilon + a)$,

$$W(\omega) = \frac{C}{4}\left[\frac{1}{a} + \frac{1}{L\epsilon}\left(1-\frac{|\omega|}{a}\right)\left(\ln\left|\frac{L\epsilon}{a-|\omega|}\right|+1\right)\right]. \tag{55b}$$

If $|\omega| > (L\epsilon + a)$,

$$W(\omega) = 0. \tag{55c}$$

$$C = \frac{2\pi}{\hbar}\frac{n}{v}\frac{8\pi\langle m^2\rangle}{3r_0^3}. \tag{55d}$$

From Eq. (55a), the quantity $\omega_{1/2}$, the half-width of the resultant $W(\omega)$, can easily be calculated. We define

$$N = \omega_{1/2}/a. \tag{56}$$

Then Eq. (55a) can be written

$$W(0) = \frac{C}{2L\epsilon}\left[1+\ln\frac{L\epsilon}{a}\right], \tag{57}$$

$$W(Na) = \frac{C}{2L\epsilon}\left[1+\frac{(N+1)}{2}\ln\frac{L\epsilon}{(N+1)a} - \frac{(N-1)}{2}\ln\frac{L\epsilon}{(N-1)a}\right]. \tag{58}$$

If the χ width $L\epsilon/2e$ is much larger than a, $\omega_{1/2}$ will be likewise much larger than a, and N will be large. If we expand the logarithms to first power in $1/N$, Eq. (58) can be reduced to

$$W(Na) = \ln(L\epsilon/Na). \tag{59}$$

If we now solve $W(Na) = \frac{1}{2}W(0)$, we obtain

$$Na = \omega_{1/2} = [2a(L\epsilon/2e)]^{1/2}. \tag{60}$$

This is a remarkable result. As the Φ width a goes to zero, $\omega_{1/2}$ of W does not approach $\omega_{1/2}$ of χ, $L\epsilon/2e$, as one would intuitively expect, but rather it approaches zero. This strange property of multiplying widths rather than adding them turns out to be very nearly true even when Φ and χ have comparable widths, as can be seen from Fig. 3. We have done the convolution of the physically real χ of *Case c*, using square waves, Gaussians, and Lorentzians for Φ. The convolutions were done numerically on the IBM 7090, and the behavior of the half-widths is illustrated in Fig. 3.

The shape of the resulting function is also noteworthy. When Φ and χ have comparable widths, the

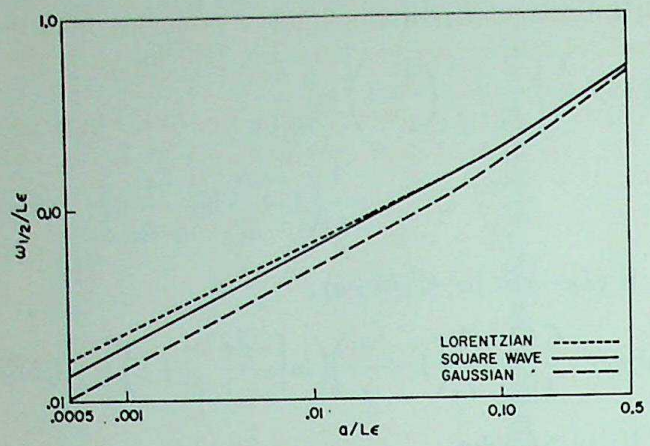

FIG. 3. Half-width ($\omega_{1/2}$) of convolution of Φ with χ_c, versus half-width (a) of Φ. For Φ = square wave, $\omega_{1/2} \sim a^{0.50}$; Φ = Gaussian, $\omega_{1/2} \sim a^{0.50}$, Φ = Lorentzian, $\omega_{1/2} \sim a^{0.48}$.

shape is nearly that of Φ. As Φ becomes narrower than χ, the shape of their convolution somewhat resembles an upside-down funnel. These changes in the shape of $W(\omega)$ are illustrated in Fig. 4. [The extreme changes in shape have necessitated drawing Fig. 4(a) on a different scale than Figs. 4(b) and 4(c), as indicated.]

The significance of the present result is that it is the key to the concentration dependence of the width of $W(\omega)$. As we have already remarked, this dependence is contained entirely in Φ. Our χ has a width of the order of the effective nearest-neighbor interaction. In general, one would expect χ to be considerably broader than Φ. If χ added width, in convolution, like normal functions, one would predict a concentration-dependent width only for very high concentrations. The unusual behavior of χ in this regard predicts a dependence proportional to the square root of the concentration, even at vanishing concentrations. Furthermore, χ introduces the multiplicative factor $(L\epsilon/e)^{1/2}$, which makes the widths substantially larger than the resonance width a. This convolution property of χ thus enables us to meet all the experimentally given requirements: to have $W(\omega)$ much narrower than either the resonant frequency or the maximum dipole energy, but much broader than the absorption width, *and* at the same time concentration-dependent.

Finally, it is clear from Figs. 2 and 3 that all the essential features of our results hold whether we use the χ of Eq. (50) or the more complicated one of Eq. (53). Thus, it is unnecessary to evaluate χ explicitly for general $\Delta\omega$ and M [Eqs. (36) and (37)]. The relevant parameters are the average of M^2, the range of f, which we have called L, and the value of r_0. These parameters can, in principle, be readily calculated for any physical situation, and they will define χ in terms of Eq. (50).

V. SUMMARY

We have laid a physical foundation for a general theory of cross relaxation, and we have applied our considerations particularly to single-spin transitions. Our formulation makes it unnecessary to appeal to moments or to plausibility arguments; rather, it yields the relevant functions exactly, within the limits of the physical assumptions. We review the principal steps of the argument.

(1) For each spin, the dipole interaction causes both diagonal, "static," energy shifts, and transitions between Zeeman levels.

(2) Due to the energy shifts, transitions between Zeeman states are possible which strictly conserve energy.

(3) The transition probability depends on the density of degenerate states. This density is obtained by counting the number of dipole configurations which meet the relevant energy constraint. The transition probability is given by integrating over this distribution the square of the off-diagonal dipole elements. We note a certain analogy to the method of the microcanonical ensemble, where the trick also is to calculate

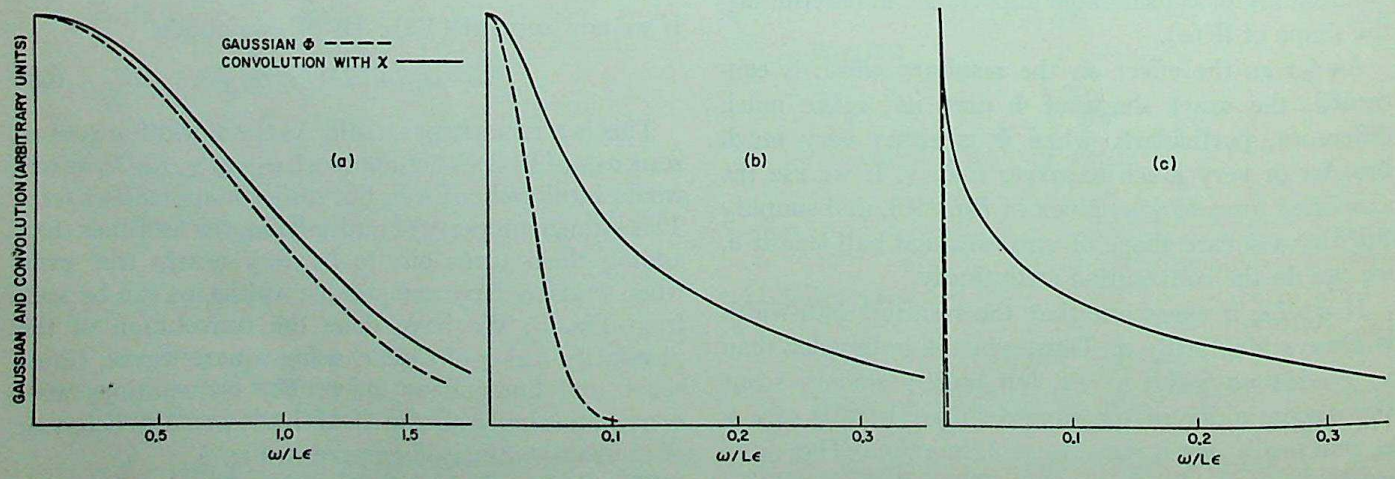

FIG. 4. Convolution of χ_c and Gaussian Φ, for various values of $\omega_{1/2}$ (Gaussian)/$\omega_{1/2}(\chi_c)$. (a) $\omega_{1/2}(G)/\omega_{1/2}(\chi_c) = 5$. (b) $\omega_{1/2}(G)/\omega_{1/2}(\chi_c) = 0.2$. (c) $\omega_{1/2}(G)/\omega_{1/2}(\chi_c) = 0.008$.

the phase volume (number of configurations) corresponding to a given energy.

(4) We showed that the equations derived in this manner can also be derived from the Fourier analysis of the dipole operator and from any of several interpretations of first-order time-dependent perturbation theory.

(5) For single flips, the transition probability $W(\omega)$ was given by the convolution of two functions, $\chi(\omega)$ and $\Phi(\omega)$. χ is essentially the power spectrum of the off-diagonal elements of $\mathcal{H}^{\rm dip}$. To an excellent approximation, it depends on ω as $\ln|1/\omega|$. Φ describes essentially the level broadening due to the diagonal elements of $\mathcal{H}^{\rm dip}$. It is equivalent to the absorption line shape. The convolution of Φ and χ, which yields $W(\omega)$, has a sharp peak whose width is proportional to the geometric mean of the χ width and the Φ width. This sharp peak is superposed on a broad spectrum whose width is of the same order as the nearest-neighbor dipole energy. The transition probability per spin is linear in the concentration n, and for low concentrations its width in ω space is proportional to the square root of the concentration.

We have considered only single-spin flips explicitly, while experimental measurements are made on double, triple, or higher multiple processes. Nevertheless, the frequency and concentration dependence of our cross-relaxation probability satisfies a number of experimental features which have not been accounted for previously in terms of a single unified calculation.

The explicit extension of the theory to multiple-spin processes is the principal subject of the succeeding paper (part II); detailed quantitative application of the entire theory to typical experiments is made in part III.

APPENDIX: EVALUATION OF χ UNDER VARIOUS APPROXIMATIONS

We refer to Eq. (46). If we assume that the diagonal perturbations $\Delta\omega$ and $-\Delta\omega$ come in pairs, then Eq. (46) becomes

$$\chi(\rho)=\int_{-1}^{1} d\cos\theta\left(\frac{m^2(\theta)}{3r_0^3}\right)\left(\frac{e^{-i\rho f(\theta)\epsilon}-e^{i\rho f(\theta)\epsilon}}{-i\rho f(\theta)\epsilon}\right) \quad \text{(A1a)}$$

$$\equiv\int_{-1}^{1} d\cos\theta\left(\frac{2m^2(\theta)}{3r_0^3}\right)\frac{\sin[\rho f(\theta)\epsilon]}{\rho f(\theta)\epsilon}, \quad \text{(A1b)}$$

where ϵ is defined in Eq. (47).

Case a. If we set $m^2(\theta)=\langle m^2\rangle$ and $f(\theta)=\langle f\rangle$, then Eq. (A1b) reduces to

$$\chi(\rho)=(4m^2/3r_0^3)\sin\epsilon\langle f\rangle\rho/\epsilon\langle f\rangle\rho). \quad \text{(A2)}$$

The Fourier transform of $(\sin x)/x$ is well known.[21] It is a square wave of amplitude π extending from -1 to 1. Hence, we arrive at the Eq. (48) for $\chi(\omega)$, given in the text.

Case b. If we replace f by a function which goes from $-L$ to L as $\cos\theta$ goes from -1 to 1, Eq. (A1) becomes

$$\chi(\rho)=\int_{-L}^{L} df\left(\frac{2\langle m^2\rangle}{3Lr_0^3}\right)\frac{\sin\epsilon f\rho}{\epsilon f\rho}. \quad \text{(A3)}$$

The integral will be recognized as essentially the sine-integral function (Ref. 20, p. 145), and so

$$\chi(\rho)=\frac{4\langle m^2\rangle}{3r_0^3}\frac{\mathrm{Si}(L\epsilon\rho)}{L\epsilon\rho}. \quad \text{(A4)}$$

The Fourier transform of $\mathrm{Si}(x)/x$ is also well known,[21] and so we arrive at Eq. (50) in the text.

Case c. If we set $f=q(3\cos^2\theta-1)$ and $m^2=g^2\sin^2\theta\times\cos^2\theta$, Eq. (A1) becomes

$$\chi(\rho)=\frac{g^2}{3r_0^3\epsilon q}\int_{-1}^{1} d\cos\theta\left(\frac{\sin^2\theta\cos^2\theta}{3\cos^2\theta-1}\right)\left(\frac{1}{-i\rho}\right)\times\{\exp[-i\rho\epsilon q(3\cos^2\theta-1)]-\exp[i\rho\epsilon q(3\cos^2\theta-1)]\}. \quad \text{(A5)}$$

The angular integrals in Eq. (A5) cannot be done analytically as they stand. Instead, we shall avail ourselves of the well-known[21] theorem that if

$$\int f(\rho)e^{-i\omega\rho}d\rho=F(\omega), \quad \text{(A6)}$$

then

$$\int\frac{f(\rho)}{-i\rho}e^{-i\omega\rho}d\rho=\int_{-\infty}^{\omega}F(\omega')d\omega'. \quad \text{(A7)}$$

We use the following ploy: First we take the Fourier transform of Eq. (A5) ignoring the $-i\rho$ in the denominator. Then we do the angular integral. Finally, we integrate with respect to ω' as indicated by Eqs. (A6) and (A7).

The first step immediately yields

$$\frac{4\pi g^2}{3r_0^3\epsilon q}\int_0^1 d\cos\theta\left(\frac{\sin^2\theta\cos^2\theta}{3\cos^2\theta-1}\right)\times\{\delta[\omega'+\epsilon q(3\cos^2\theta-1)]-\delta[\omega'-\epsilon q(3\cos^2\theta-1)]\}. \quad \text{(A8)}$$

Since the integrand is symmetric in $\cos\theta$, we have written the integral over half the interval and multiplied by 2.

We now perform the angular integral in Eq. (A8). Integrals of the form in Eq. (A8) are handled by the

[21] A. Erdely, F. Oberhettinger, W. Magnus, and F. G. Tricomi, *Tables of Integral Transforms* (McGraw-Hill Book Company, Inc., New York, 1954), Vol. I, Chaps. 1 and 2.

following general procedure:

$$\int_a^b G(x)\delta[F(x)]dx=\int_{F(a)}^{F(b)} G(x)\,(dF/dx)^{-1}\delta(F)dF$$

$$=\frac{G}{(dF/dx)}\bigg|_{F(x)=0} \quad \text{if } F(x)=0 \text{ at some point in the interval } a\leqq x\leqq b \tag{A9}$$

$$=0, \quad \text{if } F(x)\neq 0 \text{ at every point in the interval } a\leqq x\leqq b.$$

Using the first δ function in Eq. (A8), the correspondence with Eq. (A9) is

$$G(\cos\theta)=\frac{4\pi g^2}{3r_0^3\epsilon q}\,\frac{\sin^2\theta\cos^2\theta}{3\cos^2\theta-1}, \tag{A10}$$

$$F(\cos\theta)=\omega'+\epsilon q(3\cos^2\theta-1), \tag{A11}$$

$$\frac{dF}{d\cos\theta}=6\epsilon q\cos\theta. \tag{A12}$$

From Eq. (A11) we have $F=0=>\cos\theta=(\epsilon q-\omega'/3\epsilon q)^{1/2}$, and after some algebra,

$$\frac{G}{(dF/d\cos\theta)}\bigg|_{F=0}=-\frac{2\pi g^2}{27\sqrt{3}r_0^3\epsilon^2q^2}\left(1-\frac{\omega'}{\epsilon q}\right)^{1/2}\left(1+\frac{2\epsilon q}{\omega'}\right). \tag{A13}$$

This result is valid if $[\omega'+\epsilon q(3\cos^2\theta-1)]=0$ at some point on the interval $0\leqq\cos\theta\leqq 1$, or in other words, if $-2\epsilon q<\omega'<\epsilon q$. If ω' lies outside these limits, the result is 0.

We have completed the angular integral. The expression (A13) corresponds to $F(\omega')$ in Eq. (A7). It remains to integrate over ω'. The main point is that the integral over ω', from $-\infty$ to ω, must be considered separately for three cases:

(1) $\omega<-2\epsilon q$: The integrand is always 0 and the integral vanishes.

(2) $-2\epsilon q<\omega<\epsilon q$: The integrand is given by Eq. (A13) and the limits are $-2\epsilon q$ to ω.

(3) $\omega>\epsilon q$: The integrand is given by Eq. (A13) and the limits are $-2\epsilon q$ to ϵq.

The integration is straightforward. We quote only the results

$\omega<-2\epsilon q$: 0; (A14a)

$-2\epsilon q<\omega<\epsilon q$:

$$\frac{4\pi g^2}{27r_0^3\epsilon q}\left[-\frac{1}{3}\left(1-\frac{\omega}{\epsilon q}\right)^{1/2}\left(5+\frac{\omega}{\epsilon q}\right)\right.$$

$$\left.-\ln\left|\frac{[1-(\omega/\epsilon q)]^{1/2}-1}{[1-(\omega/\epsilon q)]^{1/2}+1}\right|+\sqrt{3}+\ln\frac{\sqrt{3}-1}{\sqrt{3}+1}\right]; \tag{A14b}$$

$\omega>\epsilon q$:

$$\frac{4\pi g^2}{27r_0^3\epsilon q}\left[\sqrt{3}+\ln\frac{\sqrt{3}-1}{\sqrt{3}+1}\right]. \tag{A14c}$$

These are the results for the first δ function in Eq. (A8). The computation for the second δ function is carried out analogously. The result is

$\omega<-\epsilon q$: 0; (A15a)

$-\epsilon q<\omega<2\epsilon q$:

$$-\frac{4\pi g^2}{27\sqrt{3}r_0^3\epsilon q}\left[\frac{1}{3}\left(1+\frac{\omega^{1/2}}{\epsilon q}\left(5-\frac{\omega}{\epsilon q}\right)\right)\right.$$

$$\left.+\ln\left|\frac{[1+(\omega/\epsilon q)]^{1/2}-1}{[1+(\omega/\epsilon q)]^{1/2}+1}\right|\right]; \tag{A15b}$$

$\omega>2\epsilon q$:

$$-\frac{4\pi g^2}{27\sqrt{3}r_0^3\epsilon q}\left[\sqrt{3}+\ln\frac{\sqrt{3}-1}{\sqrt{3}+1}\right]. \tag{A15c}$$

Finally, combining the results of Eqs. (A14) and (A15), we arrive at the function given in Eq. (53) in the text.

Case d. If the $\Delta\omega$'s do not occur in pairs, we revert to Eq. (46) in the text rather than to Eq. (A1). We note that the only difference between Eq. (46) and Eq. (A1) is that in Eq. (46) there is a 1 in place of one of the exponentials in Eq. (A1). The computation is therefore essentially unaltered from *Case c*, the same basic arguments applying step for step. The result of the first step [Eq. (58)] will now have one of its δ functions replaced by $\delta(\omega')$. The angular integration for that portion of Eq. (A8) which now contains $\delta(\omega')$ offers no subtleties. The final integration over ω' merely replaces the $\delta(\omega')$ by a unit step at $\omega=0$. The result for this portion of the integral is

$\omega<0$: 0; (A16a)

$\omega>0$:

$$\frac{4\pi g^2}{27\sqrt{3}r_0^3\epsilon q}\left[\sqrt{3}+\ln\frac{\sqrt{3}-1}{\sqrt{3}+1}\right]. \tag{A16b}$$

By combining Eqs. (A15) and (A16), we arrive at the $\chi(\omega)$ given by Eq. (54) in the text.

General Theory of Cross Relaxation. II. Higher Order Processes*

W. J. C. GRANT
Bell Telephone Laboratories, Murray Hill, New Jersey
(Received 30 January 1964)

The theory of part I is extended to multiple spin processes. The lowest order two-spin process yields a cross-relaxation probability W_{CR} whose principal characteristics are the same as those of W_{CR} for single spin flips. Higher order two-spin processes occur with much lower probability and this probability is not sharply peaked at harmonic coincidence. Three-spin and higher multiple K-spin processes yield functions $W_{CR}(\omega)$ whose width becomes progressively larger and less dependent on the concentration, and whose magnitude depends on the concentration n as n^K. The effects of short-range forces (exchange) are easily embodied in the theory, but in the absence of such forces special attention must be paid to the dipole fields of near neighbors, which are then likely to dominate the cross-relaxation process.

I. INTRODUCTION

IN part I[1] we presented a general formalism to describe the effect of the dipolar interaction on the otherwise uncoupled spins in a lattice. We applied our considerations particularly to nonradiative single-spin transitions. In the extension of the theory to higher order processes, we presuppose the entire machinery of part I.

In generalizing the previous results to more complex processes, we follow these steps: (1) generalize the statistical procedure developed in part I, (2) discuss two-spin processes in detail, (3) consider triple and higher multiple processes, and (4) consider subsidiary problems arising from near-neighbor interactions and inhomogeneous broadening.

II. STATISTICAL PROCEDURE

The matrix element used for single-spin flips was $\sum_i M_{1i}^2$. This element corresponded to an interaction in which spin one interacts with all the other spins in such a manner that spin one flips and all the others stay put. The spin variables of M_{1i} have a form like $S_-{}^1S_z{}^i$.

Now let us consider a double flip. By a double flip we mean a process in which spin one flips down and any one of the others flips up. What is the appropriate statistical procedure and what matrix element do we embed in this procedure?

The statistics breaks up into two parts. First, we consider the interaction between spin one and some fixed spin p. The matrix element has the form $M_{1p}(\mathbf{r}_{1p})$ with spin variables typically of the form $S_-{}^1S_+{}^p$. With this one-p combination fixed, we count the possible configurations of all the remaining spins. Secondly, we sum M_{1p} over all possible interactions. When one and p interact in a double flip, their interaction with one another is evidently on a different footing from their interaction with all the other spins.

A closely related question concerns the indistinguishability of the spins. Two spins are distinguishable if any of the following conditions obtain: (1) They belong to a different species; (2) they occupy different Zeeman states; (3) they occupy different positions in the lattice. Conditions (1) and (2) are obvious. The implication of condition (3) is that we do not get a new configuration if we interchange spin q for spin p, but we do get a new configuration if we move spin p (or spin q) to a different lattice site.

Suppose that the distinguishability conditions (1) and (2) give N_1 spins of kind 1, N_2 of kind 2, and so forth, with a total of N spins. Suppose we fix the positions of A spins: A_1 of kind 1, A_2 of kind 2, and so forth. We now distribute the remaining $N-A$ spins randomly into the remaining $M-A$ lattice sites. The number of configurations is clearly

$$C(A)=\frac{(M-A)!}{(N_1-A_1)!(N_2-A_2)!\cdots(M-N)!}. \quad (1)$$

By Stirling's approximation, this becomes

$$C(A)=\frac{(M-A)^{M-A}e^{-N+A}}{(N_1-A_1)!(N_2-A_2)!(M-N)^{M-N}}. \quad (2)$$

Now

$$\lim_{M\to\infty}(M-A)^{M-A}=\lim_{M\to\infty}M^{M-A}\times(1-(A/M))^{M-A}=M^{M-A}e^{-A}, \quad (3)$$

so that (putting $n=N/M$)

$$C(A)=[M^{N-A}/(N_1-A_1)!(N_2-A_2)!\cdots]\times[e^{-N}/(1-n)^{M-N}]. \quad (4)$$

We notice that the second bracket of Eq. (4) is independent of A and will always cancel out when we compute a fractional number of configurations. For a two-spin process involving spin 1 and spin p, we have $A_1=A_2=1$, $A=2$, and the fractional number of configurations is

$$f=\frac{C(2)}{C(0)}=\frac{N_1N_2v^2}{V^N}\int d\mathbf{r}_2d\mathbf{r}_3\cdots d\mathbf{r}_{p-1}d\mathbf{r}_{p+1}\cdots d\mathbf{r}_N, \quad (5)$$

* This work was supported in part by the U. S. Army Signal Corps. under Contract DA-36-039-sc-89169.

Digitized by Arya Samaj Foundation Chennai and eGangotri

where

$$v=V/M \tag{6}$$

and V has been replaced by $\int d\mathbf{r}$ in the numerator.

To obtain the transition probability, we need to introduce the transition operator and the appropriate energy constraint. The transition operator, as we have seen, is $M_{1p}^2(\mathbf{r}_{1p})$ summed over all $\mathbf{r}_{1p}$. The energy constraint is discussed in the next section. The transition probability may be symbolically written

$$W=\frac{2\pi}{\hbar}\frac{N_1N_2v^2}{V^N}\cdot\frac{1}{v}$$
$$\times\int M_{1p}^2 d\mathbf{r}_{1p}d\mathbf{r}_{12}\cdots d\mathbf{r}_{1,\,p-1}d\mathbf{r}_{1,\,p+1}\cdots d\mathbf{r}_{1N}$$
$$\times\text{energy constraint.} \tag{7}$$

We have introduced a factor $1/v$ to keep the units and dimensionality consistent in passing from the lattice sum for M_{1p}^2 to an integral. Also, the reference spin 1 has been chosen as origin of coordinates.

For a single-spin process, $C(1)/C(0)$ will have one N in front, and one more volume integral, so that W reduces to the expression 22 of part I.

The extension of this counting scheme to processes involving an arbitrary number of spins is obvious, and some examples will be given below.

III. TWO-SPIN PROCESSES

First, we formulate the energy constraint for the two-spin process. Second, we dicusss the first-order two-spin process. Third, we discuss a second-order two-spin process. Fourth, we consider the long-range process.

Energy Constraint

In a two-spin process, spin one flips from state A to state B, while another spin flips from state C to state D. The labels A, B, C, D designate the quantum numbers of the unperturbed single-particle states. The corresponding unperturbed energies are $E_A{}^0, E_B{}^0, E_C{}^0, E_D{}^0$. These energies are perturbed by the dipole interaction, and in first order we write

$$E^{\text{tot}}=E^0+E^{\text{dip}}. \tag{8}$$

E^{tot} and E^0 are numbers, but E^{dip} depends both on the specific configuration of all dipoles which the spin sees, and on the quantum state in which the spin finds itself. For a transition to be possible, we require zero change of over-all energy. The net change in Zeeman energy must be balanced by the net change in dipole energy:

$$(E_A{}^{\text{tot}}-E_B{}^{\text{tot}})+(E_C{}^{\text{tot}}-E_D{}^{\text{tot}})=0, \tag{9}$$

Equation (9) replaces the analogous condition $E_A{}^{\text{tot}}-E_B{}^{\text{tot}}=0$, which was appropriate for single flips.

To formulate the analogous energy constraint, we specify that: (1) spin 1 have energy $E_A{}^{\text{tot}}$ when in state A; (2) spin 1 have energy $E_B{}^{\text{tot}}$ when in state B; (3) spin p have energy $E_C{}^{\text{tot}}$ when in state C; (4) spin p have energy $E_D{}^{\text{tot}}$ when in state D; and (5) the constraint expressed in Eq. (9) holds. The total number of configurations for which Eq. (9) holds is obtained by integrating over all values of $E_A{}^{\text{tot}}, E_B{}^{\text{tot}}, E_C{}^{\text{tot}}, E_D{}^{\text{tot}}$. The energy constraint is then expressed as the operator

$$\int\delta[E_A{}^{\text{tot}}-(E_A{}^0+E_A{}^{\text{dip}})]\delta[E_B{}^{\text{tot}}-(E_B{}^0+E_B{}^{\text{dip}})]$$
$$\times\delta[E_C{}^{\text{tot}}-(E_C{}^0+E_C{}^{\text{dip}})]\delta[E_D{}^{\text{tot}}-(E_D{}^0+E_D{}^{\text{dip}})]$$
$$\times\delta[E_A{}^{\text{tot}}-E_B{}^{\text{tot}}+E_C{}^{\text{tot}}-E_D{}^{\text{tot}}]$$
$$\times dE_A{}^{\text{tot}}dE_B{}^{\text{tot}}dE_C{}^{\text{tot}}dE_D{}^{\text{tot}}. \tag{10}$$

Performing the integrations reduces expression (10) to

$$\delta[(E_A{}^0-E_B{}^0+E_C{}^0-E_D{}^0)$$
$$-(E_B{}^{\text{dip}}-E_A{}^{\text{dip}}+E_D{}^{\text{dip}}-E_C{}^{\text{dip}})]. \tag{11}$$

The first parenthesis in expression (11) is the total change in unperturbed energy and we denote it by $\hbar\omega$. The second parenthesis is the negative of the change in dipole energy. We put

$$\hbar\Delta\omega_{AB}=E_B{}^{\text{dip}}-E_A{}^{\text{dip}}, \tag{12a}$$
$$\hbar\Delta\omega_{CD}=E_D{}^{\text{dip}}-E_C{}^{\text{dip}}. \tag{12b}$$

We again assume that the contributions of all spins to $\Delta\omega$ are additive:

$$\Delta\omega_{AB}=\sum_{k\neq1}\Delta\omega_{AB}(\mathbf{r}_{1k}), \tag{13a}$$
$$\Delta\omega_{CD}=\sum_{k\neq p}\Delta\omega_{CD}(\mathbf{r}_{pk}). \tag{13b}$$

Expression (11) now becomes

$$\delta(\omega-[\sum_{k\neq1}\Delta\omega_{AB}(\mathbf{r}_{1k})+\sum_{k\neq p}\Delta\omega_{CD}(\mathbf{r}_{pk})]). \tag{14}$$

Finally, replacing the δ function by its Fourier transform, we have for the energy constraint:

$$\frac{1}{2\pi}\int_{-\infty}^{\infty}\exp\{-i\rho[\omega-\sum_{k\neq1}\Delta\omega_{AB}(\mathbf{r}_{1k})-\sum_{k\neq p}\Delta\omega_{CD}(\mathbf{r}_{pk})]\}d\rho$$
$$\equiv\frac{1}{2\pi}\int_{-\infty}^{\infty}(\exp\{i\rho[\Delta\omega_{AB}(\mathbf{r}_{1p})+\Delta\omega_{CD}(\mathbf{r}_{p1})]\}$$
$$\times\prod_{k\neq1,p}\exp\{i\rho[\Delta\omega_{AB}(\mathbf{r}_{1k})+\Delta\omega_{CD}(\mathbf{r}_{pk})]\})e^{-i\rho\omega}d\rho. \tag{15}$$

First-Order Process

We may now write the transition probability in the form of Eq. (7) using the energy constraint we have

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

just derived. We put $N_i/V=n_i/v$. We then have

$$W(\omega)=\frac{2\pi}{\hbar}\int_{-\infty}^{\infty}\frac{1}{2\pi}\Big[n_1n_2\cdot\frac{1}{v}\int M_{1p}{}^2\exp\{i\rho[\Delta\omega_{AB}(\mathbf{r}_{1p})+\Delta\omega_{CD}(\mathbf{r}_{p1})]\}d\mathbf{r}_{1p}\Big(\frac{1}{V}\int\exp\{i\rho[\Delta\omega_{AB}(\mathbf{r}_{1k})+\Delta\omega_{CD}(\mathbf{r}_{pk})]\}d\mathbf{r}_{1k}\Big)^{N-2}\Big]e^{-i\omega\rho}d\rho. \quad (16)$$

This expression is very similar to Eq. (24) of part I, with the integral containing $M_{1p}{}^2$ corresponding to χ and the round bracket raised to the $(N-2)$ power corresponding to Φ. The difference is that χ and Φ cannot now be evaluated separately. They are coupled through the dependence of Φ on $\mathbf{r}_{1p}$. This becomes more apparent if we write $\mathbf{r}_{pk}=\mathbf{r}_{1k}-\mathbf{r}_{1p}$. As we integrate over $\mathbf{r}_{1p}$ to evaluate χ, we should simultaneously have to integrate out the $\mathbf{r}_{1p}$ dependence in Φ. This calculation would be impossible.

This impasse can be overcome through the following consideration: Let us consider the limiting situations, $\mathbf{r}_{1p}\rightarrow 0$ and $\mathbf{r}_{1p}\rightarrow\infty$. In the first case, the $\mathbf{r}_{1p}$ dependence of Φ is eliminated and Φ has exactly the form we discussed in part I. It will essentially describe a quasiresonance line whose parameters are the algebraic sum of the parameters for the resonance lines $A\leftrightarrow B$ and $C\leftrightarrow D$. In the second case, we note that $\Delta\omega(\mathbf{r})$ depends on r as r^{-3}. Within any arbitrarily large neighborhood of spin 1, $\mathbf{r}_{pk}$ will be infinite, $\Delta\omega(\mathbf{r}_{pk})$ will be zero, and $\exp[i\rho\Delta\omega(\mathbf{r}_{pk})]$ will equal one. The converse is true within any arbitrarily large neighborhood of spin p. Consequently, each of the $(N-2)$ integrals in Φ breaks up into the sum of two integrals.

$$\lim\Phi_{r_{1p}\rightarrow\infty}=\Big(\frac{1}{V}\int\{\exp[i\rho\Delta\omega_{AB}(\mathbf{r})]+\exp[i\rho\Delta\omega_{CD}(\mathbf{r})]\}dr\Big)^{N-2}. \quad (17)$$

It is easily shown that Φ now corresponds to the convolution of the two resonance lines $A\leftrightarrow B$ and $C\leftrightarrow D$.

In either limit, Φ is functionally identical to an absorption line and has a width roughly twice of an absorption line. For most practical applications, this is sufficient information. If more detail is necessary one must split the calculation into two parts corresponding to $\mathbf{r}_{1p}$ very small and $\mathbf{r}_{1p}$ very large. For $\mathbf{r}_{1p}$ small it is always possible to calculate exactly the diagonal dipole elements which determine $\Delta\omega$. For $\mathbf{r}_{1p}$ large it is always possible to convolute known absorption lines.

What is the physical meaning of the preceding arguments? In the first place it is no longer exactly true that χ and Φ represent, respectively, the rf power spectrum of the dipole interaction and the level broadening. Such a separation was possible for the single-spin theory of part I because of our assumption that the interactions of spin 1 were independent. Now, however, the interactions of spin 1 are not completely independent; they are correlated with the interactions of spin p. From our present point of view, we still assign to χ a meaning as power spectrum, and take care of the correlations in Φ. In line shape language, $\Phi(\rho)$ is the coherence relaxation function and its width corresponds to T_2. When two spins are very near one another, they are very strongly correlated. With respect to the rest of the system, they behave as a coupled unit with a coherence time equal to that of a single spin. When two spins are very far apart, on the other hand, they are uncorrelated, and their joint coherence time is given by

$$1/T_2(1,2)=[1/T_2(1)]+[1/T_2(2)],$$

or, if $T_2(1)=T_2(2)$,

$$T_2(1,2)=\tfrac{1}{2}T_2(1)=\tfrac{1}{2}T_2(2).$$

The dependence of Φ on r_{1p} is thus interpretable as the dependence of the *pair* coherence time on the spin separation.

We may then write for the double-flip probability

$$W(\omega)=\frac{2\pi}{\hbar}\frac{n_1n_2}{v}\int_{-\infty}^{\infty}\chi(\rho)\Phi(\rho)e^{-i\rho\omega}d\rho, \quad (18)$$

where

$$\chi(\rho)=\frac{1}{2\pi}\int M_{1p}{}^2e^{i\rho\Delta\omega_\chi(\mathbf{r})}d\mathbf{r}, \quad (19)$$

$$\Delta\omega_\chi(\mathbf{r})=\Delta\omega_{AB}(\mathbf{r}_{1p})+\Delta\omega_{CD}(\mathbf{r}_{p1}). \quad (20)$$

We now discuss briefly the more precise functional form of M_{1p} and $\Delta\omega$ appearing in Eqs. (18) to (20). The matrix element M_{1p} is, of course,

$$\langle A(1)C(p)|\mathcal{H}^{\mathrm{dip}}|B(1)D(p)\rangle.$$

In the absence of a crystal field, we would have

$$M_{1p}=g(3\cos^2\theta_{1p}-1)/r_{1p}{}^3, \quad \Delta m_{tot}=0, \quad (21a)$$

$$M_{1p}=g\sin^2\theta_{1p}/r_{1p}{}^3, \quad \Delta m_{tot}=\pm 2. \quad (21b)$$

The quantity g is the value of the appropriate spin matrix element. Like the matrix element for single flips, M_{1p} can be expressed even in the most general case as the product of an angular function and r^{-3}.

$$M_{1p}=m(\theta_{1p})/r_{1p}{}^3. \quad (22)$$

The $\Delta\omega$'s have the same form as in the single-spin process. In the absence of a crystal field

$$\Delta\omega_{AB}(\mathbf{r}_{1k})=q_{AB}(3\cos^2\theta_{1k}-1)/r_{1k}{}^3, \quad (23)$$

with an analogous expression for $\Delta\omega_{CD}$. The q_{AB} is the difference of the values assumed by the spin variables in the matrix elements $\mathcal{H}_{AA}{}^{\mathrm{dip}}$ and $\mathcal{H}_{BB}{}^{\mathrm{dip}}$. In the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

general case, $\Delta\omega$ too can still be expressed as the product of an angular function and r^{-3}:

$$\Delta\omega(\mathbf{r}_{1k}) = f(\theta_{1k})/r_{1k}^{-3}. \tag{24}$$

We see then that the χ of Eqs. (18) and (19) is identical in form to the single-spin χ of Eqs. (25) and (38) in part I. The functions $m(\theta)$ and $f(\theta)$ are still sums of Legendre polynomials of order two.

The entire discussion χ developed in part I applies without essential change to the two-spin case. Thus, we may write

$$\begin{aligned}\chi(\omega) &= \frac{8\pi\langle m^2\rangle}{3r_0^3}\frac{1}{2L\epsilon}\ln|L\epsilon/\omega|\,, \quad |\omega|<L\epsilon \\ &= 0, \qquad\qquad\qquad\quad |\omega|>L\epsilon.\end{aligned} \tag{25}$$

Here, $\langle m^2\rangle$ is the average value of $m^2(\theta)$ over the sphere, L is the maximum value of $f(\theta)$, and $\epsilon = r_0^{-3}$. Unlike the single flip, the double flip is not characterized by the occurrence of $\Delta\omega$ and $-\Delta\omega$ in pairs. The resulting χ is asymmetric and this asymmetry is well approximated by the addition of an additive constant on one side of the origin. As mentioned in part I, such asymmetry manifests itself primarily in the wings.

The discussion of $W(\omega)$ developed in part I also applies, with two changes: (1) There is now a coefficient of n^2 instead of n, so that the transition probability depends on the square of the concentration. (2) When calculating the central peak of W, we must use a Φ that is wider than its counterpart in the single-spin transition. The theory developed in part I regarding the shape of $W(\omega)$ and the concentration dependence of this shape applies to the double flip without further modification.

Second-Order Process

So far, we have treated the two-spin process in terms of first-order theory. It may happen, however, that the "resonant" condition is met, i.e., $\Delta E_{AB}{}^0 + \Delta E_{CD}{}^0 = 0$, or $\omega = 0$, but at the same time the matrix element M_{1p} vanishes. Such is the case for ruby at a number of magnetic field values when the field is parallel to the c axis. To see what effect is expected under these circumstances, we must go to second-order theory.

The second-order matrix element is given by

$$M_{1p}{}' = \sum_{X\neq B}\sum_{Y\neq D}\frac{\langle A(1)C(p)|\mathcal{H}^{\rm dip}|X(1)Y(p)\rangle\langle X(1)Y(p)|\mathcal{H}^{\rm dip}|B(1)D(p)\rangle}{E_{XY}-E_{BD}}, \tag{26}$$

where X and Y are the intermediate states for spins 1 and p. Each of the first-order elements connecting the intermediate states to either the initial or final state is of the form of M_{1p} given in Eqs. (21) and (22). Equation (26) may be abbreviated in the notation of Eq. (22),

$$M_{1p}{}' = \sum_{XY}\frac{[m_1(\theta_{1p})m_2(\theta_{1p})/r_{1p}{}^6]}{\Delta E_{XY}}. \tag{27}$$

In other words, $M_{1p}{}'$ breaks up into products of an angular function, r^{-6}, and an energy denominator. The energy denominator is

$$\begin{aligned}1/\Delta E = 1/(\Delta E^0 + \Delta E^{\rm dip}) &= (1/\Delta E^0) \\ &\times[1-(\Delta E^{\rm dip}/\Delta E^0)+(\Delta E^{\rm dip}/\Delta E_0)^2\cdots]\,.\end{aligned} \tag{28}$$

Since, for the bulk of the transitions, $\Delta E^{\rm dip}$ is small compared to ΔE^0, we approximate the energy denominator by $1/\Delta E^0$.

The number of terms in the XY sum is generally small. The reason for this is that the vanishing of the first-order matrix element is generally due to some symmetry condition which causes many of the other matrix elements to vanish as well. For instance, in the case of ruby at 0° orientation, for $g\beta H = 4D$, the transition $(\frac{3}{2},-\frac{3}{2})\leftrightarrow(-\frac{1}{2},-\frac{1}{2})$ is linked by two intermediate states. Both terms in the sum over intermediate states are proportional to $P_{20}P_{21}r^{-6}$. The coefficients of the coordinate functions are 0.4 and -2.4 so that their sum is -2. We cite this example to illustrate that the order of magnitude of the sum is the same as the order of magnitude of each term.

We now proceed exactly as in the first-order theory. The integral for χ' is now

$$\chi'(\rho) = \frac{1}{2\pi}\cdot\frac{1}{(\Delta E)^2}\int_{r_0}^{\infty}\frac{m_1{}^2(\theta)m_2{}^2(\theta)}{r^{12}}e^{i\rho f(\theta)/r^3}d\mathbf{r}. \tag{29}$$

We identify this integral with the integral $I(\rho,4)$ of Eq. (38) in part I. Then, according to Eq. (43) of part I, the integration over r (and φ) yields

$$\chi'(\rho) = \left(\frac{1}{\Delta E}\right)^2\cdot\int_{-1}^{1}d(\cos\theta)\left(\frac{m_1{}^2(\theta)m_2{}^2(\theta)}{3r_0{}^9}\right)\times\frac{\gamma[3,-i\rho\epsilon f(\theta)]}{[-i\rho\epsilon f(\theta)]^3}, \tag{30}$$

where γ represents the incomplete γ function. We approximate $f(\theta)$, as before, by a function which assumes values $-L<f<L$ as $\cos\theta$ assumes values $-1<\cos\theta<1$, and we replace $m_1{}^2(\theta)m_2{}^2(\theta)$ by $\langle m_1{}^2m_2{}^2\rangle$. With $\epsilon = r_0^{-3}$, we then have

$$\chi'(\rho) = \frac{1}{\epsilon}\cdot\left(\frac{1}{\Delta E}\right)^2\frac{\langle m_1{}^2m_2{}^2\rangle\epsilon^4}{3L}\int_{-L}^{L}df\frac{\gamma(3,-i\rho\epsilon f)}{(-i\rho\epsilon f)^3}. \tag{31}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Through the relation[2]

$$\int \frac{\gamma(a,x)}{x^a}dx = -\frac{\gamma(a-1,x)}{x^{a-1}}, \tag{32}$$

we obtain

$$\chi'(\rho) = \frac{1}{\epsilon}\cdot\left(\frac{1}{\Delta E}\right)^2 \cdot \frac{\langle m_1^2 m_2^2\rangle \epsilon^4}{3}\cdot\left[\frac{\gamma(2,-x)-\gamma(2,x)}{x^3}\right], \tag{33}$$

where $x=-i\rho\epsilon L$. By means of the recursion formula[2]

$$\gamma(a+1,x) = a\gamma(a,x) - x^a e^{-x} \tag{34}$$

and the relation

$$\gamma(1,x) = 1-e^{-x}, \tag{35}$$

Eq. (33) may be reduced to

$$\chi'(\rho) = \frac{1}{\epsilon}\left(\frac{1}{\Delta E}\right)^2 \frac{\langle m_1^2 m_2^2\rangle \epsilon^4}{3} \times\left[e^{-x}\left(\frac{1}{x^3}+\frac{1}{x^2}\right) - e^{x}\left(\frac{1}{x^3}-\frac{1}{x^2}\right)\right]. \tag{36}$$

We have now explicitly evaluated $\chi'(\rho)$.

To obtain $\chi'(\omega)$ we need

$$\chi'(\omega) = \int_{-\infty}^{\infty} \chi'(\rho) e^{-i\omega\rho} d\rho. \tag{37}$$

This Fourier transform is obtained almost trivially from expression (36) by taking successive integrals of δ functions located at $\omega = \pm\epsilon L$. The Fourier transform of expression (36) is

$$\chi'(\omega) = \frac{2\pi\langle m_1^2 m_2^2\rangle \epsilon^2}{9 r_0^3 (\Delta E)^2}\frac{3}{4L\epsilon}\left[1-\left(\frac{\omega}{L\epsilon}\right)^2\right], \quad |\omega| < L\epsilon$$
$$= 0, \quad |\omega| > L\epsilon. \tag{38}$$

$\chi'(\omega)$ turns out to be a parabola. It has a half-width of $0.7L\epsilon$. For $L=2q$, as is appropriate for ruby at 0° orientation, this half-width corresponds to 1.4 times the effective nearest-neighbor dipole energy. This width is much larger than the width of any reasonable $\Phi(\omega)$ at low concentrations. It follows that $W'(\omega)$, obtained by convoluting Φ and χ', will have essentially the same shape as $\chi'(\omega)$.

The coefficient in front of the second-order W' is down from that of the first-order W by $\frac{1}{6}(\bar{m}\epsilon/\Delta E_0)^2$. Since $\bar{m}\epsilon$ is approximately the dipole energy and ΔE_0 is approximately the Zeeman energy, this factor is typically of order 10^{-2}. This is not all, however. The second-order $W'(\omega)$ shows no sharp resonance. If we consider a $\Phi(\omega)$ of width one-tenth the nearest-neighbor dipole energy, the sharp resonance of the first-order W decreases the ratio of $W'(0)/W(0)$ by almost another order of magnitude. Far away from the resonant condition, however, W' eventually may become comparable to W.

In summary, the second-order process gives rise to an effect which is relatively small, as expected, and which is quite spread out in its frequency dependence. One would not expect this process to be directly observable, but it does contribute, to some extent, to "general" cross-relaxation, i.e., to relaxation which appears more or less independent of any resonance condition between levels.

Long-Range Process

Finally, we consider still a third type of two-spin process. In this process, spin 1 and spin p both flip, but independently of one another. It represents, in a sense, the joint probability of two single spin flips. Because the two spins operate independently, their separation becomes irrelevant. Our theory gives a reasonable account of the nonexistence of such a process.

The matrix element governing this process is

$$M_{1p}'' = \sum_{XY}\left\{\frac{\langle A(1)X(i)|\mathcal{H}^{\rm dip}|B(1)X(i)\rangle\langle C(p)Y(j)|\mathcal{H}^{\rm dip}|D(p)Y(j)\rangle}{E_C-E_D} + \frac{\langle C(p)Y(j)|\mathcal{H}^{\rm dip}|D(p)Y(j)\rangle\langle A(1)X(i)|\mathcal{H}^{\rm dip}|B(1)X(i)\rangle}{E_A-E_B}\right\}. \tag{39}$$

The two portions of this matrix element correspond to the two possibilities of either spin 1 or spin p flipping first, thus giving rise to different intermediate states. Since our method always envisions *exact* conservation of energy in any one process, one energy denominator is the *exact* negative of the other. By abbreviating the notation in an obvious manner, we have

$$M_{1p}'' = \frac{1}{\Delta E}\sum_{XY}(M_{1i}M_{pj} - M_{pj}M_{1i}). \tag{40}$$

If $i\neq j$, the spins referred to in M_{1i} and M_{pj} are all different, M_{1i} and M_{pj} commute, and M_{1p}'' vanishes identically. If $i=j$, M_{1p}'' does not vanish. However, the extra index "uses up" one more volume integral in our configuration counting [see Eqs. (7) and (16)], and as a result, there is an extra factor of $1/V$ left over. This leads to a transition probability which is down by a factor of N, where N is the number of spins in the crystal. Physically, spin 1 and spin p cannot interact at all without any interaction mechanism. They can interact via some common third spin i, but since they act independently, the chances of their "picking" out

[2] A. Erdely, F. Oberhettinger, W. Magnus, and F. G. Tricomi, *Higher Transcendental Functions* (McGraw-Hill Book Company, Inc., New York, 1948), Vol. 2.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the same spin i from the N available spins are down by a factor of N.

This completes our treatment of the two-spin process.

IV. HIGHER ORDER PROCESSES

Triple and higher multiple spin flips are handled in a fashion quite analogous to double flips. The principal difference is that dipole operators can never connect more than two spins at a time; for this reason, multiple-spin processes must be treated in higher order perturbation theory.

We consider a triple flip in which spin 1 goes from state A to state B, spin p from C to D, spin q from E to F. If the selection rule $\Delta m=\pm 1$ holds for each spin, the possible processes are that either spin 1 or spin 2 or spin 3 flips first with the remaining two spins flipping second, or the converses of these three possibilities. There are thus six intermediate states, with a given process and its converse having energy denominators that are exact negatives of one another. These processes have been discussed in their detailed application to LiF by Pershan.[3] In the more general case, when m is not a good quantum number, there is no selection rule. The number of processes can become very large and the matrix elements very complicated. Nevertheless, a typical term, together with its converse, can be represented by

$$M_{1pq}=(M_{1p}M_{1q}-M_{1q}M_{1p})/\Delta E\,. \tag{41}$$

M_{1pq} does not vanish since M_{1p} and M_{1q} do not commute. The coordinate dependence of M_{1p} and M_{1q} is defined in Eqs. (21) and (22). We therefore have

$$M_{1pq}=\frac{1}{\Delta E}\frac{m_1(\theta_{1p})m_2(\theta_{1q})}{r_{1p}{}^3r_{1q}{}^3}\,. \tag{42}$$

When following our previous reasoning, the operator for a triple flip becomes

$$M^2=\left(\frac{1}{v\Delta E}\right)^2\int\frac{m_1{}^2(\theta_{1p})m_2{}^2(\theta_{1q})}{r_{1p}{}^6r_{1q}{}^6}d\mathbf{r}_{1p}d\mathbf{r}_{1q}\,. \tag{43}$$

In our configuration counting, we must include the fact that we have already assigned three spins to three "boxes" and thus, the analog of Eq. (5) is

$$f=\frac{C(3)}{C(0)}=\frac{N_1N_2N_3v^3}{V^N}\int d\mathbf{r}_{12}\cdots d\mathbf{r}_{1,\,p-1}\times d\mathbf{r}_{1,\,p+1}\cdots d\mathbf{r}_{1,\,q-1}d\mathbf{r}_{1,\,q+1}\cdots d\mathbf{r}_{1N}\,. \tag{44}$$

In setting up the energy constraint, we require that $\Delta E^0+\Delta E^{\rm dip}=0$ when all three spins are considered. In analogy to expression (15), this constraint turns out to be

$$\frac{1}{2\pi}\int_{-\infty}^{\infty}\exp\{i\rho[\Delta\omega_{AB}(\mathbf{r}_{1p})+\Delta\omega_{AB}(\mathbf{r}_{1q})+\Delta\omega_{CD}(\mathbf{r}_{p1})+\Delta\omega_{CD}(\mathbf{r}_{pq})+\Delta\omega_{FG}(\mathbf{r}_{q1})+\Delta\omega_{FG}(\mathbf{r}_{qp})]\}\times\prod_{k\neq 1,\,p,\,q}\exp\{i\rho[\Delta\omega_{AB}(\mathbf{r}_{1k})+\Delta\omega_{CD}(\mathbf{r}_{pk})+\Delta\omega_{FG}(\mathbf{r}_{qk})]\}e^{-i\rho\omega}d\rho\,. \tag{45}$$

Finally, defining $\Delta\omega_\chi$ in analogous fashion as in Eq. (20) we have

$$W(\omega)=\frac{2\pi}{\hbar}\frac{n_1n_2n_3}{v^2}\int_{-\infty}^{\infty}\chi(\rho)\Phi(\rho)e^{-i\rho\omega}d\rho\,, \tag{46a}$$

$$\chi(\rho)=\frac{1}{2\pi}\cdot\left(\frac{1}{\Delta E}\right)^2\int\left[\frac{m_1{}^2}{r_{1p}{}^6}e^{i\rho\Delta\omega_\chi(\mathbf{r}_{1p})}\right]\times\left[\frac{m_2{}^2}{r_{1p}{}^6}e^{i\rho\Delta\omega_\chi(\mathbf{r}_{1q})}\right]e^{i\rho\Delta\omega_\chi(\mathbf{r}_{pq})}d\mathbf{r}_{1p}d\mathbf{r}_{1q}\,, \tag{46b}$$

$$\Phi(\rho)=\left(\frac{1}{V}\int\exp\{i\rho[\Delta\omega_{AB}(\mathbf{r}_{1k})+\Delta\omega_{CD}(\mathbf{r}_{pk})+\Delta\omega_{FG}(\mathbf{r}_{qk})]\}d\mathbf{r}_{1k}\right)^{N-3}. \tag{46c}$$

Once again, χ and Φ are not really separable, but our previous discussion of this point applies without change.

A new difficulty arises, however, because χ itself is now given by two integrals which are not separable. They are not separable because of the appearance of $\mathbf{r}_{pq}$ in the third exponential. To test the effect of this coupling term, we have computed $\chi(\omega)$ numerically, both with and without the coupling term. We used P_{21} for $m(\theta)$ and P_{20} for $\Delta\omega_\chi$. We find that the two χ's generated in this way have virtually the same shape, except that the χ without the coupling term is narrower by about a factor of 1.5. It appears to be still practicable, therefore, to calculate χ on the basis of separable integrals with the proviso that one expects the correct function to be qualitatively the same but somewhat broader.

Each of the separate integrals gives the power spectrum of the projection of the dipole operator governing the interaction between spin 1 and spin p and between spin 1 and spin q, respectively. If these two interactions were completely independent, there would be no coupling term, and the joint power spectrum would simply be the convolution of the individual power spectra. But the transitions do not occur independently; hence, a coupling term. In picturesque language, the relative squiggles of spins 1 and p are modulated by the squiggles of spin q, and the spectrum is broadened.

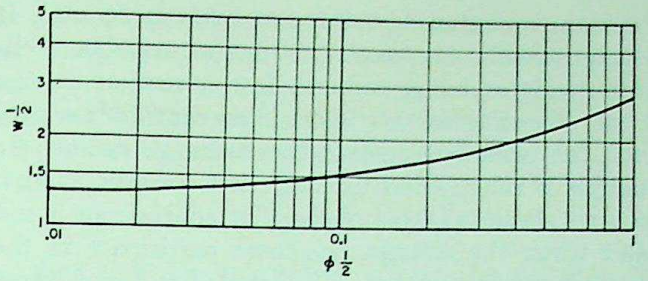

FIG. 1. Three-spin functions: W half-width versus Φ half-width in units of χ half-width.

The calculation of the triple flip $W(\omega)$ again resolves itself into the convolution of the χ and Φ functions of part I. Only now we need two χ's with their associated Φ's instead of one. We note that $W(\omega)$ will have a factor proportional to the cube of the concentration and to the square of the ratio of the dipole energy to the Zeeman energy.

Four-spin and higher order processes require no new physical or computational considerations. We note that a matrix element of the form $M_{1p}M_{qr}$ gives zero contribution. The two factors commute and the element will be identically cancelled by its converse. This is important since there is no implicit requirement in such a matrix element that spins 1 and p be near spins q and r.

When K spins flip, we will therefore require $(K-1)$ 'th-order perturbation theory, and the matrix element will be a sum of terms each of which contains $(K-1)$ products. Our counting scheme will generate a concentration dependence of order n^K, and the $(K-1)$ products of dipole operators will generate a factor of (dipole energy/Zeeman energy)$^{2(K-2)}$. The functional form can be estimated by convoluting $(K-1)$ χ functions and their associated Φ's. Owing to this increasing number of convolutions, it is clear that higher order processes will show a less and less marked resonance effect, and that their $W(\omega)$ will become more and more smeared over ω space. When this consideration is coupled with the step n dependence of these processes, we have at least a partial explanation of why the "general" cross-relaxation increases so markedly at higher concentrations.

The concentration dependence of the *shape* of $W(\omega)$ enters exclusively through the Φ functions, as we have seen in part I. We showed that $W(\omega)$ for a one-spin process has a width which varies as the square root of the Φ width. If the resonance line is homogeneous, the width of this $W(\omega)$ will vary as $n^{1/2}$. The same argument applies without change to the two-spin process. For higher multiple processes, however, the concentration dependence of the width of $W(\omega)$ is much weaker. In Fig. 1, we show the half-width of W as a function of the half-width of Φ, for a three-spin process. The curve is virtually flat until the Φ width is about one-tenth the χ width. The slope of the curve then increases gradually and reaches the value $\frac{1}{2}$ only when Φ and χ have equal widths. The concentration dependence of the width of $W(\omega)$ rapidly disappears as the number of spins involved increases. The reason for this is that the successive convolutions rapidly smear out the sharp central peak which alone depends critically on the width of Φ.

V. EXCHANGE

We have so far ignored certain considerations which do not alter the general structure of our calculation, but which nonetheless may have a pronounced effect on actual results.

An exchange interaction of the form $J(\mathbf{S}_1\cdot\mathbf{S}_2)$ frequently occurs between neighboring transition metal ions. If such an interaction is present, we distinguish two cases: (1) When the exchange energy is of the same order as the dipole energy, we treat these two interactions in parallel fashion. We still consider the unperturbed energy of the ion as an eigenvalue of a single-ion state. We consider the diagonal elements of $J(\mathbf{S}_1\cdot\mathbf{S}_2)$ as contributing to $\Delta\omega$ and we consider the off-diagonal elements as contributing to the transition matrix elements. The integral defining χ [Eq. (25), part I] will, of course, be split into two parts. The first part sums over those sites that are exchange coupled, the second over the rest of space. (2) When the exchange energy becomes comparable to the Zeeman or crystal field energy, the unperturbed states can no longer be considered as single-ion states. If J is large enough, E^0 is given by the diagonal elements in a representation in which $J(\mathbf{S}_1\cdot\mathbf{S}_2)$ is diagonal. In any case, since the energy separations between pair states are now, in general, quite different from the energy separations between single-particle states, such exchange coupled pairs do not, in general, contribute to the resonant cross-relaxation process. In terms of computational procedure, this means that the integral defining χ starts at a radius where exchange is no longer large.

This prescription is somewhat oversimplified for two reasons. First, it may happen accidentally that the separation between some of the pair levels does, in fact, coincide closely with the separation between some of the single-particle levels. Secondly, as we have seen, the frequency width of higher order processes becomes large. At the same time, the number of pair levels is $(2S+1)$ times the number of single-particle levels. As the requirement of harmonic coincidence is made less and less stringent, it becomes more and more probable that some of the level separations in the larger pair manifold will meet an approximate harmonic condition. One expects that exchange coupled pairs would, in general, enhance the probability of higher order processes, particularly under conditions where the single-particle levels alone do not exactly meet the harmonic condition. Such participation of exchange-coupled pairs in the

cross-relaxation process has been discussed by Bloembergen and Pershan[4] and by Gill and Elliott.[5]

VI. THE NEAR-NEIGHBOR SPECTRUM

From the very beginning, we have replaced lattice sums by volume integrals, using the volume per lattice site v to keep the dimensionality consistent. Clearly, such a substitution is valid when the density of lattice sites per unit solid angle is large. For the calculation of Φ this procedure will introduce a negligible error, except possibly in certain concentrated systems. The principal reason for this is that the dominant contribution to Φ comes from distant lattice sites. For the calculation of χ, the equivalence of the discrete and "continuous" lattice is of much more restricted validity, because the dominant contribution comes from close-lying sites. It is valid when a substantial number of neighbor shells are strongly exchange coupled. In this case, as we saw in the preceding section, there is no contribution to χ until the sites fall outside the exchange radius. An example is ruby, where exchange is large over at least the first seven neighbor shells. The equivalence is not valid when the nearest neighbors participate in the cross-relaxation process. The contribution of these neighbors will dominate over the contribution of the rest of the lattice because of the r^{-6} dependence of the transition operator. The integral for χ is then replaced by a sum.

$$\chi(\rho)=\frac{1}{2\pi}\sum_j \frac{m_j^2(\theta_j)}{r_j^6}e^{i\Delta\omega_j\rho}, \tag{47}$$

where the sum need extend only as far as the first few, sometimes only the first, neighbor shells. Then $\chi(\omega)$ will be given by a series of δ functions

$$\chi(\omega)=\sum_j \frac{m_j^2(\theta_j)}{r_j^6}\delta(\omega-\Delta\omega_j)\,. \tag{48}$$

Finally, $W(\omega)$ will be given by a sum of resonance curves, each displaced from the origin by $\Delta\omega_j$ and weighted by the corresponding transition operator:

$$W(\omega)\sim\sum_j \frac{m_j^2(\theta_j)}{r_j^6}\Phi(\omega-\Delta\omega_j)\,. \tag{49}$$

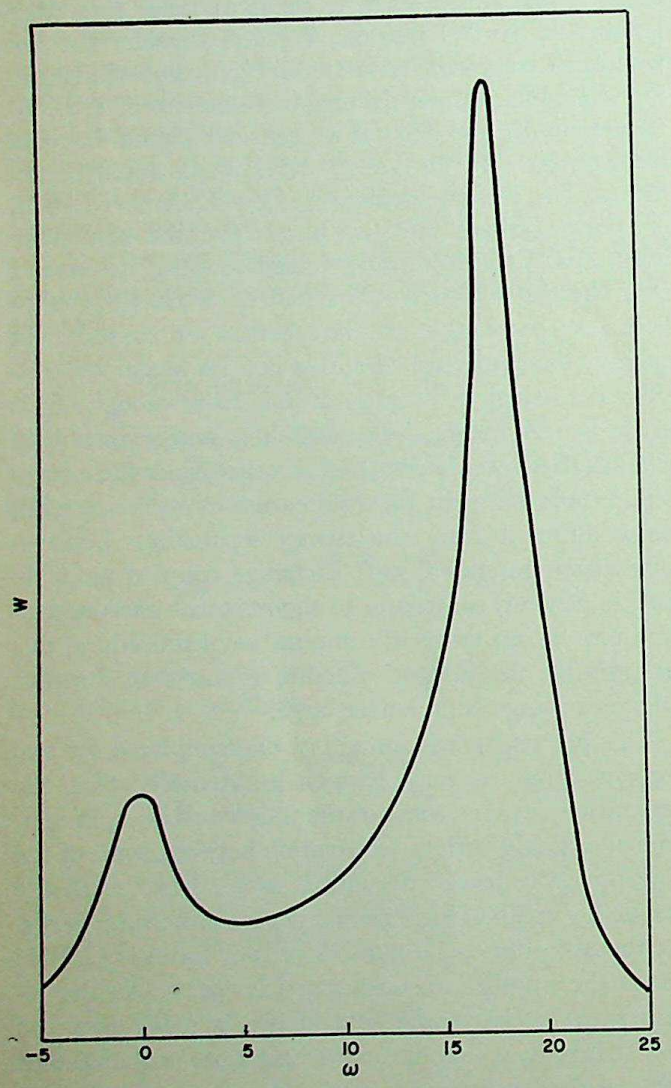

FIG. 2. $W(\omega)$ for simple cubic lattice, [001] direction, $M=\sin\theta\cos\theta$ (arbitrary units).

In systems that are very dilute and have no inhomogeneous broadening, the various Φ's may be resolvable. To illustrate, we show, in Fig. 2, $W(\omega)$ for a simple cubic lattice with the magnetic field in the [001] direction and with $\Delta\omega_j=(3\cos^2\theta_j-1)/r_j^3$, $m_j=\sin\theta_j\cos\theta_j$. The width of Φ has been taken as 1/50 the nearest-neighbor dipole energy. The peak at 18 is due to the (0,1,1) and equivalent sites. The six nearest neighbors are not effective because their m_j vanishes. If we take $m_j=(3\cos^2\theta-1)$, then the neighbors at $(0, 0, \pm1)$ will produce an effect 32 times greater than the (0,1,1) neighbors and 11 times as far away from the origin. The shape of W is quite sensitive to the angular functions involved. This means it is quite sensitive to the particular matrix element for a given process and to the direction of the magnetic field.

In more concentrated systems or in systems with substantial inhomogeneous broadening, Φ will be too broad to resolve subsidiary peaks such as shown in Fig. 2. Nevertheless, the shift of the peak away from $\omega=0$, i.e., away from the exact resonance condition, will still occur.

The shift of the peak cross-relaxation probability away from the harmonic condition becomes intuitively obvious if one considers that the matching of level separations must include the diagonal dipole energy as well as the Zeeman energy. Thus, the peak in cross re-

laxation still occurs where the total energies are exactly matched, but this point will be somewhat displaced from the point where the Zeeman energies alone are exactly matched. The amount of displacement depends rather critically on the specific operating conditions.

VII. INHOMOGENEOUS BROADENING

Inhomogeneous broadening affects the distribution of energy levels about their unperturbed value. In our formalism this distribution manifests itself in the function Φ. The question whether Φ should include the inhomogeneous broadening or not is isomorphic to the question whether the spin packets within an inhomogeneous line cross-relax together or separately. For limiting cases one can give an unequivocal answer. If the spin-diffusion time within the inhomogeneous line is much shorter than the cross-relaxation time for one packet, then the whole line relaxes together. If the spin-diffusion time is much longer than the cross-relaxation time, then the packets relax separately. To put this in terms of numbers, we take $T_2=10^{-8}$ sec and $T_{12}=10^{-3}$ sec. For T_{diff} we use Bloembergen's rule of thumb[6]

$$T_{\text{diff}}=T_2\times(T_2/T_2^*)^3, \tag{50}$$

where $1/T_2^*$ is the total width of the inhomogeneous line. We then obtain the condition that the homogeneous width of the line must be much greater than 2% of the inhomogeneous width, if the entire line is to relax as a whole. If this condition is met, Φ should therefore include the inhomogeneous broadening. If this condition is not met, the situation becomes complicated. Relaxation takes place between all the spin packets in one inhomogeneously broadened level and all the spin packets in the other inhomogeneously broadened level. At the same time spin diffusion takes place within each of the levels.

VIII. SUMMARY

We have extended the basic cross-relaxation theory of part I to relaxation processes of all orders. Among other results we have derived the following: (1) For a K-spin process, the magnitude of the transition probability depends on concentration as n^K. (2) The frequency width of the transition probability is proportional to the square root of the Φ width for one- and two-spin processes. For three-spin processes, the width of W depends on the width of Φ only when Φ and χ have comparable widths, and even then the dependence is relatively feeble. For higher multiple processes, the dependence of the W width on the Φ width is negligible. Instead, the width of the K-spin W is roughly proportional to K. (3) In the absence of strong exchange interactions, the nearest neighbors dominate the cross-relaxation process. In this case, W is obtained from the convolution of Φ functions with a discrete near-neighbor spectrum, and its peak may be displaced from the harmonic point by an amount corresponding to the nearest-neighbor dipole energy.

General Theory of Cross Relaxation. III. Application to Experiment*

W. J. C. GRANT
Bell Telephone Laboratories, Murray Hill, New Jersey

(Received 30 January 1964)

The theory developed in parts I and II is applied to the classical experiments of Mims and McGee, and Pershan. The predictions of the theory regarding the dependence of W_{CR} on the energy imbalance $\hbar\omega$ on concentration and on the exchange radius, as well as the prediction of the actual magnitude of W_{CR}, are confirmed in the Mims and McGee experiment on ruby. The crucial significance of near-neighbor dipole interactions, in particular, the effect of the associated power spectrum, which is quite broad and quite sensitive to crystal direction, is illustrated by application of the theory to Pershan's experiments on LiF.

INTRODUCTION

IN the preceding papers,[1] we have developed methods for calculating from first principles the cross-relaxation probability W_{CR} for processes of arbitrary complexity. The theory makes specific quantitative predictions about the dependence of W_{CR} on the number of spins participating in the process, on the energy imbalance involved, on the spin concentration, and on the existence of short-range forces. Our purpose now is to test the theory in its application to classical experiments in the field. We shall consider the experiments of Mims and McGee[2] on ruby and the experiments of Pershan[3] on LiF.

Transition probabilities are related to observable quantities through rate equations. The transient solutions of rate equations containing both cross-relaxation and spin-lattice terms have been discussed at length in a previous paper,[4] both in general and with particular reference to the experiments we shall discuss. We shall avail ourselves here of those results.

I. THE MIMS EXPERIMENT ON RUBY

We denote the four ground-state spin levels of Cr^{3+} in ruby by 1, 2, 3, 4 in order of decreasing energy. As discussed in detail in Mims' paper, the level separation (2–3) is held fixed at 7.17 kMc. The magnetic field strength and direction are varied to bring the (1–2) separation into coincidence or near coincidence with the (2–3) separation. Harmonic 1 : 1 coincidence occurs at about 22.3°. Levels 2 and 3 are saturated with a short pulse, and the decay of their populations is then observed. From the decays observed at a series of angles centered about 22°, the cross relaxation as a function of energy imbalance can be determined.

The details of the decay function calculated from the rate equations (see Ref. 4) depend rather critically on the assumptions one makes about the spin-lattice probabilities. Assuming equal s–l probablities W_L between all pairs of levels, the observed signal $S(t)$ is given by

$$S(t)\sim 1.5\exp(-t/\tau_1)+0.5\exp(-t/\tau_2), \quad (1a)$$

$$\tau_1^{-1}=1.5W_{CR}+4W_L, \quad (1b)$$

$$\tau_2^{-2}=4W_L. \quad (1c)$$

If one assumes s–l probabilities proportional to the energy separation of the levels one obtains

$$S(t)\sim 0.8\exp(-t/\tau_1)-0.3\exp(-t/\tau_2)+1.5\exp(-t/\tau_3), \quad (2a)$$

$$\tau_1^{-1}=2.17W_L, \quad (2b)$$

$$\tau_2^{-1}=6.28W_L, \quad (2c)$$

$$\tau_3^{-1}=1.5W_{CR}+2.23W_L. \quad (2d)$$

W_L is here taken as the s–l probability between levels 3 and 4.

When the relaxation process is dominated by cross relaxation, one obtains reasonable estimates of the cross relaxation rate regardless of detailed assumptions about s–l probabilities. It is clear, for example, that Eqs. (1a) and (2a) coalesce for times of the order of W_{CR}^{-1}, when W_{CR}/W_L becomes large.

Fortunately, many of the processes observed by Mims are indeed dominated by cross relaxation. One can fit the decay traces either by a double exponential [Eq. (1a)] or by a triple exponential [Eq. (2a)] in the region where cross relaxation is rapid. For cross-relaxation times shorter than a few msec, closely agreeing values result whether one uses equal, unequal, or infinite lattice times. The sensitivity of these particular experiments does not appear sufficient to allow consistent and quantitative interpretation of the residual trace after the fast component has been extracted.

We show in Table I the C-R probability versus the frequency separation of the (1–2) and (2–3) transitions, as derived from the Mims experiment. The same data are also presented in Fig. 1. Because of the rapid variation of the energy imbalance ω with the field direction, and because W_{CR} becomes of the same order of magnitude as W_L for large ω, the uncertainty in W_{CR} ranges from $\sim 10\%$ for small ω to a factor of 2 or so for large ω. We note that the last two points for negative ω fall outside the main sequence. This effect is sufficiently marked so that it should probably be considered real, and we shall comment on these points later.

The theoretical expression for W_{CR}, we recall, is essentially the convolution of two functions: χ, which is the power spectrum of the dipole operator, and Φ, which in the present case is itself the convolution of the $(1 \leftrightarrow 2)$ and $(2 \leftrightarrow 3)$ resonance lines. In the following computations, we have used the form of χ given in Eq. (53) of part I. This χ function was computed using matrix elements appropriate for the magnetic field parallel to the crystal axis, and is consequently not the exactly correct function. As pointed out in part I, however, the salient features of the χ function do not depend on the detailed angular functions assumed, and Eq. (53) of part I represents a close approach to the exact function, without requiring excessive numerical computation. We may then write

$$W_{CR}=[32\pi^2\langle m^2\rangle n^2/3\hbar v L\epsilon]\Psi(\omega; L\epsilon, a). \tag{3}$$

The quantity $\langle m^2\rangle$ is the square of the transition dipole matrix element, averaged over a sphere of unit radius; the quantity L is the change in dipole energy between two flipping spins, maximized with respect to angular position, and again for unit radius; v is the average volume per lattice site; ϵ is defined by the relation $\epsilon^{-1/3}\equiv r_0=$ the effective nearest-neighbor distance; n is the fractional mole concentration of Cr^{3+} in each level; a is the half-width of Φ. $L\epsilon$ is directly related to the width of χ, [Eq. (52), part I]. The numerical constants have been so chosen that Ψ is normalized for $L\epsilon=2g^2\beta^2$.

The quantities $\langle m^2\rangle$ and L are derived from matrix elements that can be calculated precisely. The quantity a can be estimated with reasonable accuracy. In the present case, as discussed in part II, it is the width of a function obtained by convoluting the $(1 \leftrightarrow 2)$ and $(2 \leftrightarrow 3)$ resonance line shapes. (These line shapes in turn can be calculated from first principles by methods closely related to our present theory.) The quantity r_0 is a free parameter, in the sense that its theoretical prediction lies altogether outside the present theory. The value of r_0 which our theory extracts from the cross relaxation data must, however, be compared with the radius of strong exchange as determined by Statz and co-workers.[5] Exchange-coupled pairs would not, in general, be expected to participate in the two-spin cross-relaxation process, with its sharply defined resonance.

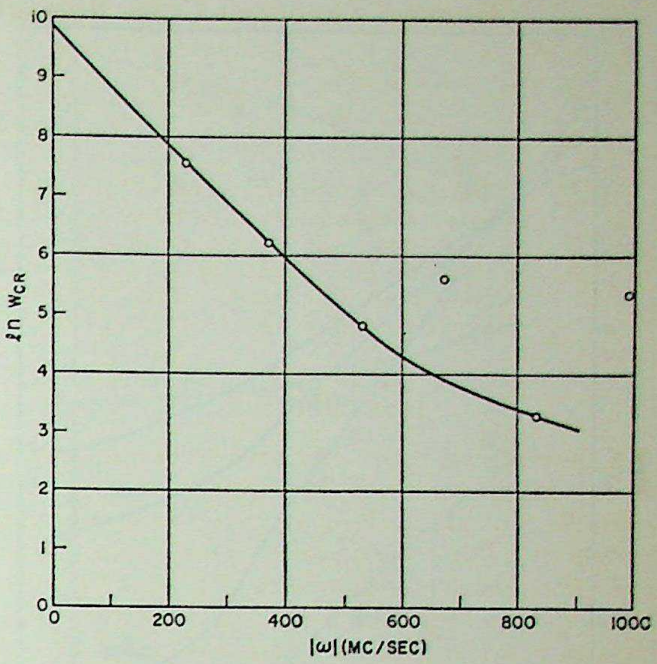

FIG. 1. Experimental data (from Mims, Ref. 2).

We first discuss the calculation of the matrix elements. These are computed from the *pair* Hamiltonian

$$\mathcal{H}_{\text{pair}}=\mathcal{H}_{\text{pair}}{}^{0}+\mathcal{H}_{\text{pair}}{}^{\text{dip}} \tag{4a}$$

$$\mathcal{H}_{\text{pair}}{}^{0}=g\beta\mathbf{H}\cdot(\mathbf{S}_1+\mathbf{S}_2)-D(S_{z1}{}^2+S_{z2}{}^2), \tag{4b}$$

$$\mathcal{H}_{\text{pair}}{}^{\text{dip}}=\frac{g^2\beta^2}{r_{12}{}^3}\left[\mathbf{S}_1\cdot\mathbf{S}_2-\frac{3(\mathbf{r}_{12}\cdot\mathbf{S}_1)(\mathbf{r}_{12}\cdot\mathbf{S}_2)}{r_{12}{}^2}\right]. \tag{4c}$$

For a particular value of $\mathbf{H}$, taking into account both its magnitude, and its direction with respect to the c axis, one diagonalizes $\mathcal{H}^0$ numerically. Then the same transformation is applied to $\mathcal{H}^{\text{dip}}$. The matrix elements relevant to a transition between the pair state (2,2) and the pair state (1,3), for example, are easily obtained from the resulting matrices. (The labels 1,2,3, refer to single-particle energy states in order of decreasing energy. They do not refer to m states, since m is not a good quantum number.) The matrix elements are complicated functions of the coordinates. For the Mims experiment they are

$$\begin{aligned}\Delta\omega\equiv&\langle(1,3)|\mathcal{H}^{\text{dip}}|(1,3)\rangle-\langle(2,2)|\mathcal{H}^{\text{dip}}|(2,2)\rangle\\&=(g^2\beta^2/r^3)[1.36(3\cos^2\theta-1)\\&\qquad+0.73\sin\theta\cos\theta+1.34\sin^2\theta]\end{aligned} \tag{5}$$

$$\begin{aligned}m\equiv&\langle(1.3)|\mathcal{H}^{\text{dip}}|(2,2)\rangle\\&=(g^2\beta^2/r^3)[0.191(3\cos^2\theta-1)\\&\qquad+1.562\sin\theta\cos\theta+1.417\sin^2\theta].\end{aligned} \tag{6}$$

These matrix elements lead to the values

$$L=2.782g^2\beta^2, \tag{7}$$

$$\langle m^2\rangle=1.425g^4\beta^4, \tag{8}$$

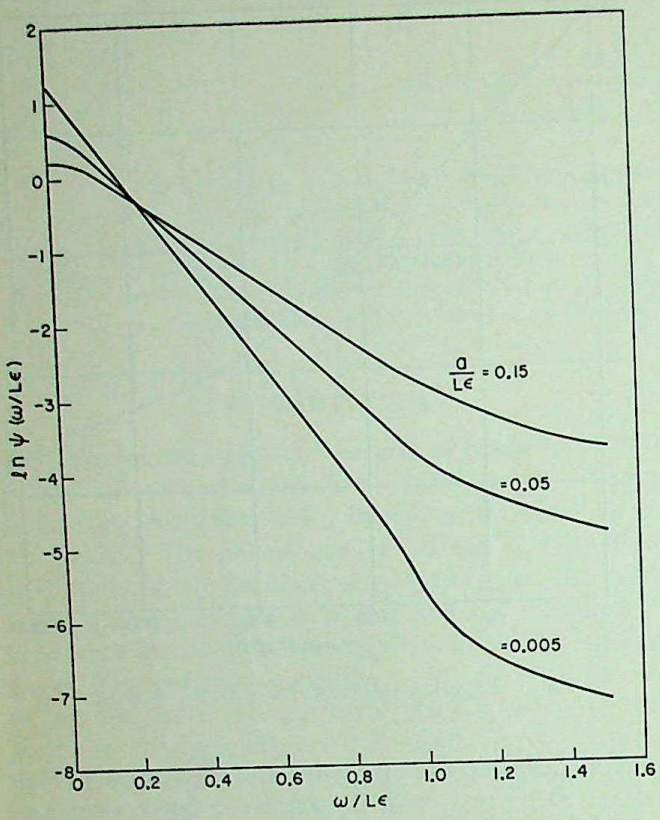

FIG. 2. ln ψ versus $\omega/L\epsilon$.

with

$$g^2\beta^2 = 5.11\times10^4 \text{ Mc(Å)}^3.$$

We note that there is no need to use projection operators. Through the device of the *pair* matrix we project the appropriate portion of the dipole operator simply by inspection of the appropriate matrix elements. Of course, the use of the pair matrix allows an exact computation of the matrix elements for any operating condition, regardless of the orientation and magnitude of **H**, that is regardless of whether or not m is a good quantum number.

We next consider the dependence of W_{CR} on a and on $L\epsilon$.

Although in principle a is determined by our knowledge of resonance line shapes, in practice the situation is complicated by the presence of inhomogeneous broadening and by the complex structure not only of the total resonance line but even of its homogeneous component. At a Cr^{3+} weight concentration of 0.05%, the half-width ascribable to homogeneous broadening is about 6 Mc, and the homogeneous line shape is a Lorentzian whose falloff gradually becomes Gaussian about 1 kMc from the center frequency. The inhomogeneous broadening is a pure Gaussian of half-width about 18 Mc. The total line is the convolution of these two. It has a half-width of about 23 Mc. At the center it is dominated by the Gaussian. At frequencies more than about 60 Mc from the center it is dominated by the Lorentzian homogeneous component. In the context of cross relaxation we are usually talking about frequency separations of the order of hundreds of Mc, where the total resonance line behaves essentially like its Lorentzian homogeneous component. Very near the exact harmonic condition, cross relaxation is so rapid that the inhomogeneous line may no longer relax as a whole, in which case we are observing relaxation of individual Lorentzian spin packets rather than of the entire system. We note that the function Φ is the convolution of the $(1\leftrightarrow2)$ and $(2\leftrightarrow3)$ resonance lines, and that in convolution, Lorentzians add width algebraically, while Gaussians add width in rms fashion. One way to overcome some of these complications is to find an approximation to Ψ [Eq. (3)] from which the dependence on $L\epsilon$ can be extracted more or less independent of detailed assumptions about a, or about the shape of the function Φ.

Fortunately, such an approximation exists. If one plots $\ln\Psi$ as a function of $\omega/L\epsilon$, one obtains curves which are very closely straight lines over several orders of magnitude in Ψ. The slope of these straight lines is dependent only weakly on the shape of Φ or on the value of a. In Fig. 2, we show $\ln\Psi$ as a function of $\omega/L\epsilon$ for various values of $a/L\epsilon$, and with Φ Lorentzian. In Fig. 3, we have plotted the quantity $(a/L\epsilon)\times d\ln W_{CR}/d(\omega/L\epsilon)$ against $a/L\epsilon$. Figure 3 is, in a sense, the meeting point between theory and experiment. If $d\ln W_{CR}/d\omega$ and a are known experimentally, then Fig. 3 determines $a/L\epsilon$, and therefore ϵ. We note that a straight line of unit slope in Fig. 3 would indicate that the slope of $\ln W_{CR}$ is independent of a. For a Gaussian Φ, the acutal curve deviates negligibly from such a straight line; for a Lorentzian Φ, it deviates only slightly for small a more seriously for large a.

Our theory then predicts that $\ln W_{CR}$ should vary almost linearly with ω over several orders of magnitude (with some rounding at the very peak of the curve). The slope of this straight line yields a close estimate of the quantity ϵ, that is, of the exchange radius r_0.

This linearity is a good approximation when $a/L\epsilon$

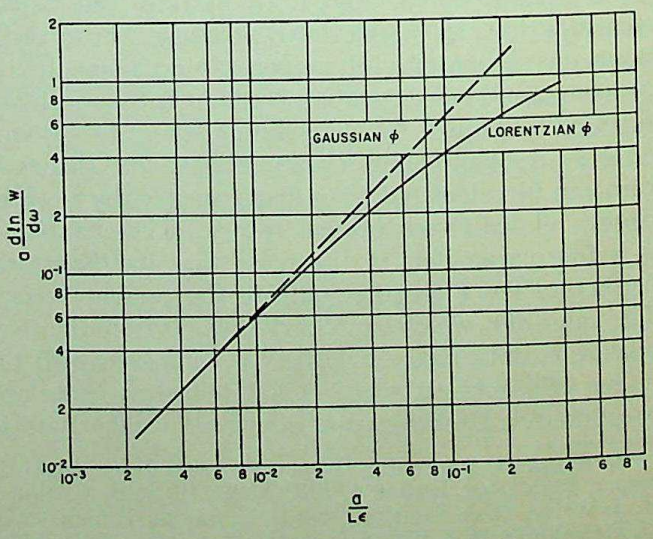

FIG. 3. $a[d(\ln\psi)/d\omega]$ versus $(a/L\epsilon)$.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

is considerably smaller than unity, that is for magnetically very dilute systems. As can be seen from Fig. 1, the linear approximation to $\ln W_{CR}$ is consistent with the data of the Mims experiment.

For the Mims experiment, $d\ln W_{CR}/d\omega = 0.010$ Mc^{-1}. For a Lorentzian of half-width 12 Mc (the convolution of two Lorentzians of 6 Mc each), one obtains $r = 6.28$ Å. For a Gaussian of half-width 32 Mc (the convolution of two Gaussians of 23 Mc each) one obtains $r_0 = 6.15$ Å. In this case, therefore, it happens to make very little difference whether one uses the width of the entire resonance line or only its homogeneous component. While this is partly fortuitous, it is primarily due to insensitivity of $L\epsilon$ to the shape of Φ.

The work of Statz and co-workers[5] indicates that the exchange radius lies between about 5.5 and 6.5 Å. Thus, our value of 6.15 ± 0.15 Å is in excellent agreement with his. We feel that such corroboration is rather encouraging in view of the startling conclusion that the first twelve or thirteen neighbor shells, or about the first fifty nearest-neighbor sites, are sufficiently exchange coupled to be excluded from this cross-relaxation process.

Because of the trick of working with the derivative of $\ln W_{CR}$, we have so far concerned ourselves exclusively with the shape of $W_{CR}(\omega)$, completely separating out the question of its magnitude. The magnitude of W_{CR} depends sharply on the concentration, and the absolute concentration is difficult to determine accurately. Nominal values of concentration are accurate within about 50%. Furthermore, there is some evidence of pronounced variations in concentration, over a scale of the order of microns, which makes the value of the true effective concentration even more obscure. In view of these uncertainties, the absolute magnitude of the cross-relaxation probability calculated by our theory, as we shall now show, agrees astonishingly well with the experiments of Mims.

Since we have already accounted for the shape of $W_{CR}(\omega)$, it suffices to calculate its magnitude at one point. For convenience, we choose the peak of the curve, $W_{CR}(0)$. The required value is given by Eq. (3), using $\Psi(0; L\epsilon, a)$. For the Mims experiment, $\Psi(0; L\epsilon, a) = 2.9$, if one assumes a Lorentzian Φ. L and $\langle m^2 \rangle$ are given by Eqs. (7) and (8). The nominal weight concentration of 0.05% corresponds to a molar concentration of 0.00034 or to a concentration per level of 8.2×10^{-5} One then computes $W_{CR}(0) = 25\,900$ sec^{-1}. Extrapolation of the curve of Fig. 1, yields $W_{CR}(0) = 18\,000$ sec^{-1}.

Even leaving out of account the considerable experimental uncertainties in the determination of the points in Fig. 1, the discrepancy between these two values can be accounted for by an actual concentration 17% below nominal. One must also bear in mind that the χ function on which this analysis is based is inexact, and that truly precise numbers cannot therefore be expected. In view of these circumstances, the agreement with experiment is excellent.

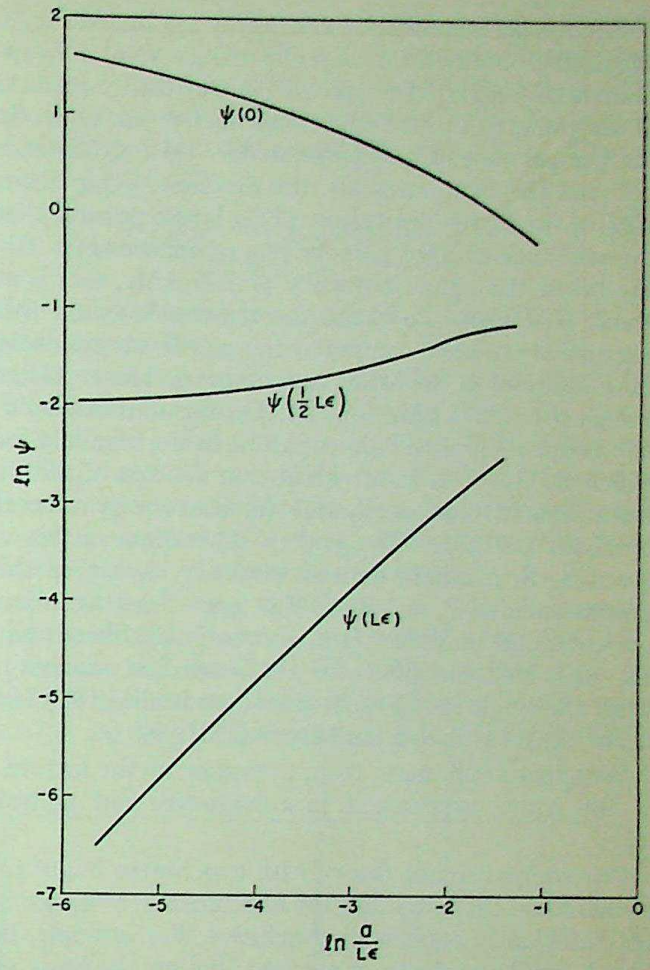

FIG. 4. $\ln\psi$ versus $\ln(a/L\epsilon)$.

We note that a linear concentration dependence of W_{CR} would give values that deviate from those observed by more than four orders of magnitude.

The interpretation of a direct measurement of the concentration dependence must be made with some care, since the concentration enters not only as a coefficient, but also determines the shape of Ψ via the parameter a. In Fig. 4 we show $\ln\psi$, evaluated at various values of ω as a function of $\ln(a/L\epsilon)$. The curves are not linear and depend drastically on the value of ω. As $a/L\epsilon$ becomes larger, the curves would all approach one another, and all would approach negative unit slope. This can be seen intuitively because ψ is normalized and approaches the normalized function Φ as $a/L\epsilon$ becomes large. The curve for $\psi(\omega = 0)$ already has a slope of -0.8 at $a/L\epsilon = 1/e$. For 0.05% ruby, $a/L\epsilon$ is about 1/20, and the slope of $\psi(0)$ is about -0.5. Since a varies almost linearly with the concentration n in this region, one would expect to measure a dependence of $n^{1.5}$ for the peak value of the cross-relaxation probability, the dependence becoming less steep at higher concentrations. Such a prediction is somewhat sanguine, since it depends not only on the precise form of χ and Φ but also on the precise values of a and $L\epsilon$.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Finally, we comment on the "stray" points in Fig. 1, which are obtained for negative values of ω. Two explanations suggest themselves: (1) Our theory predicts an asymmetry in general, if $|\Delta\omega\,\max| \neq |\Delta\omega\,\min|$. In the present case [Eq. (5)] there does exist a difference between the two extremals, the difference being about 10% of the extremum values. (2) It is also possible that the exchange-coupled pairs have a resonance about 800 Mc below the signal frequency of 7.17 kMc, that is at about 6.37 kMc. To check the reasonableness of this suggestion we have computed the pair levels assuming the conditions of the Mims experiment and an exchange energy J of 28.75 kMc (or $5D$). The antiferromagnetically coupled pairs will almost all be in the manifold for which $\mathbf{S}_1\cdot\mathbf{S}_2=9/4$. It turns out that two out of the six transitions within this manifold have an energy interval of about 6.4 kMc. The energy separations within a given $\mathbf{S}_1\cdot\mathbf{S}_2$ manifold depend only very feebly on the precise value of J, as long as J is large. For this reason our computation indicates a reasonable likelihood that the pairs will contribute to the single ion relaxation when the single ion $(1\leftrightarrow 2)$ transition is about 800 Mc below the cross-relaxation harmonic frequency.

We appear to be able, then, to explain all the features of the Mims experiment in a consistent and unified way.

Our comparison of theory with experiment might be criticized on the basis that the experimental evidence is not sufficiently copious or conclusive. For example, in Fig. 1, we have drawn a straight line on the basis of three points—an extrapolation which admittedly lacks uniqueness. Nevertheless, we can assert minimally that our calculations are consistent with the experimental data available. These data include independently the cross-relaxation decay studies, the available information regarding the structure and concentration dependence of the absorption resonance, the independent determination of the exchange radius. The area of consistency extends not only to the shapes of the functions, not only to parametric dependence, but, what is most important, to actual magnitudes. We are thus actually able to tie together, in a fully quantitative way, a substantial amount of dispersed experimental evidence.

II. PERSHAN'S EXPERIMENTS ON LiF

We next consider the cross-relaxation process in LiF, which has been investigated experimentally and theoretically by Pershan,[3] in a notable study which established decisively the existence of cross relaxation. Pershan interpreted his experiments in terms of moment theory and the convolution of Gaussian resonance lines. We shall see that our own theory leads in some circumstances to similar conclusions as Pershan's; but certain experimental features which proved anomalous in terms of his formalism find their natural place in ours.

Cross relaxation in LiF contrasts sharply in several respects with cross relaxation in ruby: (1) The process of main interest is a three-spin process involving two Li's flipping opposite one F, which requires slightly more complicated rate equations. Furthermore, neglecting quadrupole interactions, there is no zero-field splitting. The 4 Li levels are equally spaced, and transitions occur simultaneously between all pairs of adjacent levels. (2) There is no exchange interaction in LiF. This frees us from some of the major concerns in ruby, namely the extent of the exchange radius and the possible influence of exchange-coupled pairs. On the other hand, as we have seen in part II, the dipole interaction itself is now dominated by nearest, or by near, neighbors. This means that the use of a χ function based on a continuous dipole density is not justified. To obtain the correct χ we must sum over the discrete sites. (3) LiF is a magnetically concentrated system. The shape of Φ is Gaussian, and there is no question of inhomogeneous broadening.

The three-spin process can occur in any of nine mutually exclusive ways, since each of the two Li atoms can be in any one of three initial states. In addition, a second-order two-spin process can occur in which a single Li spin changes its z component by two magnetons. Two initial states are possible for this process. The decay constants for each of these relaxation modes are obtained from rate equations in Ref. 4, where it is also shown that the observed decay constant is their average.

The calculation of the matrix element governing each of these decay modes has been discussed in general in part II and with special reference to LiF in Pershan's paper.[3] We recall that each matrix element is a second-order element consisting of a sum running over six terms. The intermediate states correspond to the possiblities of any one of the three spins flipping first, and the converse. The actual computations gain considerably in simplicity and lucidity by evaluating the matrix elements of products of spin operators directly in the appropriate pair manifold.

The function $\chi(\omega)$ is given by an expression analogous to Eq. (48) of part II:

$$\chi(\omega)=2\pi\sum_{pq}M^2(\mathbf{r}_{1p},\mathbf{r}_{1q})\times\delta[\Delta\omega_\chi(\mathbf{r}_{1p})+\Delta\omega_\chi(\mathbf{r}_{1q})+\Delta\omega_\chi(\mathbf{r}_{pq})-\omega]. \quad (9)$$

An Li is here taken as the reference atom 1; p labels all other Li atoms; and q labels the F atoms. The $\Delta\omega_\chi(\mathbf{r}_{ij})$ are the changes in dipole energy induced by the flipping of atoms i and j, as discussed in detail in part II. As discussed in part II, correlations are explicitly included through the term $\Delta\omega_\chi(\mathbf{r}_{pq})$. M^2 is the square of the transition matrix element we have just discussed. It consists of a series of terms typically of the form

$$(1/\Delta E)^2[m_1^2(\theta_{1p})m_2^2(\theta_{1q})/r_{1p}{}^6r_{1q}{}^6]. \quad (10)$$

The symbols m^2 and ΔE have been defined and discussed in part II, Eqs. (41)–(45), and (28). In the present case

$\Delta E = g_{Li}\beta H$ when an Li flips first, $\Delta E = g_F\beta H$ when an F flips first.

We have computed the pq sums in Eq. (9) twice, once including the first neighbor shell only, and then the first two neighbor shells. The first shell consists of the nearest 6 F atoms and 12 Li atoms. The second shell contains the next 8 F atoms and 6 Li atoms. There are thus 72 terms in the first sum, 252 in the second. Each of the calculations has been done for the [001], [011], and [111] directions. It turns out that for the [001] direction the second shell already contributes only a small correction. For the other directions, the sum is also converging, but clearly has not yet reached its limit. Nevertheless, the main features of interest to us already appear clearly, as we shall see, from the summations over the first and second shells. For this reason we feel that the very steep escalation in computation time and labor, which would be necessary to carry the sum further, is unwarranted.

The appropriately weighted average of the χ functions is presented in Fig. 5, for each of the three-crystal directions. The units along the ω axis are gauss, with the correspondence $\omega = (2g_{Li} - g_F)\beta H$ or 1 G = 0.697 kc. The δ functions of Eq. (9) have been smoothed by averaging over 0.6-G intervals. The ω^{-2} dependence arising from the energy denominator has been suppressed. The reason is that this factor is excluded from the convolution integral for the transition probability. That is

$$W_{CR}(\omega) \sim \frac{1}{\omega^2} \int \chi'(\omega')\Phi(\omega - \omega')d\omega', \qquad (11)$$

where χ' is ω^2 times the χ defined in Eq. (9), or in Eq. (46b) or part II.

The crucial point in Fig. 5 is that χ for the [111] direction is narrowly peaked around the origin, but χ for the [001] direction is spread out to a distance of 24 G. In part II we pointed out that the existence of large components of $\chi(\omega)$ far from the origin will result in an apparent shift of the C–R shape function away from the point of harmonic coincidence.

In the final step, convoluting χ with a Gaussian, the standard deivation σ used was 13 G for the [111] direction, 14 G for the [011] direction, and 19 G for the [001] direction. Pershan obtained a best fit using 12.7 G for the [111] direction and 14.8 G for the [011]

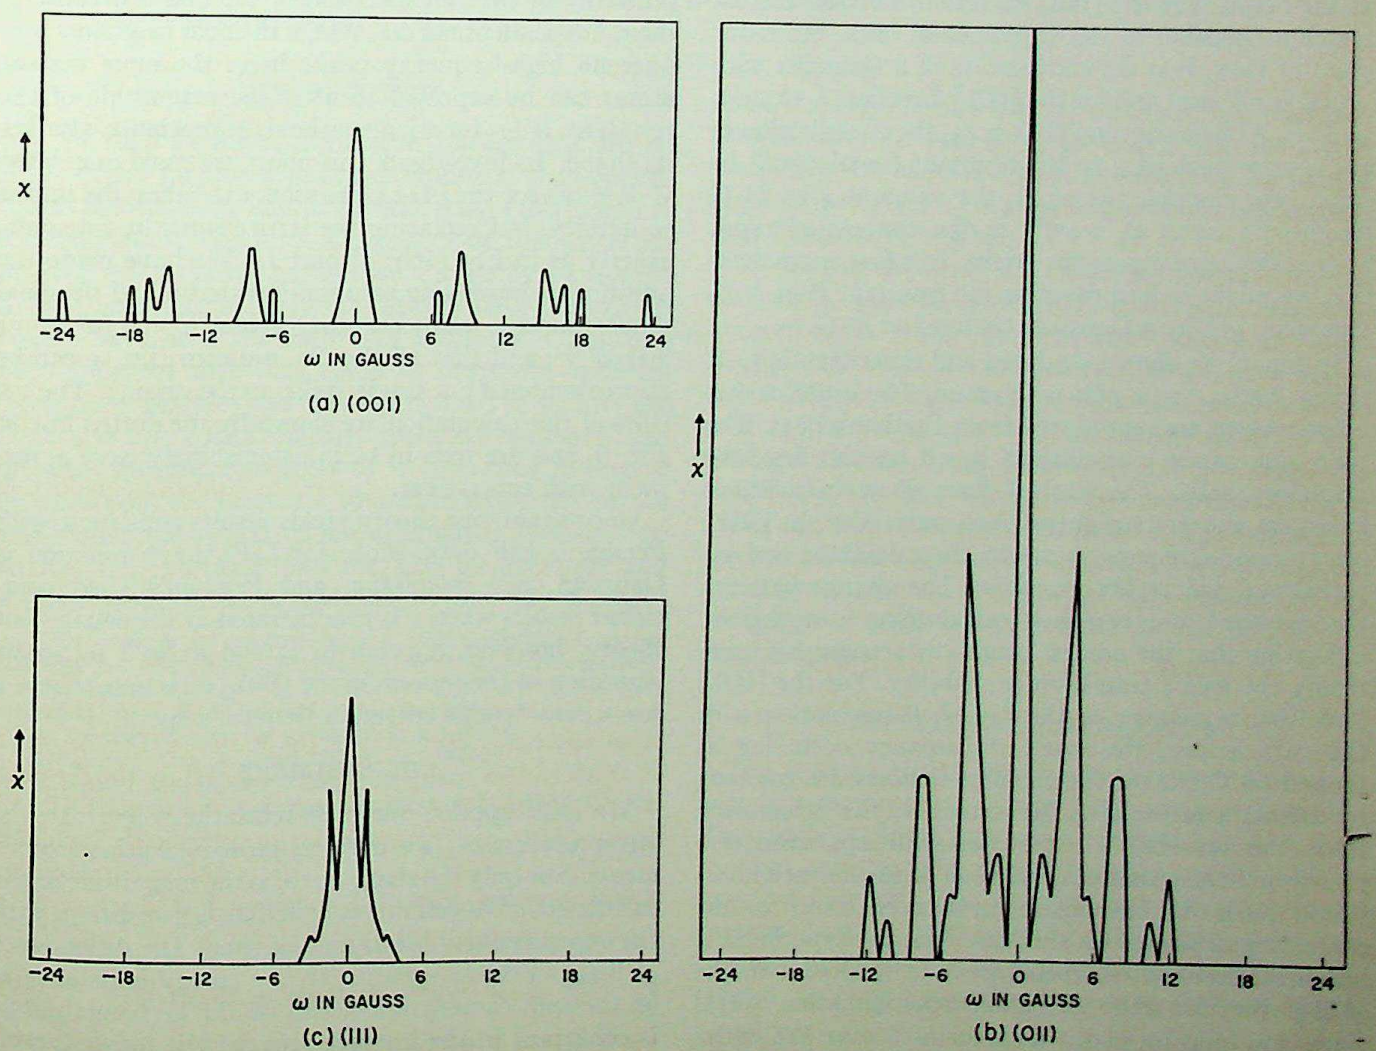

FIG. 5. $\chi(\omega)$ for LiF.

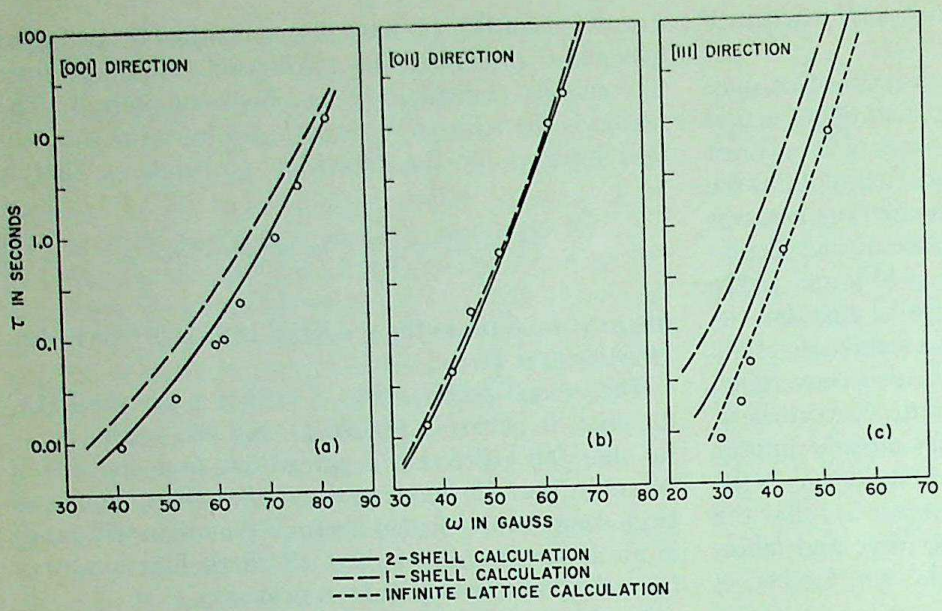

FIG. 6. C–R times for LiF.

direction. This slightly larger σ for the [011] direction compensates for his implicit approximation of χ by a δ function at the origin. For this direction, our χ does not vanish until 12 G, although it has an enormous peak at the origin. For the [001] direction, Pershan cannot match a Gaussian to the experimental data. From our point of view, it is the convolution of a Gaussian with χ that is relevant and for the [001] direction, χ extends to 24 G. At fields beyond 20 G or so, the contribution of the central peak of χ to the resultant function will be small. For example, at 65 G, the value of χ at 24 G weights 34 times as heavily in the convoluted result as does the value of χ at the origin. To a first approximation we might indeed describe the resultant W_{CR} by a Gaussian, but by a Gaussian centered at 24 G.

In Fig. 6, we show calculated and experimental C–R times. Again, the ω axis is in gauss. The experimental points shown are reproduced from Pershan's data. The solid lines show calculations based on the first two neighbor shells. The dashed lines show calculations based on the first neighbor shell only. For the [011] orientation, agreement between the calculated and experimental values are excellent. The change between the one-shell and two-shell calculations is negligible, indicating that the nearest neighbors account for practically the entire transition probability. For the [001] direction, agreement of the two-shell calculation with the data is fair, the worst discrepancy occurring at around 60 G, where the calculated times are too long by almost a factor of 2. Nevertheless, the progression from the one-shell to the two-shell approximation clearly indicates that the inclusion of further neighbors would push the calculated curve even closer to the experimental points. In this case too, the experimental numbers decisively corroborate our theory. For the [111] direction, the two-shell approximation yields times too long by about a factor of 2 over the entire observed range; the one-shell calculation yields times too long by about a factor of 10. This is to be expected. The χ function for this case consists essentially of a single sharp peak at the origin.

The contribution of the more distant neighbors is primarily in the neighborhood of the origin because of the r^{-3} dependence of $\Delta\omega$. Where the near neighbors produce no high-frequency peaks in χ, the more distant atoms can be expected to alter the magnitude of the resultant W_{CR} function, without appreciably altering its shape. To investigate this point, we have calculated C–R times for the [111] direction, extending the lattice to infinity, but replacing the lattice sums by integrals, exactly as in Eq. (46b) of part II. We have made the additional simplifying assumptions that all off-diagonal dipole matrix elements are given by $g_{\mathrm{Li}}^2\beta^2/r^3$ or $g_{\mathrm{Li}}g_{\mathrm{F}}\beta^2/r^3$, and that all the $\Delta\omega_\chi$ are zero (i.e., χ can be approximated by a single spike at the origin). The results of this calculation are shown by the dotted line in Fig. 6, and are seen to be in astonishingly close agreement with experiment.

Once again, our theory yields results consistent with Pershan's LiF data. Since for LiF, the Φ function is Gaussian, our calculation and Pershan's yield coincident results when χ is concentrated at the origin. Our theory, however, appears to extend as well to an explanation of the process in the [001] direction, where χ has a considerable spread in frequency space.

III. SUMMARY

We have applied our cross-relaxation theory to the interpretation of two classical cross-relaxation experiments. Not only the shape but also the magnitude of the calculated cross-relaxation function is consistent with the experiments of Mims and Pershan. The dependence of W_{CR}, in dilute systems, on the energy imbalance ω, on the spin concentration, and on the exchange radius is confirmed in the interpretation of the Mims experiment. The dependence of W_{CR}, in concentrated systems,

on interactions with near neighbors, and its associated spread and displacement in frequency is confirmed in the interpretation of Pershan's experiment.

IV. COMPUTATIONAL NOTE

This study has involved a sizeable mass of numerical detail. The generation and manipulation of large pair matrices, the tabulation of the various χ functions, the evaluation of different convolution integrals, to mention only the more obvious computational tasks, have had to be performed on a mass-production basis. The use of the Bell Telephone Laboratories IBM-7090 computer has proved indispensable. The computer programs were written by the author.

Molecular Field Model and the Magnetization of YIG*

ELMER E. ANDERSON
U. S. Naval Ordnance Laboratory, White Oak, Maryland
and
The University of Maryland, College Park, Maryland
(Received 7 January 1964)

The susceptibility and magnetization of YIG of high purity have been measured from 4.2 to 650°K by means of a precision vacuum balance. The spontaneous magnetization has a saturation value of 37.90 emu/g at 4.2°K and 27.40 emu/g at 292°K. The Curie point is at 559°K as determined by both the vanishing of the spontaneous moment and the discontinuity in the susceptibility curve. Using a program written for the IBM 7090, the molecular field coefficients were determined by fitting the experimental total magnetization curve. The sublattice magnetizations and the exchange interactions are calculated and compared with other results. On the basis of the molecular field model the intrasublattice interactions must be larger than previously supposed.

INTRODUCTION

ACCURATE sublattice magnetization data are required for an adequate description of such quantities as the magnetic anisotropy and magnetostriction in ferrimagnetics. The first calculations of the sublattice magnetizations in the garnets were made by Pauthenet in 1957 based on the molecular field model.[1] Though his results have been the only ones available it has long been apparent that they could be improved upon by using purer samples and a better method of solving the molecular field equations. An alternative approach is to measure the magnetization of a sublattice indirectly by observing the magnetic resonance frequency or the Mössbauer absorption of nuclei situated in that sublattice. This was first done for YIG by Solomon[2] and Robert[3] and has been repeated by several others,[4–9] some of whose results will be discussed in a later section. It may be said here, however, that the NMR measurements have not been extended to sufficiently high temperatures to represent any real improvement over Pauthenet's results.

In this present study the total spontaneous magnetization was obtained by subtracting the field-dependent magnetization from the measured values for high-purity YIG over the temperature range from 4.2 to 650°K. These values of the spontaneous magnetization were fed into a program written for the IBM 7090 by Gerhard Heiche of this laboratory and the molecular field equations were solved for all temperatures. The molecular field coefficients computed in this manner are used to calculate the sublattice magnetizations and the exchange interaction energies for YIG. Similar results for the three sublattice garnets will be the subject of a separate paper.

EXPERIMENTAL APPARATUS

The technique used for the measurements reported here is a modification of the Curie method.[10] Briefly, the sample is placed in a magnetic field having a large gradient and the force on the sample is measured by a sensitive balance. The essential unit is an automatic vacuum balance and recorder which can weigh accurately to 3×10^{-5} g. A quartz sample holder is suspended from one pan of the balance so that the sample

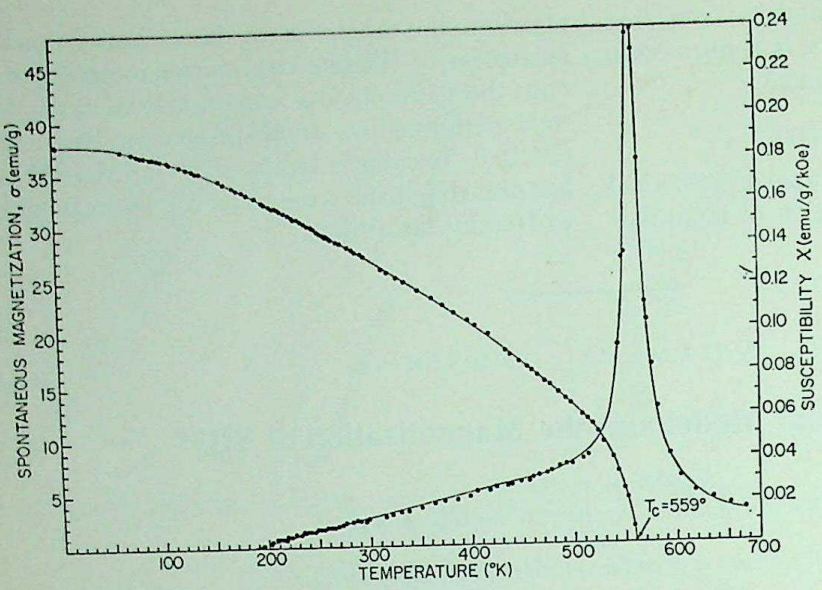

FIG. 1. Spontaneous magnetization and susceptibility of YIG.

is at the point where the magnetic field gradient is a maximum. The sample holder is protected by a vacuum-tight glass tube which may be either evacuated or subjected to a helium atmosphere at any desired pressure. For low-temperature measurements a stainless-steel double Dewar is used. High temperatures are achieved by using a noninductive wire-wound heater whose magnetoresistance coefficient is extremely low. The temperature of the sample is monitored by two thermocouples which are mounted close to the sample on the inside of the protective tube. In the interval from 50 to 250°K the maximum temperature error is estimated at ±0.5°C and above room temperature it is probably less than ±0.2°C. The magnetic field is provided by an electromagnet having parabolic pole pieces situated so as to produce a large gradient in the vertical direction. The maximum field attainable is 10 kG and the corresponding gradient is 1241 G/cm at the optimum sample position. The latter was determined by mapping the field of the magnet and choosing the point where $\partial^2 H/\partial z^2=0$. Ideally, if $\partial H/\partial z$ is the only nonzero derivative, then the force per gram of sample is given by

$$F=\sigma(\partial H/\partial z). \tag{1}$$

The gradient was determined for each value of magnet current from measurements on spectroscopically pure nickel (Johnson Matthey Code 890) using the value of 54.39 emu/g for nickel at 20°C.[11] The precision of this calibration is better than ±0.1% and includes any errors due to sample weight, sample position, and field current setting. It also includes any uncertainties due to sample shape since spherical and nonspherical samples were used to make the calibration runs.

SAMPLES

YIG single crystals were grown from the melt by J. Richard Cunningham, Jr., of this laboratory using oxides of 99.99% purity. Polycrystalline samples were made by ceramic techniques using ultrapure yttrium oxide (Lindsay Code 1118). The single crystals were ground into spheres and were x-ray oriented so that the applied field could be directed along a [111] axis. Measurements on the polycrystalline samples were made on sintered powders as well as on spheres ground from toroids of high density. X-ray diffraction patterns were obtained for all of the polycrystalline materials using a Norelco high-angle goniometer spectrometer. The scanning rate was $\frac{1}{4}$° per minute using unfiltered chromium radiation. None of the samples showed any unwanted phases or impurities and the powders appeared to be homogeneous and completely reacted.

MOLECULAR FIELD THEORY OF YIG

On the basis of the two sublattice model for ferrimagnetics [12] the molecular field equations for YIG may be expressed as follows:

$$\begin{aligned}
&\sigma=\sigma_d-\sigma_a,\\
&\sigma_a=75.70B_{5/2}(3.359\times10^{-4}/T)H_a,\\
&\sigma_d=113.55B_{5/2}(3.359\times10^{-4}/T)H_d,\\
&H_a=\lambda_{aa}\sigma_a-\lambda_{ad}\sigma_d,\\
&H_d=-\lambda_{ad}\sigma_a+\lambda_{dd}\sigma_d.
\end{aligned} \tag{2}$$

In Eqs. (2), σ is the total magnetization, σ_a is the magnetization of the octahedral sublattice and σ_d is the magnetization of the tetrahedral sublattice, all expressed in emu/g. $B(x)$ is the Brillouin function, T is the absolute temperature, and $H_{a,d}$ is the molecular field in gauss. The molecular field coefficients λ_{ij} are related to the n_{ij} of Pauthenet[1] by

$$\lambda_{ij}=92.25n_{ij}.$$

They may also be expressed in terms of the three

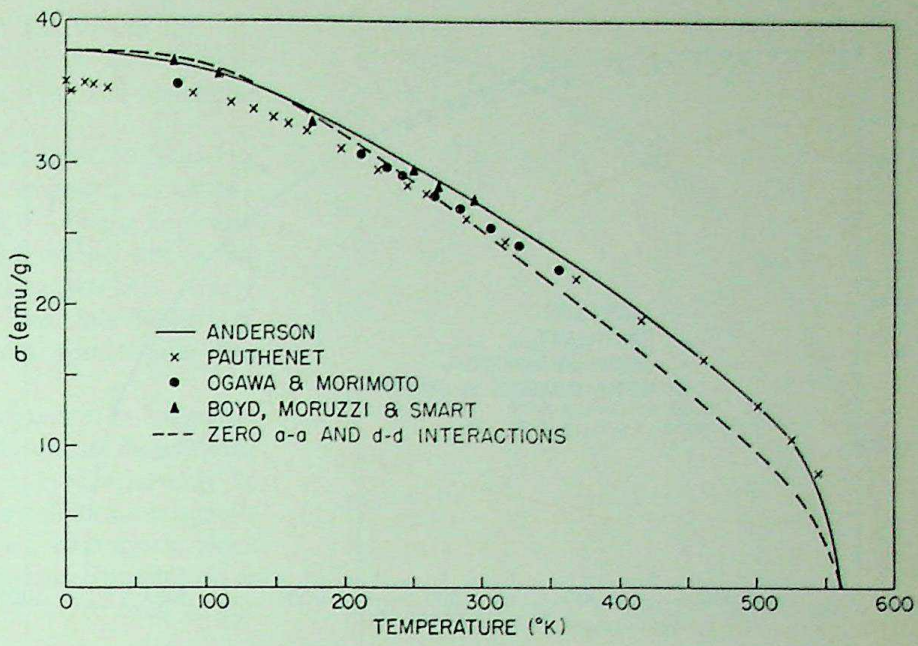

FIG. 2. Spontaneous magnetization of YIG. The solid curve is the experimental curve of Fig. 1 with data points omitted. The broken curve is the molecular field solution using the coefficients in line 2 of Table I.

exchange energies as follows:

$$\lambda_{aa}=5661J_{aa},$$
$$\lambda_{dd}=1887J_{dd}, \qquad (3)$$
$$\lambda_{ad}=2821J_{ad},$$

where the J_{ij} are in units of cm^{-1}.

Equations (2) were solved by means of a computer program designed to determine the molecular field coefficients by fitting the experimentally determined total magnetization curve.

EXPERIMENTAL RESULTS

The spontaneous magnetization and the susceptibility of YIG are shown in Fig. 1 in units of emu/g. The value of 37.90 emu/g at absolute zero corresponds to slightly over 5 Bohr magnetons and is in excellent agreement with the value of 5.01 reported by Geller *et al.*[13] This is about 5% higher than Pauthenet's value and attests to the purity and homogeneity of these samples. The Curie temperature is 559°K and is indicated by the discontinuity in the susceptibility curve as well as the vanishing of the magnetic moment. There is little question about the shape of the magnetization curve as is evidenced by the smoothness of the data. The points shown in Fig. 1 represent only about one-fourth of those measured and the omitted points fit the curve just as smoothly. The total magnetization is again shown in Fig. 2, where it is compared with the data of Pauthenet and the NMR results. The latter, unfortunately, do not extend much above room temperature and thus shed no light on the region where the magnetization changes most rapidly. The broken curve in Fig. 2 is the molecular field solution obtained by assuming that the *a–a* and *d–d* interactions are zero. Adjusting the *a–d* interaction coefficient to give the experimental Curie temperature of 559°K, one obtains the results shown in line 3 of Table I. However, the experimental curve (solid line) of Fig. 2 is best fit by the two sets of coefficients in lines 1 and 2 of Table I. The coefficients of line 1 were obtained by assuming them to be independent of temperature while those of line 2 were given Aléonard's temperature dependence, namely,

$$\lambda(T)=\lambda(o)\cdot(1-1.3\times10^{-4}T).$$

The magnetization curve calculated from each of these sets of coefficients is extremely close to the experimental values. The relative error is generally less than a few tenths of a percent except near the Curie point. Two factors probably contribute to the latter: (1) The spontaneous magnetization in this region is quite small and the measured magnetization consists largely of the field-dependent contribution. Thus, a small error in the susceptibility will produce a large relative error in spontaneous moment. (2) The molecular field model neglects short-range order which is known to play an ever increasing role as the long-range order disappears.

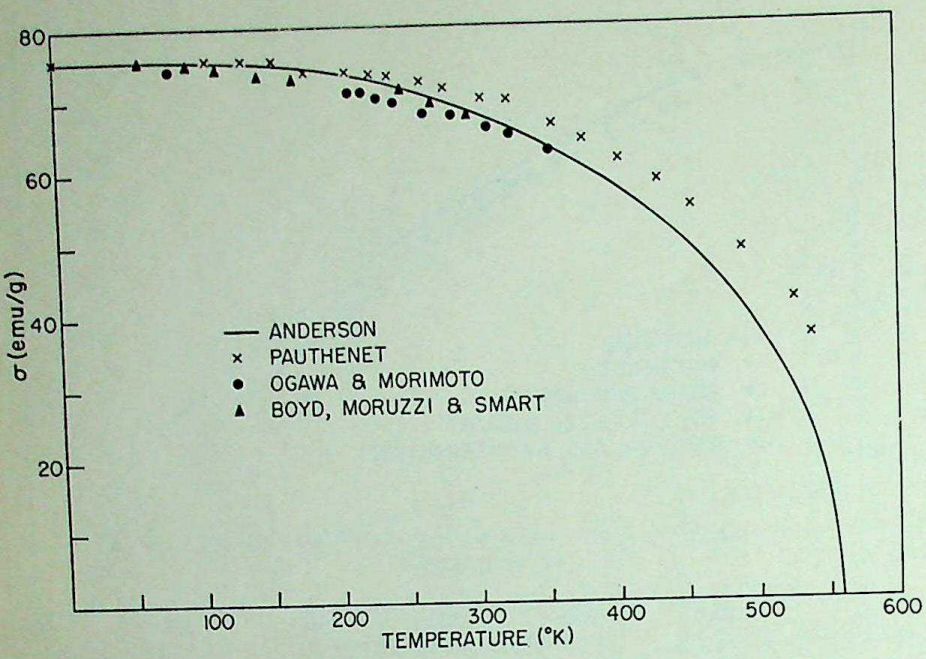

FIG. 3. Magnetization of the octahedral sublattice of YIG. The solid curve was calculated using the coefficients in line 1 of Table I.

DISCUSSION

It is evident from Fig. 2 that the shape of the total magnetization curve is not very sensitive to the values of the a–a and d–d interactions provided the a–d interaction is constrained to satisfy the Curie temperature. Thus, scattered data can be approximately fitted by a wide range of values for the coefficients. The curve in Fig. 1, however, is sufficiently smooth to give the unambiguous sets of molecular field coefficients of lines 1 and 2, Table I. These coefficients and the calculated exchange energies are compared with earlier values in the table. The tabulated values for the Curie temperature are all calculated values which were obtained from the solution of Eqs. (2) using the corresponding sets of coefficients. Note that the coefficients of lines 1–3 are the only ones that give a Curie temperature which agrees with the experimental value of 559°K. Pauthenet obtained a Curie temperature of 560°K experimentally but his temperature-dependent coefficients predict a value 40° higher.

Applying the results of spin-wave theory[16–18] to YIG, the dispersion constant D and the Landau-Lifshitz exchange constant A are related to the J's as follows:

$$\omega\hbar = Dk^2 = (a^3A/4S)k^2 = \tfrac{5}{16}(5J_{ad}-8J_{aa}-3J_{dd})a^2k^2. \quad (4)$$

Using $a=12.376\times10^{-8}$ cm and $S=\frac{5}{2}$,

$$D=4.787\times10^{-15}(5J_{ad}-8J_{aa}-3J_{dd}),$$
$$A=2.525\times10^{7}(5J_{ad}-8J_{a1}-3J_{dd}).$$

A summary of the values of D and A that have been obtained by magnetization, specific heat[19–22] and microwave measurements[23,24] is given in Table II. The values calculated from lines 1 and 2, Table I are smaller than the earlier magnetic results and are much less than those obtained from specific heat measurements. The discrepancy with the other magnetic results arises

principally from the differences in the values for J_{aa}. The disagreement with the specific heat data is probably due to differences in the spin wave and molecular field models.

Figures 3 and 4 show the octahedral and tetrahedral sublattice magnetizations for all temperatures as calculated using the coefficients of line 1 (solid line) and line 3 (dashed line) of Table I. The dashed line is not shown for the octahedral sublattice since it nearly coincides with the solid curve. The calculations of Pauthenet and some of the NMR results are also shown.

In Mössbauer and NMR experiments in magnetic materials it is assumed that the temperature dependence of the effective field at the nucleus is due entirely to the temperature dependence of the sublattice magnetization. This is probably not a bad assumption since it has been shown[25] that the hyperfine interaction is the dominant contributor to the effective field at the nucleus.

The hyperfine term of the Hamiltonian may be written in the form

$$H = -g_I \beta_I \mathbf{I} \cdot \mathbf{H}_{\text{eff}}, \tag{5}$$

where

$$\mathbf{H}_{\text{eff}} = (8\pi/3)\rho(0) g\beta \mathbf{S} \tag{6}$$

is the effective field seen by the nuclear spin. Since $\rho(0)$ is nonzero only for s electrons, it is not obvious why Fe^{3+}, which has no unpaired s electrons, should have an effective field at the nucleus. Sternheimer[26] suggested that a net unpaired spin density at the nucleus is produced by a polarization of the core electrons due to the spin of the d electrons. If this core polarization is essentially constant up to the Curie temperature, then H_{eff} and the hyperfine energy will show the same temperature dependence as the sublattice magnetization. That this assumption is valid, at least up to 430°K in YIG, is borne out by the NMR data in Figs. 3 and 4.

SUMMARY OF RESULTS

(1) The saturation moment of YIG is 37.90 emu/g (5.01 Bohr magnetons) at absolute zero and 27.40 emu/g (3.62 Bohr magnetons) at 292°K. The Curie temperature is 559°K. The magnetic susceptibility vanishes below 190°K.

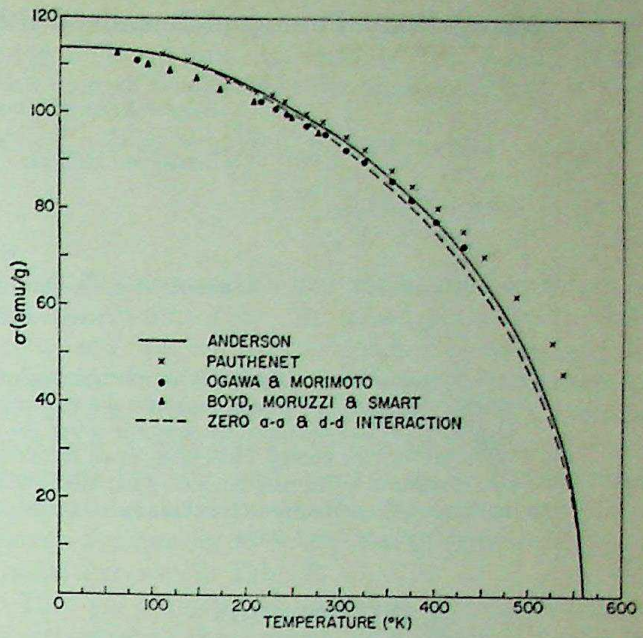

FIG. 4. Magnetization of the tetrahedral sublattice of YIG. The solid curve was calculated using the coefficients in line 1 of Table I, the broken curve using line 3.

(2) The experimental magnetization curve can be reproduced by means of the molecular field model. However, a unique set of interaction coefficients cannot be obtained by this method if there is much scatter in the data.

(3) The sublattice magnetizations are less sensitive than the total magnetization to the exact values of the interaction coefficients.

(4) The sublattice magnetizations reported here are in good agreement with available NMR results.

(5) On the basis of this model the a–a interaction must be larger than previously supposed.

ACKNOWLEDGMENTS

I am especially grateful to Professor Ralph D. Myers for his guidance during the course of this work. I wish to also thank J. Richard Cunningham, Jr., for growing the crystals, and Gerhard Heiche for writing the computer program for the solution of the molecular field coefficients.

Note added in proof. A. B. Harris [Phys. Rev. **132**, 2398 (1963)] gives the following values for the molecular field coefficients of YIG: $\lambda_{ad} = 89\,700$, $\lambda_{aa} = 35\,950$ and $\lambda_{dd} = 11\,980$. However, this set of coefficients results in a Curie temperature that is greater than 900°K.

Many-Body Theory of Localized d States in Metals. II. Pair of Impurities*

P. GOTTLIEB
Hughes Research Laboratories, Malibu, California
and
University of California, San Diego, La Jolla, California

AND

H. SUHL
University of California, San Diego, La Jolla, California

(Received 20 January 1964)

A previous rotationally invariant perturbation treatment of localized d states is extended to the case of neighboring sites interacting via direct d-d exchange and indirect s-d scattering. It is found that the parallel alignment of two localized moments is never the ground state of the pair. For certain values of the unperturbed d-state energy (depending upon the exchange interactions) only one of the sites will be occupied by a d electron so the pair can have a net moment. If the conditions are such that both sites are occupied by d electrons, these electrons must be aligned antiparallel so there is only a small net moment due to scattering to and from the band states.

I. INTRODUCTION

IN a previous paper,[1] a rotationally invariant perturbation calculation of the susceptibility of a localized d state in a metal was made, using a model of this state proposed by Anderson.[2] In this model the "d state" is assumed to have no orbital degeneracy, and to have a wave function distinct from the Wannier functions of electrons on the sites of the host lattice. When this state is singly occupied, its energy is ϵ_d, when doubly occupied by electrons with antiparallel spins, is $2\epsilon_d+U$, where U is positive. The Hamiltonian of the model consists of the band electron energies, the aforementioned "d state" energies, and a scattering term capable of converting electrons on the local "d" site into band electrons and conversely. No other terms (such as Coulomb interaction between conduction electrons and electrons on the "d" site) are included. Physical reasons for restriction of the energies to the ones mentioned above, are given by Anderson.[2] Within the framework of this model, he showed that, provided the scattering to the band was not too strong relative to the correlation energy U, and provided ϵ_d was below the Fermi surface and $2\epsilon_d+U$ above, a localized magnetic moment would result, which could be calculated by the Hartree-Fock method. Since this method violates rotational invariance, it is hard to see how one can use it to compute a Curie constant as distinct from a saturation magnetization.

In SFI it was shown how this calculation may be done by perturbation theory. The method divided the possible states of the system into magnetic and nonmagnetic ones, and calculated two partition functions $\mathfrak{Z}_M$, $\mathfrak{Z}_S$ in these two manifolds. The Curie constant then has the form

$$C_{\text{eff}}=C_{1/2}[\mathfrak{Z}_M/(\mathfrak{Z}_M+\mathfrak{Z}_S)].$$

The actual calculation used the resolvent technique, deriving resolvents $\mathfrak{R}_M$ and $\mathfrak{R}_S$ for the two manifolds with the help of projection operators. These resolvents were then evaluated by perturbation theory, keeping only the lowest order self-energy corrections and, in fact, only their imaginary parts. The crucial point is the following: If these imaginary parts (due, of course, to the band scattering) were neglected, the partition function $\mathfrak{Z}_S$ of the nonmagnetic manifold would be smaller than $\mathfrak{Z}_M$ by a factor $e^{\beta\epsilon_d}$, for the "empty" component of the nonmagnetic manifold, and by a factor $e^{-\beta(2\epsilon_d+U)}$ for the "filled" component of that manifold. (Energies are measured from the Fermi level.) Hence, at very low temperatures, the magnetic moment would be essentially that of the isolated "d" state without scattering to the band. The imaginary parts of the self-energies appropriate to $\mathfrak{Z}_S$, which are in effect the damping rates of the states of S due to the presence of M, cause $\mathfrak{Z}_S$ to assume the *same* exponential dependence on the temperature as that of $\mathfrak{Z}_M$. For this reason there is always a reduction of the moment. Qualitatively, the results agreed with those of Anderson, except no sharp cutoff was found in the moment, which tended to zero smoothly with increasing scattering. This might be a basic feature of perturbation theory, unless prescriptions are found for solving for the self-energies consistently in the way in which this is done in other many body problems. The complicating feature here, which makes the standard recipes hard to apply, is that the "d"-state correlation energy is treated rigorously as part of the unperturbed propagator.

In the case of two d states, we distinguish between two situations: (1) The d sites are nearest neighbors and electrons on them interact directly, and (2) the d sites are far apart and interact only via band electrons.

In case (1), we must include in the Hamiltonian an

essentially single-particle scattering between electrons on the two "d" sites. In addition, we will show that the direct Coulomb interaction between electrons on these sites may become important even if smaller than the former, provided its exchange part has ferromagnetic sign. To these interactions we must, of course, add the same Hamiltonians as in SFI, one for each site. In case (2), all direct d interaction is neglected and only the sum of the two Hamiltonians of SFI remains.

Problem (1) has also been treated in Hartree-Fock approximation by Alexander and Anderson,[3] who conclude that the pair aligns antiparallel with zero net moment unless one of the energies ϵ_d or $2\epsilon_d+U$ is close to the Fermi level. In that event, they can obtain parallel coupling, and therefore a net moment. As we shall see, perturbation theory parallels these conclusions somewhat.

II. RESOLVENT METHOD

We will treat the "d" pair Hamiltonian rigorously, and, as in SFI, only the band scattering as a perturbation. (A simultaneous treatment of both these mechanisms will be briefly considered at the end of this paper.) Then we may divide the unperturbed states of the system into three manifolds, broadly describable as singlet, doublet, and triplet, and the effective Curie constant, by a trivial generalization of the formula in SFI as[4]

$$C_{\text{eff}}=\frac{C_1\mathfrak{Z}_T+C_{1/2}\mathfrak{Z}_D}{\mathfrak{Z}_T+\mathfrak{Z}_D+\mathfrak{Z}_S}, \tag{1}$$

where C_1 and $C_{1/2}$ are the "bare" Curie constants appropriate to a free spin one and a free spin $\frac{1}{2}$, respectively, and $\mathfrak{Z}_T$, $\mathfrak{Z}_D$, $\mathfrak{Z}_S$ are the partition functions of the three manifolds. These manifolds, split into submanifolds, which may be classified according to their origin before the single particle scattering between the two sites is turned on. The result is as follows:

(S) One electron on each site, the pair forming a singlet. Two antiparallel electrons on one site, the other site empty. Both sites doubly occupied by antiparallel electrons. Both sites empty.

(D) One electron on either site, the other empty. Two antiparallel electrons on one site, the other singly occupied.

(T) One electron on each site, the pair forming a triplet.

Including the possible S_z states in D and T, this gives a total of 16 *unperturbed basis states*. When the single-particle scattering between the two sites is turned on, some of these form admixtures. The d part of the Hamiltonian (exclusive of the band scattering) is

$$\mathfrak{H}_d=\sum_\sigma \epsilon_d(n_{1\sigma}+n_{2\sigma})+U(n_{1\uparrow}n_{1\downarrow}+n_{2\uparrow}n_{2\downarrow}) +V_{12}\sum_\sigma(d_{1\sigma}{}^*d_{2\sigma}+d_{2\sigma}{}^*d_{1\sigma}), \tag{2}$$

where d^*, d are creation and annihilation operators on the sites indicated by the subscripts, σ is the spin index and the n's are occupation numbers on the indicated sites. Coulomb interation is neglected for the present. Under the V_{12} term in Eq. (2), the submanifolds enumerated above (linearly combined where required) combine and regroup as in the following table. In the ket symbols, the first and second places denote occupancies of sites 1 and 2, respectively. The results are given in Table I.

The low-temperature behavior of the partition functions of *all* these manifolds is dictated by that of the partition function of the energetically lowest manifold. (Just as in SFI, the others are "damped" by lowest manifold and so acquire its temperature dependence.) For this reason we need only determine which energy is lowest as the parameters ϵ_d, U and V_{12} are varied.

We assume $\epsilon_d<0$, $2\epsilon_d+U>0$ so that the isolated sites favor single occupancy let $V_{12}>0$. If $V_{12}>\frac{2}{3}U$, the $E(S_{m1})$ is always lowest. If $V_{12}<\frac{1}{3}U$, then $E(S_{m1})$ or $E(D_1{}^+)$ is lowest according to whether

$$-\epsilon_d \gtrless V_{12}\{1-8(V_{12}/U)[1+(1+(16V_{12}{}^2/U^2))]^{-1}\}.$$

If $V_{12}<0$, the same result holds, but with V_{12} replaced by $|V_{12}|$ and $D_1{}^+$ by $D_1{}^-$. Presumably for *reasonably* small V_{12}, the situation with singlet lowest is more common. Only when ϵ_d approaches the Fermi level to within $\sim V_{12}$, can the doublet energy become lowest.

It follows that in the common situation, any moment exhibited by the pair is due to band scattering. For small values of the scattering energy V, such moment as there is comes principally from $\mathfrak{Z}_D$, since the doublet manifold can reach the singlet manifold by lowest order damping involving V^2. The triplet manifold connects to the singlet only in order V^4. Qualitatively, this agrees with the Hartree-Fock procedure of Alexander and Anderson, who find no moment at all unless $|V_{12}|\sim|\epsilon_d|$.

The triplet energy is *always* above $E(S_{m1})$. It is also below $E(D_1{}^+)$, unless

$$V_{12}>-\epsilon_d>V_{12}\{1-8(V_{12}/U) \times[1+(1+(16V_{12}{}^2/U^2))^{1/2}]^{-1}\},$$

in which case $E(D_1{}^+)$ lies between the singlet S_{m1} and the triplet. In that case the triplet partition function acquires the exponential temperature dependence of that of the doublet, but at temperatures such that kT is much less than a quantity of order $V_{12}{}^2/U$, the damping process still favors the singlet.

[3] S. Alexander and P. W. Anderson, Phys. Rev. 133, A1594 (1964).

[4] It should be emphasized again that formulas like (1) and (7a) of SFI give *only* the thermal expectation value of $n_{d\uparrow}-n_{d\downarrow}$ in the case of (7a) SFI, and of the total moment on the pair of d sites alone in the case of (1) of the present paper. Any polarization effects of the conduction electrons over and above their background Pauli moment are not determined by these formulas.

TABLE I. Energies of various states.[a]

States	Energies
Singlets	
both sites empty, $S_e=\|0;0\rangle$	0
both sites filled, $S_f=\|\uparrow\downarrow;\uparrow\downarrow\rangle$	$4\epsilon_d+2U$
"polar" singlet; $S_p=(2)^{-1/2}(\|\uparrow\downarrow;0\rangle-\|0;\uparrow\downarrow\rangle)$	$2\epsilon_d+U$
"mixed" singlets	
$S_{m1}=(2)^{-1/2}[a(\|\uparrow;\downarrow\rangle-\|\downarrow;\uparrow\rangle)+b(\|\uparrow\downarrow,0\rangle+\|0,\uparrow\downarrow\rangle)]$	$2\epsilon_d-U\sinh^2(\theta/2)$
$S_{m2}=(2)^{-1/2}[-b(\|\uparrow;\downarrow\rangle-\|\downarrow;\uparrow\rangle)+a(\|\uparrow\downarrow,0\rangle+\|0,\uparrow\downarrow\rangle)]$	$2\epsilon_d+U\cosh^2(\theta/2)$
Doublets	
one-electron doublets; $D_1^{\pm}=(2)^{-1/2}(\|\uparrow,0\rangle\pm\|0,\uparrow\rangle)$	$\epsilon_d\mp\frac{1}{4}U\sinh\theta$
three-electron doublets: $D_3^{\pm}=(2)^{-1/2}(\|\uparrow\downarrow,\uparrow\rangle\pm\|\uparrow,\uparrow\downarrow\rangle)$	$3\epsilon_d+U\mp\frac{1}{4}U\sinh\theta$
and two similar pairs with the spins reversed.	
Triplets	
$\|\uparrow;\uparrow\rangle$	$2\epsilon_d$
$T=(2)^{-1/2}(\|\uparrow;\downarrow\rangle+\|\downarrow;\uparrow\rangle)$	$2\epsilon_d$
$\|\downarrow;\downarrow\rangle$	$2\epsilon_d$

[a] In this table $\sinh\theta=4V_{12}/U$, $a=-\coth(\theta/2)/[1+\coth^2(\theta/2)]^{1/2}$, and $b=1/[1+\coth^2(\theta/2)]^{1/2}$. For brevity, the energies of these states S_f, S_p, etc. will be denoted by $E(S_f)$, $E(S_p)$, etc.

Finally, when $E(D_1^+)$ is also below $E(S_{m1})$ (see inequality), the susceptibility for small band scattering is dominated by spin $\frac{1}{2}$ with V^2 corrections from spin 1, and spin 0. This is the situation in which Alexander and Anderson find triplet coupling favored. In the present theory no such coupling ever occurs.

However, some caution is indicated by the fact that in the present model the singlet-triplet separation is only of order V_{12}^2/U. If a Coulomb interaction between the electrons on the d sites is added, and its exchange energy W, say, turns out to have ferromagnetic sign, the above conclusions become invalid as soon as W exceeds V_{12}^2/U. The triplet would then tend to be lowest, and the susceptibility would be dominated by spin one.

III. EVALUATION OF THE PARTITION FUNCTIONS

We use the resolvent technique (as in SFI) for evaluation of the partition function. The complete Hamiltonian is taken to be

$$\mathcal{H}=\sum_{k,\sigma}\epsilon_k c_{k,\sigma}^{\dagger}c_{k,\sigma}+V\sum_{k,\sigma}\sum_{i=1}^{2}(e^{+i\mathbf{k}\mathbf{r}}c_{k,\sigma}^{*}d_{i,\sigma}+e^{-i\mathbf{k}\mathbf{r}}d_{i,\sigma}^{*}c_{k,\sigma})+\mathcal{H}_d$$
$$\equiv\mathcal{H}_b+\mathcal{H}_d+\mathcal{V}=\mathcal{H}_0+\mathcal{V}, \tag{3}$$

where $\mathcal{H}_d$ is the Hamiltonian of the "d" states alone, $\pm\mathbf{r}$ are the position vectors of the sites, and $\mathcal{V}$ is the band scattering operator. The resolvent operator $\mathfrak{R}=(\mathcal{H}-z)^{-1}$, could be projected onto the unperturbed singlet, doublet, and triplet manifolds as in SFI. The result will involve "nested" propagators and have an extremely complicated appearance, each propagator involving the manifold one more remote than its predecessor. We have calculated one of these nested expressions in the approximation in which, at most, two conduction electrons or holes are excited in the intermediate states.

The resolvent for the D_1 state (which exhibits the behavior of resolvents of other states as well), with the denominator evaluated to first order in Δ ($\Delta=\pi\rho V^2$, $\rho=$density of states), may be written as

$$\mathfrak{R}_{D_{1(z)}}=[E(D_1)-z+\sum_k \mathcal{T}_k+i\delta]^{-1}, \tag{4}$$

where δ is an infinitesimal,

$$\mathcal{T}_k=\frac{|\langle D_1|\mathcal{V}|T\rangle|^2 n_k}{E(T)-z-\epsilon_k}+\sum_{S'}\frac{|\langle D_1|\mathcal{V}|S'\rangle|^2 n_k}{E(S')-z-\epsilon_k}+\frac{|\langle D_1|\mathcal{V}|S_e\rangle|^2(1-n_k)}{-z+\epsilon_k},$$

and $\sum_{S'}$ means the sum over the three singlet states with two d electrons, S_p, S_{m1}, S_{m2}. The matrix elements may be evaluated with the aid of the wave functions derived above. For example, $N|\langle D_1^+|\mathcal{V}|S_{m1}\rangle|^2=\gamma_+V^2\times\cos^2\mathbf{k}\cdot\mathbf{r}$, $N|\langle D_1^+|\mathcal{V}|T\rangle|^2=3V^2\sin^2\mathbf{k}\cdot\mathbf{r}$, where $\gamma_{\pm}=1\pm[4V_{12}/(U^2+16V_{12}^2)^{1/2}]$. The summation over k is somewhat complicated by the presence of $\sin^2\mathbf{k}\cdot\mathbf{r}$ (etc.). Since ϵ_k is isotropic, the angular integration will give

$$\int d\Omega\begin{Bmatrix}\sin^2\mathbf{k}\cdot\mathbf{r}\\ \cos^2\mathbf{k}\cdot\mathbf{r}\end{Bmatrix}=2\pi\begin{Bmatrix}1-\dfrac{\sin 2kr}{2kr}\\ 1+\dfrac{\sin 2kr}{2kr}\end{Bmatrix}=2\pi\begin{Bmatrix}\mu_-\\ \mu_+\end{Bmatrix}.$$

If we assume

$$|\epsilon_k(dk/dE)_F|\ll\max(k_F,1/r),$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

then

$$\frac{\sin 2kr}{2kr}=\frac{\cos 2k_Fr\sin 2[\epsilon_k(dk/dE)_Fr]+\cos 2[\epsilon_k(dk/dE)_Fr]\sin 2k_Fr}{2[k_F+\epsilon_k(dk/dE)_F]r}\approx\frac{\sin 2k_Fr}{2k_Fr}.$$

Then $\mu_\pm$ becomes

$$\alpha_\pm=1\pm(\sin 2k_Fr/2k_Fr).$$

Now we will neglect the real part of $\sum_k\mathcal{T}_k$, and calculate

$$\begin{aligned}(2/\Delta)\mathrm{Im}\sum_k\mathcal{T}_k=&3n[E(T)-z]\alpha_-\\&+n[E(S_p)-z]\alpha_-+n[E(S_{m1})-z]\alpha_+\gamma_-\\&+n[E(S_{m2})-z]\alpha_+\gamma_++2n[-z]\alpha_+,\end{aligned}\quad(5)$$

where $n[z]$ is the Fermi distribution. Following the procedure of SFI, the partition function may be written as

$$\begin{aligned}\mathfrak{Z}_{D1}{}^+&=\int_{-\infty}^{+\infty}\mathrm{Im}\mathfrak{N}(z)e^{-\beta z}dz\\&=e^{-\beta E(D_1{}^+)}\int_{-\infty}^{+\infty}\frac{[\delta+\Delta I(\zeta)]e^{-\beta\zeta}d\zeta}{\zeta^2+[\Delta I(\zeta)+\delta]^2},\end{aligned}\quad(6)$$

where

$$I(\zeta)=\frac{1}{\Delta}\mathrm{Im}\sum_k\mathcal{T}_k$$

and we have substituted $\zeta+E(D_1{}^+)=z$.

$I(\zeta)$ will be infinitesimally small unless $\zeta>E(S_{m1})-E(D_1{}^+)$, and the integrand of Eq. (6) will be infinitesimally small unless $\zeta<0$. The problem then requires consideration of two separate cases depending on the sign of $E(S_{m1})-E(D_1{}^+)$.

A. Magnetic: $E_0=E(S_{m1})-E(D_1{}^+)>0$

In this case the integrand behaves like a delta function near $\zeta=0$, in the limit $\delta\to0$. The $I(\zeta)$ term in the numerator can only contribute for $\zeta>E_0$, and, since $e^{-\beta E_0}\ll1$, this contribution is negligible. (For large negative values of ζ the integrand could become large because of the exponential factor, even compensating for the small factor δ. However, either the band bottom or the finite spatial extent of the impurity potential V will introduce a cutoff before this happens.) The partition function for the magnetic case is now simply

$$\mathfrak{Z}_{D_1}{}^+=e^{-\beta E(D_1{}^+)}.\quad(7)$$

B. Nonmagnetic: $E_0=E(S_{m1})-E(D_1{}^+)<0$

$I(\zeta)$ is now finite at $\zeta=0$ so there is no contribution from the δ in the numerator in the limit $\delta\to0$. If we make the transformation

$$e^{-\beta\zeta}n(\alpha-\zeta)=e^{-\beta\alpha}n(\zeta-\alpha),$$

then we immediately see that the largest term in $e^{-\beta\zeta}I(\zeta)$ is

$$\tfrac{1}{2}e^{-\beta E_0}\alpha_+n(\zeta-E_0)\gamma_-.$$

Hence, the partition function may be written

$$\mathfrak{Z}_{D_1}{}^+=\gamma_-e^{-\beta E(S_{m1})}\frac{\Delta}{2}\int_{-\infty}^{E_0}\frac{\alpha_+d\zeta}{\zeta^2}.$$

The $I(\zeta)$ does not contribute to the denominator because we are integrating over that portion of the ζ axis where $I(\zeta)=0$. The straightforward evaluation of the integral then gives

$$\mathfrak{Z}_{D_1}{}^+=-(\Delta/2E_0)\gamma_-\alpha_+e^{-\beta E(S_{m1})}.\quad(8)$$

Calculation of Curie constant. We could proceed to evaluate all the other partition functions in the same manner. However, examination of Eqs. (7) and (8) and the analogous results in SFI will enable us to write the following set of simplifying rules for the calculation of the partition functions:

(1) All partition functions have the form $n_iA_ie^{-\beta E_l}$, where A_i is independent of temperature, $E_l=\min\times[E(S_{m1}),E(D_1{}^+)]$, and n_i is an integer indicating the multiplicity of the state.

(2) The partition function for the state of lowest energy has $A=1$.

(3) For any state coupled to the lowest state to first order in $\mathcal{U}$ (states coupled in higher order are neglected in the present paper),

$$A_i=(\Delta\gamma_\pm\alpha_\pm)/(E_i-E_l).$$

The α and γ factors are determined from the square of the appropriate coupling matrix element.

Applying these rules, we can calculate the effective Curie constant from Eq. (1) for the two cases.

Nonmagnetic: $E_0=E(S_{m1})-E(D_1{}^+)<0$

$$C_{\mathrm{eff}}=C_{1/2}F/(1+F),\quad(9)$$

where

$$F=\frac{\Delta}{2}\left[\frac{\alpha_+\gamma_-}{E(D_1{}^+)-E(S_{m1})}+\frac{\gamma_+\alpha_-}{E(D_1{}^-)-E(S_{m1})}+\frac{\gamma_+\alpha_+}{E(D_3{}^+)-E(S_{m1})}+\frac{\gamma_-\alpha_-}{E(D_3{}^-)-E(S_{m1})}\right].$$

The labelings of the energies in the denominators of F indicate the four levels to which S_{m1} is coupled in first order.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Magnetic: $E_0=E(S_{m1})-E(D_1^+)>0$

$$C_{\rm eff}=\left\{C_{1/2}+\frac{3C_1\Delta\alpha_+}{2[E(T)-E(D_1^+)]}\right\}\times\left\{1+\frac{\Delta}{2}\left[\frac{\gamma_+\alpha_+}{E(S_{m2})-E(D_1^+)}+\frac{\gamma_-\alpha_+}{E(S_{m1})-E(D_1^+)}+\frac{\alpha_+}{E(S_p)-E(D_1^+)}+\frac{3\alpha_+}{E(T)-E(D_1^+)}\right]\right\}^{-1}. \quad (10)$$

Each doublet state is actually counted twice, but since all the terms represent doublets, the factors of two cancel out. The accuracy of these expressions requires $\Delta\ll|E(S_{m1})-E(D_1^+)|$. In the region of transition from magnetic to nonmagnetic, the two levels cross and this inequality cannot hold. We must therefore do a more detailed calculation involving only the S_{m1} and D_1^+ levels.

IV. ZERO TEMPERATURE LEVEL SPLITTING

When the S_{m1} and D_1^+ levels are close together, we are permitted to rediagonalize them with respect to $\mathcal{U}$ and ignore the other levels. In this section we will therefore assume $|E(D_1^+)-E(S_{m1})|\ll|E(T)-E(D_1^+)|$, $|E(S_{m2})-E(D_1^+)|$, etc. For $E(S_{m1})<E(D_1^+)$ it is appropriate to consider a two-electron manifold. We take the wave function for this restricted manifold to be of the form

$$\psi=\sum_{k,\sigma}a_{k,\sigma}|D_1^+\rangle c_{k,-\sigma}+b|S_{m1}\rangle, \quad (11)$$

with the coefficients normalized so that

$$\sum_{k,\sigma}|a_{k,\sigma}|^2(1-n_k)+|b|^2=1.$$

The renormalized eigenvalues are found by minimizing the energy [calculated with Eq. (11) as wave function], minus the normalization condition multiplied by λ, with respect to a_k and b. This procedure gives the equations

$$\begin{aligned}&[E(D_1^+)+\epsilon_k-\lambda]a_k+V(\gamma_-\alpha_+/2)^{1/2}b=0,\\ &V(\gamma_-\alpha_+/2)^{1/2}\sum_k a_k(1-n_k)+[E(S_{m1})-\lambda]b=0,\end{aligned} \quad (12)$$

determining the new energies as solutions of

$$-\lambda+E(S_{m1})=\tfrac{1}{2}V^2\gamma_-\alpha_+\sum_k\frac{1-n_k}{E(D_1^+)+\epsilon_k-\lambda}. \quad (13)$$

It should be noted that we have actually renormalized only the states S_{m1} and D_1^+ accompanied by an electron. If $E(S_{m1})>E(D_1^+)$, the appropriate manifold contains only one-electron states. The wave function is then of the form

$$\psi=a|D_1^+\rangle+\sum b_k|S_{m1}\rangle c_k. \quad (14)$$

This leads to the characteristic equation

$$-\lambda'+E(D_1^+)=\tfrac{1}{2}V^2\gamma_-\alpha_+\sum_k\frac{n_k}{E(S_{m1})=\epsilon_k-\lambda'}, \quad (15)$$

which renormalizes the states D_1^+ and S_{m1} accompanied by a hole.

It can be seen at once that for $|E(D_1^+)-E(S_{m1})|\gg\Delta$, we have $\lambda=E(S_{m1})$, $\lambda'=E(D_1^+)$. Using this value of λ, and the normalization condition we find

$$a_k=\frac{V(\gamma_-\alpha_+/2)^{1/2}}{(1+F')^{1/2}[E(S_{m1})-E(D_1^+)-\epsilon_k]},$$

where

$$F'=\tfrac{1}{2}V^2\gamma_-\alpha_+\sum_k\frac{1-n_k}{[E(S_{m1})-E(D_1^+)-\epsilon_k]^2}.$$

If the summation is performed, it is readily seen that F' is the same as the first term of the F used in Eq. (9). With this value of a_k, we can obtain the result

$$C_{\rm eff}=C_{1/2}\sum_k a_k^2(1-n_k), \quad (16)$$

which is the same as Eq. (9), except that the terms involving levels other than S_{m1} and D_1^+ are missing. Hence, the choice of the wave function given by Eq. (11) corresponds to choosing $E(S_{m1})<E(D_1^+)$, as would be expected.

By the same reasoning, we can use $\lambda'=E(D_1^+)$ to find the coefficient a for the wave function given by Eq. (14). In this case

$$C_{\rm eff}=C_{1/2}a^2, \quad (17)$$

which is easily seen to correspond to Eq. (10), with the terms involving states other than S_{m1} and D_1^+ removed. In order to determine the energy eigenvalues λ' when the states are close together, we rewrite Eq. (15) as

$$+y'=\tfrac{1}{2}V^2\gamma_-\alpha_+\sum_k\frac{n_k}{y'-\epsilon_k+E_0}, \quad (18)$$

where

$$y'=E(D_1^+)-\lambda'.$$

For positive E_0, Eq. (17) will always have one positive root, which gives the shift in energy of the D_1^+ state when it is lowest. If we approximate the density of states by a parabolic band starting at $k=0$, then the sum can be converted to an integral from $k=0$ to $k=k_F$ which can be easily evaluated. If $|y+E_0|\ll E_F$, then the resulting equation simplifies to

$$y'=3V^2\left[\frac{1}{2E_F}\ln\frac{4E_F}{y'+E_0}-\frac{1}{E_F}\right]. \quad (18a)$$

For a convenient numerical example, the parameters $3V^2/E_F^2=10^{-4}$, $E_0=0$ give the solution

$$y'=3.6\times10^{-4}E_F.$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The solution of Eq. (13) is quite similar, provided certain approximations are made. The k summation is over all electron states above the Fermi surface, so a simple parabolic density would cause the integral to diverge. This divergence is always stopped by the actual high-momentum cutoff of the interaction potential V (which has here been assumed independent of k). For purposes of simplicity we will assume the density of conduction electron states to be symmetric with respect to the Fermi surface, although this is actually inconsistent with the assumption of a parabolic band. If we change variable to $y=E(S_{m1})-\lambda$, then Eq. (13) becomes

$$y=\tfrac{1}{2}V^2\gamma_-\alpha_+\sum_k\frac{1-n_k}{y+\epsilon_k-E_0}=\tfrac{1}{2}V^2\gamma_-\alpha_+\sum_k\frac{n_k}{y-\epsilon_k-E_0}.$$

For $E_0<0$ (singlet lowest) this always has a positive root, and the result of the summation is the same as Eq. (18a) with the substitutions $y'\Rightarrow y$, $E_0\Rightarrow -E_0$. Hence, in this approximation, the unperturbed crossing point remains unshifted. Using the value of y' calculated from Eqs. (18a), (16) gives

$$C_{\rm eff}=\frac{C_{1/2}}{1+[\Delta\gamma_-\alpha_+/2(y'+E_0)]},\quad E_0>0 \qquad (19a)$$

and

$$C_{\rm eff}=\frac{C_{1/2}\Delta\gamma_-\alpha_+/2(y-E_0)}{1+[\Delta\gamma_-\alpha_+/2(y-E_0)]},\quad E_0<0. \qquad (19b)$$

The only restriction on the size of Δ is that Δ be very much smaller than the "distance" between $E(S_{m1})$ or $E(D_1{}^+)$ and any of the neglected states. There is, however, a limitation on the size of the correction term since $\ln 4E_F/y>1$, Eq. (18a) shows that y, $y'>V^2/E_F\approx\Delta$ (for anything resembling a parabolic band), so the Δ terms never become larger than one. This implies that the effective moment is always larger for $E_0>0$ than for $E_0<0$, in agreement with the previous distinction between magnetic and nonmagnetic cases. In general in this order there will be a sharp discontinuity (but no longer an infinity) in the moment at the boundary between the two regimes.

Equation (18a) will permit positive solutions for y' for slightly negative E_0. These solutions are slightly larger than for small positive values of E_0. However, this does not mean that the corrected energies do not cross. The increase in y' is only logarithmic in E_0 while the unperturbed separation of energies is linear in E_0, and therefore the latter is dominant.

V. LONG-RANGE EFFECT

If the two impurities are separated by many lattice spacings, the d-d exchange interaction V_{12} is negligible. In this case, the s-d scattering will dominate, and the resolvent can be calculated with respect to a simpler set of wave functions than those used above. For the magnetic case ($\epsilon_d<0$; $\epsilon_d+U>0$) the unperturbed ground state consists of single occupancy of the d level of each site. The two electrons can form a spin singlet or triplet, and these two levels will be degenerate in energy (to zero order in V). In order to determine whether the pair is magnetic or nonmagnetic, we must examine the manner in which the s-d interaction removes the degeneracy.

In the unperturbed representation, the triplet and completely empty and filled states are the same as were used previously. The other states are:

State	Energy
$S_1=\lvert\uparrow\downarrow;0\rangle$	$2\epsilon_d+U$
$S_2=\lvert 0;\uparrow\downarrow\rangle$	$2\epsilon_d+U$
$S_m=(2)^{-1/2}(\lvert\uparrow;\downarrow\rangle-\lvert\downarrow;\uparrow\rangle)$	$2\epsilon_d$
$D_1{}^{1,2}=\lvert\uparrow;0\rangle,\lvert 0;\uparrow\rangle$	ϵ_d
$D_3{}^{1,2}=\lvert\uparrow;\uparrow\downarrow\rangle,\lvert\uparrow\downarrow;\uparrow\rangle$	$3\epsilon_d+U$

S_m and T are the degenerate unperturbed ground states. As far as s-d scattering is concerned, the only difference between the S_m and T states is that the T state (because of the exclusion principle) will not allow a scattering from the d to the conduction band and back to the d of the opposite site.

The lowest order terms to show this effect will involve coupling the S_m or T to the S_1 or S_2 via D_1 or D_3 intermediate states. For example, the interaction term for the sequence $S_m\rightarrow D_1{}^1\rightarrow S_1\rightarrow D_1{}^1\rightarrow S_m$ and $T\rightarrow D_1{}^1\rightarrow S_1\rightarrow D_1{}^1\rightarrow T$ is

$$\frac{\tfrac{1}{2}V^4\sqrt{2}\ \mathrm{Tr}(c_{\mathbf{k}''\uparrow}c_{\mathbf{k}''\uparrow}{}^*\pm c_{\mathbf{k}''\downarrow}c_{\mathbf{k}''\downarrow}{}^*)(c_{\mathbf{k}'\uparrow}c_{\mathbf{k}\uparrow}{}^*\pm c_{\mathbf{k}'\downarrow}c_{\mathbf{k}\downarrow}{}^*)\cos(\mathbf{k}+\mathbf{k}'-\mathbf{k}''-\mathbf{k}'')\cdot\mathbf{r}}{(+\epsilon_d-z+\epsilon_{\mathbf{k}}-\epsilon_{\mathbf{k}'}+\epsilon_{\mathbf{k}''})(2\epsilon_d+U-z+\epsilon_{\mathbf{k}}-\epsilon_{\mathbf{k}'})(\epsilon_d-z+\epsilon_{\mathbf{k}})}, \qquad (20)$$

where the upper (+) signs refer to the S_m sequence and the lower (−) signs refer to the T sequence. Taking the trace of the c_k operator product gives

$$[n_{\mathbf{k}'\uparrow}(1-n_{\mathbf{k}\uparrow})+n_{\mathbf{k}'\downarrow}(1-n_{\mathbf{k}\downarrow})]\delta_{\mathbf{k}'\mathbf{k}''}\delta_{\mathbf{k}\mathbf{k}''}+[(1-n_{\mathbf{k}''\uparrow})\pm(1-n_{\mathbf{k}''\downarrow})][(1-n_{\mathbf{k}\uparrow})\pm(1-n_{\mathbf{k}\downarrow})]\times\delta_{\mathbf{k}\mathbf{k}'}\delta_{\mathbf{k}''\mathbf{k}'''}. \qquad (21)$$

The first term of this expression is the same for both S_m and T; hence, it does not help remove the degeneracy. It is also independent of position because the δ function conditions make the argument of the cos in Eq. (20) equal to zero. The second term will give zero in the T state unless the conduction electrons are polarized. We will therefore consider only that part of Eq. (20) which is due to the second term of Eq. (21). If we assume the density of conduction electrons to be isotropic and sum over k', k''', average the directions of k and k'', and replace k'' by k' for simplicity, then we

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

have

$$\frac{V^4}{8r^2}\sqrt{2}\frac{f^2}{2\epsilon_d+U-z},$$

where

$$f=\sum_k \frac{(1-n_k)\sin 2kr}{k(\epsilon_d-z+\epsilon_k)}.$$

(It should be noted that this sum is really no longer discrete because the angle has been averaged out.) There are three other sequences of this class, and they are obtained by substituting D_3 and D_1 in one or both places. The result of adding all four terms together is

$$\tau=\frac{V^4\sqrt{2}}{8r^2}\frac{(f+g)^2}{2\epsilon_d+U-z},$$

where

$$g=\sum_k \frac{n_k \sin 2kr}{k(3\epsilon_d+U-z-\epsilon_k)}.$$

The main contribution to the partition function integral will come from z close to $2\epsilon_d$. Both f and g are real in this region. If we make the approximations

$$k_F r\gg 1, \quad -(r\epsilon_d m/hk_F)\gg 1,$$

and neglect terms which are exponentially small in these quantities, then an asymptotic approximation gives

$$f=\frac{\rho_s \cos 2k_F r}{rm(\epsilon_d-z)}, \quad g=\frac{\rho_s \cos 2k_F r}{rm(3\epsilon_d+U-z)}.$$

Now τ only occurs for S_{m1}, and for $z\approx 2\epsilon_d$ we find $\tau>0$. Hence, the S_{m1} is lowered with respect to the T state.

VI. SIMULTANEOUS CONSIDERATION OF *d-d* EXCHANGE AND BAND SCATTERING

The above calculations seem to indicate that the singlet (S_{m1}) is always lower than the triplet (T). In order to show that this is not due to our perturbation treatment for the band scattering, we have performed the diagonalization procedure of Sec. II, with the additional inclusion of all those states coupled by V. (This will be exact in the two-electron manifold.) The trial function consists of the four possible states with two d electrons with opposite spins ($d_{1\uparrow}{}^* d_{2\downarrow}{}^*$, $d_{1\downarrow}{}^* d_{2\uparrow}{}^*$, $d_{1\uparrow}{}^* d_{1\downarrow}{}^*$, $d_{2\uparrow}{}^* d_{2\downarrow}{}^*$), the four possible states with one electron and one conduction electron ($d_{1\uparrow}{}^* c_{k\downarrow}$, $d_{2\uparrow}{}^* c_{k\downarrow}{}^*$, $d_{1\downarrow}{}^* c_{k\uparrow}{}^*$, $d_{2\downarrow}{}^* c_{k\uparrow}{}^*$, with the conduction electron averaged over k states as in Sec. IV), and finally the four possible states with three d electrons and one conduction hole ($d_{1\uparrow}{}^* d_{2\uparrow}{}^* d_{2\downarrow}{}^* c_{k\downarrow}$, $d_{2\uparrow}{}^* d_{1\uparrow}{}^* d_{1\downarrow}{}^* c_{k\downarrow}$, $d_{1\downarrow}{}^* d_{2\uparrow}{}^* d_{2\downarrow}{}^* c_{k\uparrow}$, $d_{2\downarrow}{}^* d_{1\uparrow}{}^* d_{1\downarrow}{}^* c_{k\uparrow}$, with the conduction holes averaged over k). Using the method of Sec. IV we can diagonalize the energy by means of the equations obtained from the energy by differentiating with respect to each of the twelve coefficients of the trial states (remembering that eight of these coefficients depend upon k). The solutions are rather cumbersome, but if we assume $k_F r\gg 1$, then the four states with two d electrons combine in a manner similar to that found in Sec. II. The wave functions and energy eigenvalues have the same form as S_p, S_{m1}, S_{m2}, T ($S_z=0$) with the modifications

$$V_{12}\Rightarrow V_{12}'=V_{12}\left[1+V^2\sum_k \frac{1-n_k}{(\epsilon_d+\epsilon_k-\lambda)^2-W^2} + V^2\sum_k \frac{n_k}{(3\epsilon_d+U-\epsilon_k-\lambda)-W^2}\right]$$

and

$$\epsilon_d\Rightarrow \epsilon_d'=\epsilon_d-V^2\sum_k \frac{(\epsilon_d+\epsilon_k-\lambda)(1-n_k)}{(\epsilon_k+\epsilon_k-\lambda)^2-W^2} - V^2\sum_k \frac{(3\epsilon_d+U-\lambda)n_k}{(3\epsilon_d+U-\epsilon_k-\lambda)^2-W^2}.$$

As in Sec. IV, λ is simply the corrected energy of the state under consideration. Since these corrections have the same form for both S_{m1} and T, it is apparent that they have no effect on the previous conclusion that $E(S_{m1})<E(T)$.

VII. CONCLUSION

The calculations of this paper indicate that in perturbation theory neither the *d-d* exchange, the *s-d* scattering, nor any combination of the two will produce a parallel alignment of a pair of localized moments. The analysis does, however, show that the pair can show a sizable magnetic moment provided that the *d-d* exchange is such that $E(D_1{}^{\pm})<E(S_{m1})$. The conditions required for this relation are similar to those required by Alexander and Anderson[3] for parallel alignment. This suggests that the two methods may be equivalent, even though the representation of Alexander and Anderson[3] does not characterize the parallel alignment as either doublet or triplet.

Low-Temperature Magnetoresistance in Magnesium and Aluminum Containing Small Concentrations of Manganese or Iron*

F. T. HEDGCOCK AND Y. MUTO†
The Franklin Institute Laboratories for Research and Development, Philadelphia, Pennsylvania
(Received 20 January 1964)

Magnetoresistance measurements in magnetic fields up to 21 kOe have been made on Mg-Mn, Mg-Cd, Mg-Al, Al-Mn, and Al-Fe alloys in the temperature region of liquid helium. Magnesium alloys containing more than 0.1-at.% Mn which exhibit a resistance maximum and minimum in zero field, show a negative magnetoresistance, whereas the more dilute samples (0.001–0.1 at. % Mn) show a positive magnetoresistance, the magnitude of which decreases with decreasing temperature. The magnesium alloys containing non-transition element impurities, as well as the aluminum alloys containing transition metal impurities, are found to obey Kohler's rule. From an analysis of these data it is found that the magnetoresistivity of a dilute alloy of magnesium containing manganese, can be considered as the sum of a normal positive magnetoresistivity (obeying Kohler's rule) and an anomalous term which is negative in sign, does not obey Kohler's rule and is presumably due to a magnetic scattering of the conduction electrons. Using values of the *s-d* exchange integral and the Coulomb scattering integral derived from an analysis of the zero-field resistivity permits an explanation of the magnetoresistivity based on Kasuya's theory, at temperatures near the Néel point.

1. INTRODUCTION

NUMEROUS studies made on dilute monovalent and divalent[1,2] metals containing paramagnetic impurities have indicated a negative magnetoresistance at low temperature when the alloy exhibits both a low temperature resistance minimum and maximum. Recent studies on the[3] Cu-Fe and[4] Zn-Mn known to exhibit only a minimum down to the lowest temperatures available indicate the presence of a negative magnetoresistance in the more concentrated samples. A magnesium alloy containing small concentrations of manganese has been shown[5] to exhibit deviations from the Kohler rule, but no conclusive evidence for a negative magnetoresistance was found even at the lowest temperature (1.3°K) and the highest magnetic field available (25 kOe). Magnetoresistance studies on dilute aluminum alloys containing either manganese or iron have been carried out at liquid-helium temperatures at magnetic fields of[6] 1.5 kOe and no anomalies were found. In the present paper we wish to report some magnetoresistance studies on Mg alloys known to exhibit both a resistance minimum and a maximum[7] as well as measurements on normal magnesium alloys exhibiting no resistance anomalies. Also included in the present work are studies on aluminum-manganese and aluminum-iron alloys where the magnetoresistivity is studied to fields of 21 kOe.

2. SPECIMEN PREPARATION AND EXPERIMENTAL METHOD

The dilute Mg-Mn, Al-Mn and Al-Fe alloys used in the present investigation are the same as those used earlier in the studies of the electrical and magnetic properties of these systems.[7–9] The high-concentration Mg-Mn alloys were prepared by quenching from near the melting point after the samples had received a high-temperature homogenizing anneal. The manganese concentration of each Mg alloy was estimated from the

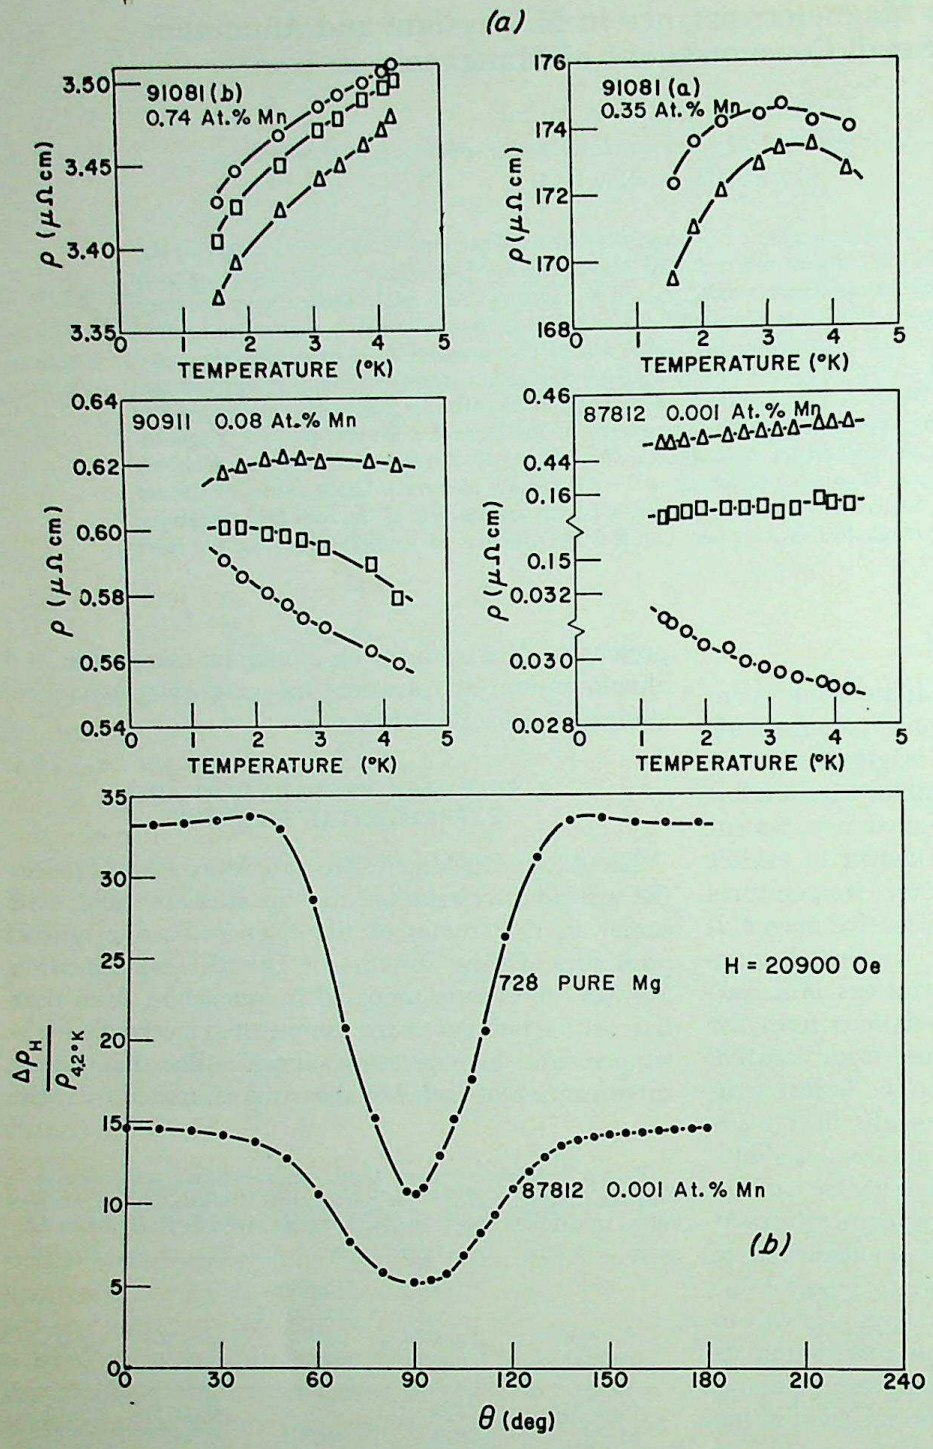

FIG. 1. (a) Resistivity of some Mg-Mn alloys as a function of temperature in a constant magnetic field. ○: 0 kOe; □: 9.93 kOe; △: 20.9 kOe. (b) Anisotropy in the magnetoresistivity at 4.2°K for pure Mg and the most dilute Mg-Mn samples. The angle axis was selected to obtain agreement in the minimum value of $\Delta\rho_{H\max}/\rho_{4.2°K}$ for both samples. $\Delta\rho_{H\max}$ means $\Delta\rho$ at the maximum field studied (20.9 kOe).

smoothed graph of resistance ratio versus nominal composition.[10] The concentration and resistivity of the Mg-Al and Mg-Cd alloys were derived from the earlier data reported by Salkovitz[11] *et al.*[12] The concentration of manganese or iron in the aluminum alloys is derived from the spectroscopic analysis. Table I contains values of the resistance ratio and resistivity for the alloys studied. The resistance samples were in the form of rolled strips (approximately $10\times0.3\times0.03$ cm); the contacts in the form of knife edges were pressed into place on a bakelite former containing the sample. A current-potential method was used for the resistance measurements with a galvanometer amplifier to read the voltages. The sensitivity of the amplifier was better than 3×10^{-9} V/mm deflection. The galvanometer and current stability did not result in more than a 2% change in calibration during any one magnetoresistance run. Since the magnetoresistance of the more highly concentrated samples was small while the zero-field

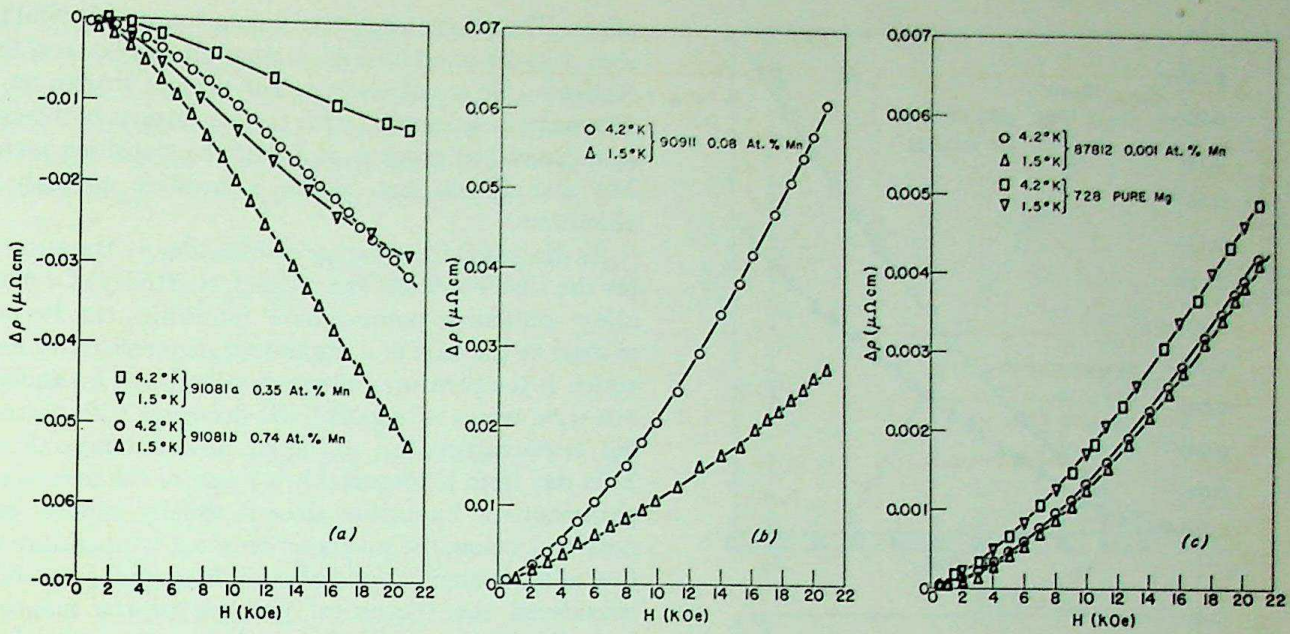

FIG. 2. $\Delta\rho$ as a function of the magnetic field strength for a number of Mg-Mn alloys: (a) for samples 91081(a) and (b); (b) for the sample 90911; (c) for samples 87812 and 728 (pure Mg).

resistance was comparatively high, the magnetoresistance measurements on these samples was accomplished by suppressing the zero-field sample voltage with the aid of a Leeds and Northrup Type K-2 potentiometer. A Harvey Wells Corporation electromagnet was used which produced fields of approximately 21 kOe in a gap of 1.25 in. with a stability of magnet current of one part in 10^5 at midcurrent values. All measurements were made at 4.2°K or lower by pumping on liquid helium. The vapor pressure of the bath was controlled by a Cartesian manostat.

3. EXPERIMENTAL RESULTS

Figure 1(a) shows the resistivity of some of the Mg-Mn alloys as a function of temperature in a constant magnetic field and it can be noticed that all of the samples exhibit anomalies in the temperature-dependent resistivity. At the maximum field available samples 87812 and 90911 exhibit a positive magnetoresistance, while both samples exhibit a resistance minimum. Samples 91081(a) and (b) exhibit an absolute decrease in the resistivity on the application of a magnetic field, the magnitude of the decrease increasing with magnetic field strength in the temperature region studied. These samples exhibit resistance maxima (and minima) in agreement with earlier reports.[7]

There is a marked anisotropy in the magnetoresistivity for Mg samples which is presumably due to preferred orientation induced by cold working the samples. The magnitude of the anisotropy can be seen for samples 728 and 87812 shown in Fig. 1(b). The maximum magnetoresistance values were used, and at this value very little angular dependence could be noted in the relative magnetoresistivity. For more concentrated samples, the anisotropy is so small that no significant difference appears for any chosen direction.

Figure 2 shows the magnetoresistance as a function of magnetic field strength for a number of specimens. As seen in Fig. 2(a) there is presumably sufficient magnetic scattering in the alloys to make the sign of the magnetoresistivity totally negative for samples 91081(a) and (b). Samples 90911 in Fig. 2(b) and sample 87812 in Fig. 2(c) show that $\Delta\rho$ is smaller at the lower temperature, while no such temperature dependence is observed for a pure magnesium sample exhibiting no anomalous behavior in the zero field resistivity. [See sample 728, Fig. 2(c).] It can therefore be suggested that there is a negative magnetoresistivity component in the more dilute Mg-Mn samples. Figures 3(a) and 3(b) show $\Delta\rho/\rho_{4.2°K}$ as a function of magnetic field strength for a sample of Mg-Cd and Mg-Al, respectively. As would be expected, $\Delta\rho/\rho_{4.2°K}$ increases with increase in magnetic field, and the magnitude of the change at fixed field decreases with impurity concentration increase (i.e., normal impurity scattering). Figures 4(a) and 4(b) show $\Delta\rho/\rho_T$ as a function of magnetic field for an Al-Fe and Al-Mn sample, where it can be seen that there is no temperature dependence to the magnetoresistance in these alloys.

4. DISCUSSION

The change in resistivity $\Delta\rho$ in a magnetic field H is given by the Kohler rule as

$$\Delta\rho/\rho_T = F(H\rho_\theta/\rho_T), \qquad (1)$$

where[13] ρ_θ is the resistivity at the Debye temperature θ

[13] As there is some uncertainty in the value of θ to be used in alloys, most workers approximate by using the value of resistivity at the ice point and we will follow the same approximation.

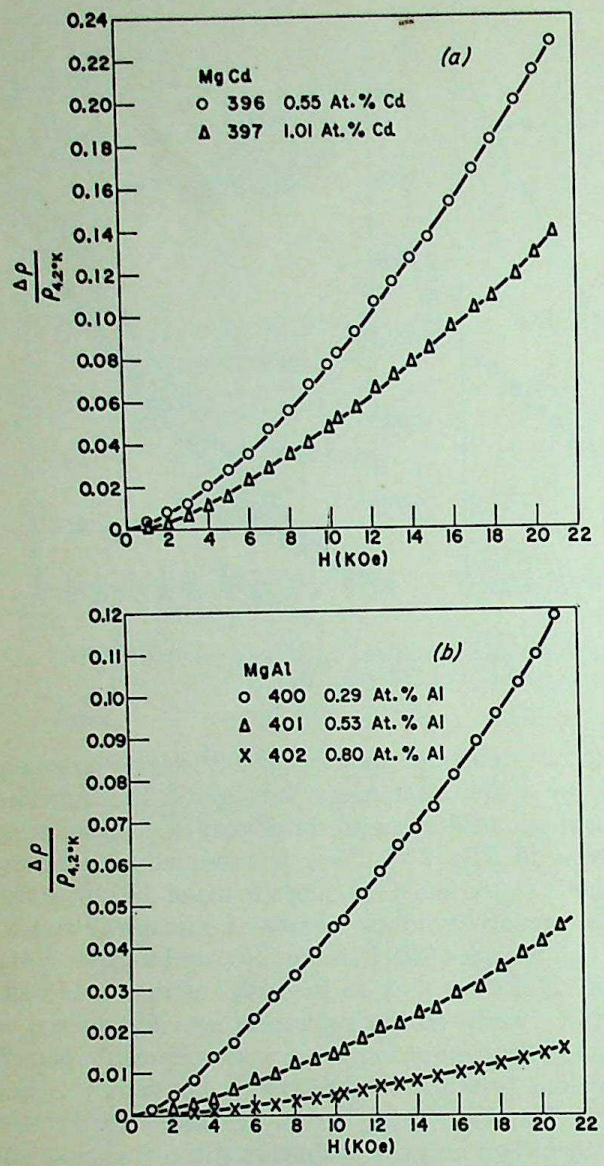

FIG. 3. $\Delta\rho/\rho_{4.2°K}$ as a function of magnetic field strength: (a) Mg-Cd and (b) Mg-Al alloys.

and ρ_T the resistivity at temperature T, the functional form of F being unspecified. Kohler's graph for some of the Mg and Al alloys is shown in Figs. 5 and 6, where it can be seen that all of the alloys presented obey the Kohler's rule. It can be noticed that the deviation from Kohler's rule is larger for the Mg-Al alloys than for the Mg-Cd alloys, and it could be speculated that this is a result of the difference in valence between solute and solvent in the case of the Mg-Al alloys. In Fig. 5 is the magnetoresistivity data at 4.2°K for the more dilute Mg-Mn alloys. It can be seen that Kohler's rule is obeyed which is in agreement with the previous conclusions of Webber,[5] Yntema,[14] and Thomas and Mendoza.[6] As we will see later this Kohler behavior is a result of the fact that although there is a negative component in the magnetoresistivity of these alloys it is much smaller than the normal positive magnetoresistivity of these alloys. The magnetoresistivity data for sample 90911 is shown as an insert in Fig. 5, where it can be seen that Kohler's rule is not obeyed. The present studies on Al alloys are in agreement with the conclusions of Thomas *et al.*,[6] and Hedgcock *et al.*,[8] that the transition metals Mn and Fe do not induce a resistive anomaly in aluminum.

As discussed in an earlier publication by the authors[3] for the Cu-Fe system, the magnetoresistivity of a dilute alloy containing paramagnetic impurities can be considered as the sum of a normal magnetoresistivity term which is temperature independent (ρ_n) and an anomalous term which is negative and decreases with decreasing temperature (ρ_s) at liquid helium temperatures. This last term is presumably a result of the presence of paramagnetic impurities since it usually appears only near and below the magnetic ordering temperature for the alloy system. Yosida[15] and Kasuya[16] have both considered the theoretical problem of the magnetic interaction between conduction electrons and localized magnetic ions where an *s-d* exchange interaction is assumed to produce a molecular field. Below a magnetic ordering temperature (usually antiferromagnetic in nature) theory predicts a monotonic decrease of resis-

tance as the temperature is lowered. Both theories predict a negative magnetoresistance which is proportional to the square of the magnetization at low magnetic field strengths. Neglecting a small term in Kasuya's expressions for the magnetoresistivity under various field and temperature conditions, we can write

$$H=0,\ T=0 \quad \rho_0=\frac{3\pi}{2}\frac{m^*}{\hbar\zeta}\frac{C}{Ne^2}[A^2+(g-1)^2j^2J^2], \tag{2}$$

$$H=0,\ T\geq T_N \quad \rho_{T_N}=\frac{3\pi}{2}\frac{m^*}{\hbar\zeta}\frac{C}{Ne^2}\times[A^2+(g-1)^2j(j+1)J^2], \tag{3}$$

$$H\neq 0,\ T\neq 0 \quad \rho=\frac{3\pi}{2}\frac{m^*}{\hbar\zeta}\frac{C}{Ne^2}\frac{[A^2+\langle j^2\rangle_{\rm av}J^2]^2}{A^2+\left(\langle j_z^2\rangle_{\rm av}-\bar{j}_z\frac{2xe^x}{(e^x-1)^2}\right)J^2}, \tag{4}$$

where m^* and e are the electron effective mass and charge, respectively, ζ is the Fermi energy, C is the concentration of paramagnetic ions, N is the number of atoms/cm^3, J is the s-d exchange interaction constant, A is the Coulomb interaction constant, $x=g\mu_BH/kT$, $\bar{j}_z$ is the average z component of the angular momentum j of the paramagnetic ion, and $\langle\bar{j}_z^2\rangle_{\rm av}$ is the average of the square of the angular momentum of the paramagnetic ion. For the method of finding these averages, the reader is referred to the original publication of Kasuya.[16] Using a simple molecular-field model, $H=H_0$ when $H_{\rm app}=0$, and if H_0 is zero, then it has the value $H_{\rm app}$ in the presence of an external field. Collings and Hedgcock[9] have shown through electron spin resonance and susceptibility studies that an antiferromagnetic transition occurs in the Mg-Mn system in the region of the resistance maximum. If one neglects the presence of the resistance minimum in these alloys and assumes the temperature of the maximum to be the Néel temperature,[17] we can use Eqs. (2) and (3) to calculate A and

average	0.48	2.78	5.80	

[17] Magnetic studies on these alloys (Ref. 9) have shown that only in the most concentrated sample is there any evidence for a Néel temperature but there are deviations from Curie's law in the region of the resistance anomaly for all of the Mg-Mn sample studies. Whether the temperature of the resistance maximum occurs at what one normally considers the Néel temperature is certainly still an open question theoretically. [See M. Baiyln, Westinghouse Research Report 029-B000-P1, 1961 (unpublished).]

J. This has been done for a number of alloys and the resulting values of A and J are listed in Table II. It can be seen that the values so derived for the various alloys are independent of concentration and result in an average value of 0.48×10^{-12} erg for J and 2.78×10^{-12} erg for A. The manganese ion is assumed to be in an S state with the value of the effective magneton number as derived from susceptibility studies ($S=2$). The free ion value of J derived for the Mn^{+} ion would yield a value of 0.35×10^{-12} erg, whereas a value of J for the Cu-Mn system derived from the experimental results is 0.67×10^{-12} erg.

Using the values of A and J derived from the zero-field results and expression (4) of Kasuya, it is possible to calculate the magnetoresistance as a function of magnetic field. Shown in Fig. 7(a) is the result of such a calculation for a sample 91081(a) and (b) at the temperature of 4.2°K. The difference between the calculated and experimental curves can be assumed due to the positive normal magnetoresistance component ρ_n. If the difference between the theoretical and experimental curves is in fact equal to ρ_n, then the difference should obey the Kohler rule. This difference is shown in Fig. 5 where as good a fit to the Kohler rule is found as for alloys containing nontransition metal impurities. Figure 7(b) shows the same calculation done at 1.5°K. The solid curve corresponds to that calculated from Eq. (4) and the dashed curve after allowance has been made for ρ_n, the normal impurity scattering discussed above. As can be seen, the agreement between experiment and theory at this temperature is not good. If one suggests a cooperative magnetic interaction and a resulting internal field, H_0 will shift the zero on the field axis but will not alter the magnitude of the magnetoresistance. Only by altering A/J could agreement with experiment for a particular magnetic field be found, but it is unlikely that these constants should be a function of temperature or magnetic field—certainly no theoretical treatment suggests that they should be.[18] It therefore seems that some essential feature is lacking in the Kasuya theory for the temperature dependence of the magnetoresistance in metal alloys containing transition metal impurities.

Although there is no adequate theory to explain the resistance minimum, it is interesting to apply Kasuya's expression for the magnetoresistivity in those alloys exhibiting a resistance minimum only [Eq. (4)]. For example, by assuming the same value of J and A as for the more concentrated alloys exhibiting a maximum, an estimate of $\Delta\rho$ at maximum magnetic field for sample 90911 yields $\Delta\rho_s=-2.4\times10^{-8}$ Ω-cm at 4.2°K. This can be compared with the experimentally observed value of $\Delta\rho=6.1\times10^{-8}$ Ω-cm. Therefore, the normal magnetoresistivity term, the difference of these two values, equals 8.5×10^{-8} Ω-cm. Then $\Delta\rho_n/\rho_{4.2°K}=0.152$ for $H\rho_{273}/\rho_{4.2°K}=149$ kOe. This point is shown as A in Fig. 5, giving better agreement to the initial Kohler curve plotted for this alloy. If this improvement in the fit is a result of the influence of $\Delta\rho_s$, then it could be speculated that the magnetoresistance of alloys exhibiting a minimum will be negative[19] when A/J is small and the concentration relatively large and becomes positive when A/J is large and the concentration of paramagnetic ions is smaller.

5. CONCLUSIONS

(1) From the temperature dependence of the electrical resistivity of concentrated Mg-Mn alloys in zero magnetic field a value of the s-d exchange integral J and the Coulomb integral Q of 0.48×10^{-12} erg and 2.78×10^{-12} erg, respectively, are found which are independent of manganese concentration up to the solid solubility limit.

(2) For Mg-Mn alloys exhibiting both a resistance

[18] Yosida pointed out that experimental agreement with his theory worsened as the temperature was lowered below the Néel point. Kasuya remarked on the discrepancy and suggested the magnetically ordered states should be represented by some sort of collective spin mode at sufficiently low temperatures.

[19] A total negative magnetoresistivity has been observed in Cu-Fe, Cu-Mn and Zn-Mn alloys exhibiting only a resistive minimum. (See Refs. 3 and 4.)

minimum and maximum the total magnetoresistance is negative. This magnetoresistance can be separated into a negative (ρ_s) and positive (ρ_n) component. The spin component ρ_s can be explained using the same J and A values as derived above at temperatures near the Néel temperature. The normal component (ρ_n) is found to obey Kohler's rule. The observed temperature dependence of the negative component (ρ_s) does not follow from the existing theory.

(3) For the more dilute Mg-Mn alloys exhibiting only a resistance minimum, there appears to be a negative magnetoresistivity component again requiring the same A and J values as above. The positive magnetoresistance component obeys Kohler's rule.

(4) Magnesium containing nontransition impurities follow Kohler's rule as do the alloys of aluminum containing transition metal impurities.

F-Band Shape in the CsCl Structure Under Pressure*†

D. B. FITCHEN‡
Department of Physics, University of Illinois, Urbana, Illinois
(Received 24 January 1964)

Color centers have been formed by x irradiation of RbCl above the polymorphic transition pressure, and the shape of the new F band at 509 mμ in this CsCl-type structure has been examined under a pressure of 6200 atm at liquid-helium temperature. The band shows no evidence of the multiplet structure observed in the cesium halides, thus indicating that the lattice structure is not responsible for this effect. The F band in CsCl has also been formed and studied under pressure at helium temperature, and the triplet components show the usual relative intensity and the characteristic F-band shift. No evidence of K' bands was observed for these hydrostatic pressures.

INTRODUCTION

RECENT studies of color centers in CsCl and CsBr[1–3] revealed structure on the principal absorption band, in contrast to the usual F band in alkali halides with the NaCl-type lattice. This structure, which Rabin and Schulman[2] decomposed into three components at liquid-helium temperature, appears to be identical for centers formed by x irradiation or additive coloring, is unaffected by bleaching or heat treatment, and is not sensitive to sample purity. It therefore seems reasonable to associate these multiplets with a single electron-excess center, presumably an F center composed of an electron bound to a negative-ion vacancy. Rabin and Schulman[2] first proposed that if these components are all due to one center, then they must represent a splitting of the excited F state by a crystal-field effect peculiar to the CsCl-type lattice, or a splitting caused by the cesium ion itself.

The present work was undertaken to determine the influence of crystal structure by studying the F band formed in the pressure-induced simple cubic phase of a normally face-centered cubic alkali halide. RbCl transforms from the NaCl lattice structure to the CsCl lattice structure at about 5000–6000 atm. On the basis of a Mollwo relation between peak position and lattice constant for other CsCl-type crystals, one expects the F center to appear at about 520 mμ in the high-pressure form. Jacobs[4] looked for this peak in RbCl crystals x rayed or additively colored at atmospheric pressure prior to the structure transformation, but was unable to detect any new center. Drickamer *et al.*[5,6] found a new band, which they called the K' band, which replaced the F band in simple cubic phases at very high pressures and room temperature.

With the apparatus described below, it is possible to transform the crystal first and then form the CsCl-type centers by x raying under pressure at room or low temperatures. In particular it is possible to form

and study the new F center at helium temperature to investigate whether it has the triplet structure observed in the cesium halides.

In addition, the F band was formed in CsCl under pressure at helium temperature to verify that the triplet components grow in the same ratio and exhibit the characteristic F-band pressure shift.

EXPERIMENTAL PROCEDURES

The four-window pressure cell and cryostat used in this experiment have been described in detail elsewhere.[7] Color centers were produced at high pressure and low temperature by irradiating the sample with 50-kV x rays through a beryllium window in the pressure cell. Optical absorption spectra were measured at right angles through sapphire windows, using a Beckman DU spectrophotometer. The sample was suitably masked to measure only a region of nearly uniform coloration, and the radiation-induced coloration was determined by subtracting the pre-irradiation spectrum from those measured at later times. Helium gas was used to apply hydrostatic pressure in the range 0–8000 atm, the pressure being determined with a manganin gauge except at temperatures where the helium solidified, when thermodynamic PVT data for solid helium were used to estimate[7] the pressure in the cell.

RESULTS AND DISCUSSION

a. RbCl

Two runs were made using samples 0.43 and 0.27 mm thick cleaved from a piece of "pure" Korth RbCl. Pressure was applied at room temperature at a rate of about 300 atm per min, and the transition pressure was detected by monitoring the optical transmission of the sample. At about 7300 atm, the transmission dropped abruptly to 0.17% in the first case and 1% in the second case. These values correspond to an optical density of roughly 80 cm^{-1}.

The crystallographic aspects of this type of structure transformation, which achieves a 15% reduction in volume,[8] have been discussed by Buerger[9] and applied to the phenomenon of opacity by Jacobs.[4] The transformation proceeds from a large number of nucleation centers giving rise to many mismatched grains. Light is scattered at the boundaries of these microscopic regions causing the observed opacity.

The transition in RbCl has been observed at 5700 atm by Bridgman,[8] 6000 atm by Pierce,[10] and 6500 atm by Jacobs, who also used the opacity as an indicator. The higher transition pressure seen in this case could be due to three causes. In another study of the polymorphic transformation in RbI with helium gas as a pressure fluid, Jacobs[11] found that the initial transformation for a virgin crystal occurred at about 10% higher pressures with the purely hydrostatic helium pressure medium than for liquid media. Apparently, the slight shear stresses due to viscosity of the liquid help to initiate the local shear involved in the transformation. A second reason might be hysteresis during the relatively rapid pressure rise, since Pierce found that the initial transformation required nearly 45 min to go to completion. However, no change in transmission was seen until the sudden abrupt and complete change. Finally, the crystals of less than "atomic-weight purity" usually have a higher transition pressure, but Pierce observed the transition at a lower pressure in Korth RbCl which had been doped with additional divalent impurity. Therefore, the first explanation seems the most probable here.

After the crystal had been transformed, it was cooled to helium temperature and x rayed under pressure. A preliminary run on the coloration of Korth RbCl at helium temperature below the transformation pressure had shown that the normal F band grows very slowly at about 590 mμ. In the present runs, the principal absorption grew slowly at about 510 mμ. Because of the very high background absorption, only the range of 420–620 mμ could be measured with any certainty, and readings outside this range fluctuated erratically. No systematic growth of any other major center was detected.

The shape of the new center was measured carefully twice in each run, and no indication of structure appeared, as shown in Fig. 1.

In the first run, a small peak was seen at 600 mμ, presumably due to NaCl-type F centers formed in portions of the crystal which had not completely transformed. When pressure was released slowly at nitrogen temperature, very marked hysteresis was observed and the new centers were unaffected to about 3500 atm, at which point they disappeared and the NaCl-type F center appeared with almost identical magnitude at 600 mμ. In the second run, the crystal was allowed to warm to room temperature under pressure and was then x rayed again. Instead of growth, the irradiation appeared to remove most of the residual centers which remained after warming. Similar hysteresis occurred when releasing pressure at room temperature. The optical density only began to decrease at about 4500 atm. At atmospheric pressure, the transmission had returned to about 20% of its initial value. The samples appeared milky and were highly strained but still intact.

The parameters of the new center as measured at various pressures and temperatures are listed in Table I.

While the designation of this new band as the F band is still tentative, the following evidence supports

TABLE I. Parameters of the principal absorption band in transformed RbCl.

Temperature	Pressure (atm)	λ_m (mμ)	H (eV)
Helium	6400	509	0.22±0.01
Nitrogen	5230	517	0.25±0.01
Room	7370	514	0.35±0.03

it. The band appears to be the principal absorption center formed and has a shape and half-width similar to the F center in the low-pressure form. The peak of this new center shifts with temperature and pressure in the same manner as the F center, and its half-width increases with temperature in the same way. In the first run, it was possible to convert these centers directly to the normal F centers by returning to the low-pressure structure at nitrogen temperature. Finally, the new band appears at just the position predicted by a Mollwo-like relation for the CsCl structure, $\lambda_m = K(d)^n$, where d is the interionic distance. Using values of λ_m and d at low temperature for CsCl and CsBr,[2] and the value of d for the high-pressure form of RbCl from Bridgman's density measurements,[8] the new F center should appear at 514 mμ, in good agreement with experiment.

The lack of structure on this new F band in RbCl indicates that the triplet structure observed for CsCl and CsBr at liquid-helium temperature is not caused by a crystal-field effect indigenous to the CsCl-type lattice. Hughes and Rabin[12] have confirmed this result by their observation of clearly resolved peaks in the principal absorption band of CsF, the only cesium halide having the NaCl-type lattice. Thus the cause of the splitting seems to be the cesium ion itself.

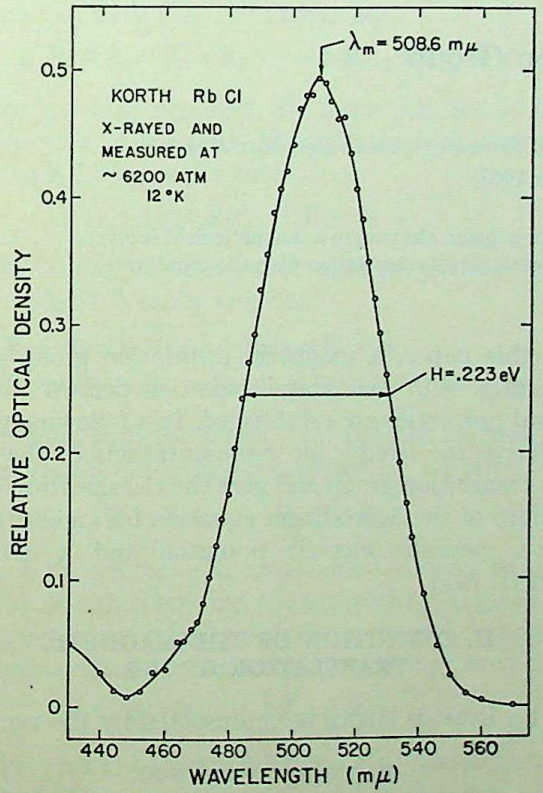

FIG. 1. Shape of the F band formed in the high-pressure CsCl phase of RbCl. The curve shows the difference in optical density measured before and after x irradiation for 220 min at this temperature and pressure for a sample 0.27 mm thick.

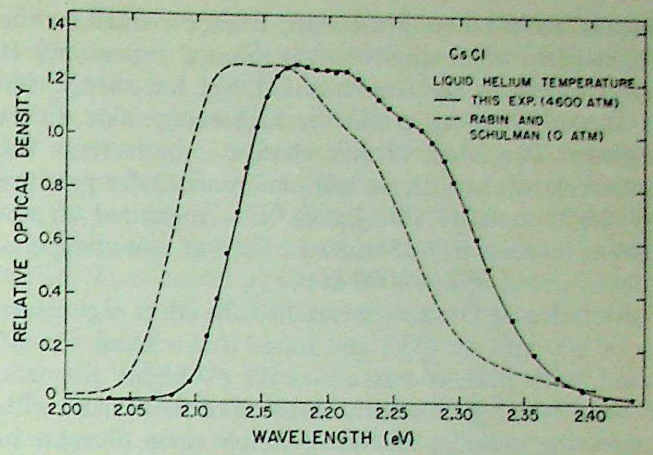

FIG. 2. Pressure shift of the F band in CsCl. The solid curve is for centers formed at this temperature and pressure after x irradiation for 15 min with a sample 0.84 mm thick. The comparison curve is taken from Ref. 2.

Speculation has centered on relativistic effects which would be appreciable only for the cesium halides. A calculation by Suffczynski[13] of the spin-orbit splitting for a localized excited state in a cesium halide gave a result orders of magnitude smaller than the observed effect. Recently, Knox[14] has proposed that a spin-orbit type splitting of the conduction band might be responsible. Calculations[15,16] of the other relativistic effects on band structure for heavy ions suggest that these might also contribute for cesium.

b. CsCl

A subsidiary experiment was performed to test whether the three components of the principal absorption band observed in CsCl at helium temperature would exhibit the characteristic pressure shift of the F band.

A freshly cut and polished platelet of Semi-Elements CsCl was x rayed and measured at approximately 4600 atm and 11°K. Figure 2 shows one of the measured spectra with a zero-pressure spectrum of Rabin and Schulman[2] normalized to the same peak height for comparison. The component structure is clearly visible and appears essentially unchanged after a pressure shift of $\Delta E/E \simeq 0.021$. (This shift is within 4% of

Jacobs' room-temperature shift[4] when corrected for the change in compressibility with thermal expansion.) If the two curves are superimposed, the low-energy side is almost identical, while the high-energy side differs slightly. The effect of this change is to increase the apparent total width at half-maximum under pressure by 3.5% to 0.017 eV. Jacobs[4] also measured an apparent increase in half-width in CsCl at room temperature of about 5% in 4000 atm.

Maisch and Drickamer[5] studied the effect of pressure to 50 000 atm on CsCl and found a new band, the K' band, with peak energy about 0.1 eV higher than the F band which grows at the expense of the F band with increasing pressure and is reversible upon decrease in pressure. It is thus possible that the high-energy component of the triplet is related to this K' band and is increasing in relative importance with pressure. However, no such K' band was seen in this range of hydrostatic pressures either for RbCl above or below its transition pressure, or for KBr, in which they observed a prominent K' band at considerably higher pressures. Either the K' band is not observable in the present range of pressures, or its appearance in Drickamer's experiments is due to shear and pressure inhomogeneities in his apparatus which are not present in our gas system.

SUMMARY

Using a novel technique a new absorption band has been formed by x irradiation of RbCl above its polymorphic transition pressure. The position, width, and temperature and pressure dependence of this band support its designation as the new F band in this CsCl-type phase. The band could be converted to the normal F band by reversing the transition at low temperatures. The shape of this new band has been examined under pressure at liquid-helium temperature, and shows no evidence of the multiplet structure observed in the cesium halides, thus indicating that the lattice structure is not responsible for this effect.

The pressure measurements on CsCl prove that for still another way of forming and observing the principal band, the triplet components all appear to be due to the F center.

Magnetic Translation Group*

J. ZAK

National Magnet Laboratory,† Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received 6 December 1963)

In this paper a group-theoretical approach to the problem of a Bloch electron in a magnetic field is given. A magnetic translation group is defined and its properties, in particular its connection with the usual translation group, are established.

I. INTRODUCTION

THE translation symmetry of the Hamiltonian for an electron in a periodic potential leads to the classification of the solutions of the corresponding problem by means of a wave vector $\mathbf{k}$ and to the possibility of introducing Bloch functions. When a constant magnetic field is also present, the Hamiltonian is no longer invariant under the translation group. However, operators may be defined which commute with the Hamiltonian of a Bloch electron in a magnetic field.[1,2]

In this paper, a magnetic translation group which commutes with the Hamiltonian is defined and its general properties are established. In a following paper, we derive the irreducible representations of the magnetic translation group and give the classification of the solutions of the Schrödinger equation for an electron in both a periodic electric potential and a constant magnetic field.

II. DEFINITION OF THE MAGNETIC TRANSLATION GROUP

Let a Bravais lattice be represented by the vectors

$$\mathbf{R}_n = n_1\mathbf{a}_1 + n_2\mathbf{a}_2 + n_3\mathbf{a}_3 \quad (1)$$

(where $\mathbf{a}_1$, $\mathbf{a}_2$, $\mathbf{a}_3$ are the unit cell vectors and n_1, n_2, n_3 are integers), each of which defines a point in the Bravais lattice. Let us define a path joining the origin O with the

Digitized by Arya Samaj Foundation Chennai and eGangotri

point defined by $\mathbf{R}_n$. We start from point O and move in a direction of another lattice point, say, given by $\mathbf{R}_1$; from $\mathbf{R}_1$ we move in a direction, say, $\mathbf{R}_2$ to the point given by $\mathbf{R}_1+\mathbf{R}_2$ and so on until we achieve the point given by $\mathbf{R}_n$. Clearly, the point given by $\mathbf{R}_n$ can be achieved by different choices of vectors $\mathbf{R}_1$, $\mathbf{R}_2$ and so on. Let *one* of the possibilities be given by the vectors $\mathbf{R}_1, \mathbf{R}_2, \cdots, \mathbf{R}_i$. We denote the described path by the symbol

$$|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i). \tag{2}$$

According to (2) we achieved the point of $\mathbf{R}_n$ by means of i steps. Also,

$$\mathbf{R}_n=\mathbf{R}_1+\mathbf{R}_2+\cdots+\mathbf{R}_i. \tag{2a}$$

In a similar way, we could choose another set of vectors satisfying (2a) and define a different path joining O with the point defined by $\mathbf{R}_n$.

Let us now define an operator which depends on both the vector $\mathbf{R}_n$ and the path joining the point O to the point defined by $\mathbf{R}_n$:

$$\begin{aligned}\tau(\mathbf{R}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)&\\ =\exp\{(i/\hbar)\mathbf{R}_n\cdot[\mathbf{p}+(e/c)\mathbf{A}]\}&\\ \times\exp\{(i/2)[\mathbf{R}_1\times\mathbf{R}_2+\mathbf{R}_1\times\mathbf{R}_3+\cdots&\\ +\mathbf{R}_{i-1}\times\mathbf{R}_i]\cdot\mathbf{h}\},&\end{aligned} \tag{3}$$

where $\mathbf{h}=e\mathbf{H}/\hbar c$, $\mathbf{H}$ is the magnetic field, $\mathbf{A}$ is the vector potential of the magnetic field, $\mathbf{p}$ is the momentum operator of the electron, and e is its charge. The order of the vectors in the vector products in (3) is given by their order in path (2). The expression

$$\tfrac{1}{2}[\mathbf{R}_1\times\mathbf{R}_2+\mathbf{R}_1\times\mathbf{R}_3+\cdots+\mathbf{R}_{i-1}\times\mathbf{R}_i]\cdot\mathbf{h} \tag{4}$$

has a very simple meaning. To show this, let us take the projection of the path (2) onto the plane perpendicular to $\mathbf{h}$. This gives a path

$$|\mathbf{R}_1{}^p,\mathbf{R}_2{}^p,\cdots,\mathbf{R}_i{}^p), \tag{5}$$

where $\mathbf{R}_k{}^p$ is the projection of $\mathbf{R}_k$ onto the plane perpendicular to $\mathbf{h}$. It is easily seen that

$$\begin{aligned}&\tfrac{1}{2}[\mathbf{R}_1\times\mathbf{R}_2+\mathbf{R}_1\times\mathbf{R}_3+\cdots+\mathbf{R}_{i-1}\times\mathbf{R}_i]\cdot\mathbf{h}\\ &=\tfrac{1}{2}[\mathbf{R}_1{}^p\times\mathbf{R}_2{}^p+\mathbf{R}_1{}^p\times\mathbf{R}_3{}^p+\cdots+\mathbf{R}_{i-1}{}^p\times\mathbf{R}_i{}^p]\cdot\mathbf{h}.\end{aligned} \tag{6}$$

The brackets with the factor $\frac{1}{2}$ on the right side of (6) give the area of the polygon enclosed by the vectors

$$\mathbf{R}_1{}^p,\ \mathbf{R}_2{}^p,\ \cdots,\ \mathbf{R}_i{}^p,\ -\mathbf{R}_n{}^p \tag{7}$$

(in which the vector $-\mathbf{R}_n{}^p$ was added in order to close the path). We thus see that the expression (4) gives the flux of the magnetic field (with the factor $e/\hbar c$) through the polygon which is obtained by projecting the vectors

$$\mathbf{R}_1,\ \mathbf{R}_2,\ \cdots,\ \mathbf{R}_i,\ -\mathbf{R}_n \tag{8}$$

onto the plane perpendicular to $\mathbf{H}$. Therefore, the elements (3) may be written in a different form

$$\begin{aligned}\tau(\mathbf{R}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)=\exp\{(i/\hbar)\mathbf{R}_n\cdot[\mathbf{p}+(e/c)\mathbf{A}]\}&\\ \times\exp\{i\varphi(\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)\},&\end{aligned} \tag{9}$$

where $\varphi(\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)$ is the flux of the magnetic field through the polygon (7) multiplied by $e/\hbar c$. It should be noted that the path (2), and therefore its projection onto the plane perpendicular to $\mathbf{H}$, can be very complicated. For example, from the point given by $\mathbf{R}_n$, which may be reached along the path (2), one may continue along the vector $-\mathbf{R}_n$ and then again turn back to point $\mathbf{R}_n$ by path (2). In such a case, the area in (6) will be doubled. The second exponent in the definition of the elements (3) or (9) thus expresses the curl nature of the magnetic field.

One may now show that the operators defined in (3) or (9) commute with the Hamiltonian of a Bloch electron in a magnetic field for a proper choice of the gauge. The Hamiltonian is

$$H=1/2m[\mathbf{p}-(e/c)\mathbf{A}]^2+V(\mathbf{r}), \tag{10}$$

m is the mass of the electron and $V(\mathbf{r})$ is the potential of the periodic field. It is easily shown that

$$\left[p_i+\frac{e}{c}A_i,\ p_k-\frac{e}{c}A_k\right]=i\hbar\frac{e}{c}\left[\frac{\partial A_k}{\partial x_i}+\frac{\partial A_i}{\partial x_k}\right]. \tag{11}$$

Therefore, if the gauge in (10) is chosen in a way that

$$\partial A_k/\partial x_i+\partial A_i/\partial x_k=0;\quad i,k=1,2,3, \tag{12}$$

the commutator (11) will vanish and the operators (3) will commute with the Hamiltonian (10). Relation (12) holds, for example, for a gauge

$$\mathbf{A}=\tfrac{1}{2}[\mathbf{H}\times\mathbf{r}]. \tag{13}$$

In order to show that the operators defined in (3) form a group, we shall check that a product of two such operators is again an operator of the same form. Let us take two operators

$$\tau(\mathbf{R}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)\quad\text{and}\quad\tau(\mathbf{R}_n'|\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_k').$$

Their product is

$$\begin{aligned}&\tau(\mathbf{R}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)\tau(\mathbf{R}_n'|\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_k')\\ &=\exp\{(i/\hbar)(\mathbf{R}_n+\mathbf{R}_n')\cdot[\mathbf{p}+(e/c)\mathbf{A}]\}\\ &\times\exp\{(i/2)[\mathbf{R}_1\times\mathbf{R}_2+\cdots+\mathbf{R}_1\times\mathbf{R}_1'+\cdots\\ &+\mathbf{R}_{k-1}'\times\mathbf{R}_k']\cdot\mathbf{h}\},\end{aligned} \tag{14}$$

where the second exponent is defined by the path

$$|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i,\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_k'). \tag{15}$$

In obtaining relation (14) we used the following expressions:

$$\left[\frac{i}{\hbar}\mathbf{R}_n\cdot\left(\mathbf{p}+\frac{e}{c}\mathbf{A}\right),\frac{i}{\hbar}\mathbf{R}_n'\cdot\left(\mathbf{p}+\frac{e}{c}\mathbf{A}\right)\right]=i(\mathbf{R}_n\times\mathbf{R}_n')\cdot\mathbf{h} \tag{16}$$

(without any gauge limitations) and

$$e^Ae^B=e^{A+B+\frac{1}{2}[A,B]}$$

for A and B such that $[A,B]$ commutes with both

A and B. The product (14) can be written according to the definition (3) as follows:

$$\tau(\mathbf{R}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)\tau(\mathbf{R}_n'|\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_k') = \tau(\mathbf{R}_n+\mathbf{R}_n'|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i,\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_k'). \quad (17)$$

We now have a multiplication rule for the elements defined in (3): In order to multiply two elements [left side of (17)], we have to add the vectors $\mathbf{R}_n$ and $\mathbf{R}_n'$, and the paths $|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)$ and $|\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_k')$; the vector on which the product [right side of (17)] depends is $\mathbf{R}_n+\mathbf{R}_n'$ and the path is $|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i,\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_k')$ [the latter is obtained by displacing the path $|\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_k')$ by the vector $\mathbf{R}_n$, thus obtaining a path joining point O with the point defined by the vector $\mathbf{R}_n+\mathbf{R}_n'$]. Thus, the product of two elements of the form (3) is an element of the same form. One sees that the elements defined in (3) form a group because one may also easily show that $\tau(-\mathbf{R}_n|-\mathbf{R}_i,-\mathbf{R}_{i-1},\cdots,-\mathbf{R}_1)$ is reciprocal to the element $\tau(\mathbf{R}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)$. We shall call this group the magnetic translation group (M.T.G.) and denote it by G.[2a] It should be noted that the operators

$$\exp\{(i/\hbar)\mathbf{R}_n\cdot(\mathbf{p}+(e/c)\mathbf{A})\} \quad (18)$$

do not form a group (as pointed out by Brown[2]), because a product of two such operators is not an operator of the form (18).

The group G defined in (3) is an infinite group for two reasons. First, there are an infinite number of vectors $\mathbf{R}_n$. Secondly, for any vector $\mathbf{R}_n$ an infinite number of different paths joining point O with $\mathbf{R}_n$ can be defined. We can, for instance, obtain from path P a different one P' by starting at and returning to any point belonging to the Bravais lattice on path P and adding a closed path to the path P at the mentioned point.

The structure of the group G becomes more apparent after its connection with the usual translation group, denoted by R, is established. To do this, let us define, for every vector $\mathbf{R}_n$, a set of elements $H(\mathbf{R}_n)$ to which all the elements $\tau(\mathbf{R}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)$ of G belong. Each such set $H(\mathbf{R}_n)$ consists of an infinite number of elements. It is easy to see that we can look at the sets $H(\mathbf{R}_n)$ as at elements of a group. If we multiply an element of the set $H(\mathbf{R}_n)$ by an element of set $H(\mathbf{R}_n')$, we shall get an element of the set $H(\mathbf{R}_n+\mathbf{R}_n')$. $H(\mathbf{O})$ is the identity and $H(-\mathbf{R}_n)$ is reciprocal to $H(\mathbf{R}_n)$. This group, denoted by H, is an infinite commutative group, and is isomorphic to the translation group R. The isomorphism follows from the one-to-one correspondence between $\mathbf{R}_n$ and $H(\mathbf{R}_n)$. The group G is homomorphic to H,

$$\tau(\mathbf{R}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)\rightarrow H(\mathbf{R}_n), \quad (19)$$

where the arrow shows the one-sided correspondence of the elements of G with those of H. From the homomorphism of G to H and the isomorphism of H and R, it follows that the magnetic translation group G is homomorphic to the usual translation group R. The last fact will be used to introduce the Born-von Karman boundary conditions for the representations of the magnetic translation group.

The group G has an invariant subgroup which is of great importance for constructing its irreducible representations. Consider the vectors r_m in the plane $\mathbf{a}_1$, $\mathbf{a}_3$ and construct elements of the group G:

$$\tau(\mathbf{r}_m|\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_f') = \exp\{(i/\hbar)\mathbf{r}_m\cdot[\mathbf{p}+(e/c)\mathbf{A}]\} \times\exp\{(i/2)[\mathbf{R}_1'\times\mathbf{R}_2'+\mathbf{R}_1'\times\mathbf{R}_3'+\cdots +\mathbf{R}_{f-1}'\times\mathbf{R}_f']\cdot\mathbf{h}\}, \quad (20)$$

where

$$\mathbf{r}_m=m_1\mathbf{a}_1+m_3\mathbf{a}_3 \quad (21)$$

and $\mathbf{R}_1'$, $\mathbf{R}_2'$, $\cdots$, $\mathbf{R}_f'$ are arbitrary vectors of (1) except for the requirement that they form a path joining point O with the point defined by $\mathbf{r}_m$. The elements in (20) form a subgroup of G because a product of any two elements from (20) is also an element belonging to (20). Let us denote this subgroup by F. A similarity transformation by means of any element $\tau(\mathbf{R}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)$ of G when applied to an element $\tau(\mathbf{r}_m|\mathbf{R}_1',\mathbf{R}_2',\cdots\mathbf{R}_f')$ of F gives the following result:

$$\tau^{-1}(\mathbf{R}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)\tau(\mathbf{r}_m|\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_f') \times\tau(\mathbf{R}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i) = \tau(\mathbf{r}_m|-\mathbf{R}_i,-\mathbf{R}_{i-1},\cdots,-\mathbf{R}_1,\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_f',\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i). \quad (22)$$

The relation (22) shows us that subgroup F is an invariant subgroup of group G. It is clear that another invariant subgroup of G can be obtained by taking in (20) vectors $\mathbf{r}_m'$ in the plane $\mathbf{a}_2$, $\mathbf{a}_3$. This latter invariant subgroup is isomorphic to F. With respect to the invariant subgroup F, group G can be written as follows:

$$G=\tau(\mathbf{O}|\mathbf{O})F+\tau(\mathbf{a}_2|\mathbf{a}_2)F+\cdots +\tau(n_2\mathbf{a}_2|n_2\mathbf{a}_2)F+\cdots. \quad (23)$$

It is of interest to note that when the magnetic field $\mathbf{H}$ is in the direction $\mathbf{a}_3$ the subgroup F is a commutative one, while the elements of F do not commute with those elements of G that do not belong to F.

So far, the groups have all been infinite. For constructing their irreducible representation, it is convenient to deal with finite groups. To do this, the Born-von Karman boundary conditions can be applied.

III. FINITE MAGNETIC TRANSLATION GROUP

The finiteness of the usual translation group is achieved by looking for its special representations, namely, by seeking representations which satisfy the

[2a] After the abstract of this paper appeared in Phys. Rev. Letters, Gerald A. Peterson pointed out (private communication) that in his Ph.D. thesis he has defined a closed set of magnetic translation operators and has called it magnetic translation group [G. A. Peterson, Ph.D. thesis, Cornell University, 1960 (unpublished)].

Born-von Karman boundary conditions

$$D\{(\epsilon|\mathbf{a}_1)^N\}=D\{(\epsilon|\mathbf{a}_2)^N\}=D\{(\epsilon|\mathbf{a}_3)^N\}=D\{(\epsilon|0)\}\,, \quad (24)$$

where $(\epsilon|\mathbf{a}_1)$, $(\epsilon|\mathbf{a}_2)$, $(\epsilon|\mathbf{a}_3)$ are translations in the directions of the unit cell vectors (ϵ is the identity of the rotation group in the usual notation[3]), N is a large integer, and D denotes a representation of the translation group R. When seeking representations of R which satisfy the conditions (24), we can consider the group R as being a finite group $\bar{R}$ of order N^3, the elements of which are given by the direct product of the following three groups:

$$(\epsilon|\mathbf{a}_1)^i;\ (\epsilon|\mathbf{a}_2)^j;\ (\epsilon|\mathbf{a}_3)^k;\quad i,\,j,\,k=1,\,2,\,\cdots,\,N\,. \quad (25)$$

Similarly, in order to make G finite, we require similar boundary conditions to those imposed for the representations of the translation group (24). To do this, we use the fact that the translation group R is isomorphic to H and require the following conditions on the representations of H:

$$D\{H^N(\mathbf{a}_1)\}=D\{H^N(\mathbf{a}_2)\}$$
$$=D\{H^N(\mathbf{a}_3)\}=D\{H(\mathbf{O})\}\,. \quad (26)$$

With the conditions (26), the group H can be considered as being finite and given by the direct product of the following three groups:

$$\{H^i(\mathbf{a}_1)\};\ \{H^j(\mathbf{a}_2)\};\ \{H^k(\mathbf{a}_3)\};$$
$$i,\,j,\,k=1,\,2,\,\cdots,\,N\,. \quad (27)$$

Let us denote the last group by $\bar{H}$ and the corresponding M.T.G. by $\bar{G}$. It is clear that again $\bar{R}$ and $\bar{H}$ are isomorphic.

The requirements (26) mean that elements

$$\tau(Na_k|\mathbf{R}_1,\mathbf{R}_2,\cdots\mathbf{R}_f);\quad k=1,\,2,\,3\,, \quad (28)$$

of G can be considered as constant factors. From this it follows that the elements (28) commute with all the elements of G. It is easy to show that

$$\tau(\mathbf{R}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)\tau(\mathbf{R}_n'|\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_k)$$
$$=\tau(\mathbf{R}_n'|\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_k')\tau(\mathbf{R}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)$$
$$\times\exp\{i(\mathbf{R}_n\times\mathbf{R}_n')\cdot\mathbf{h}\}\,. \quad (29)$$

Hence, the elements (28) commute with all the elements of G if the exponential term in (29) equals 1 for $\mathbf{R}_n=N\mathbf{a}_k$ ($k=1,\,2,\,3$). We have therefore the following condition:

$$(N\mathbf{a}_k\times\mathbf{R}_n')\cdot\mathbf{h}=2\pi m;\quad k=1,\,2,\,3\,, \quad (30)$$

where m is an integer and $\mathbf{R}_n'$ is any vector from (1). Before discussing condition (30), let us derive another condition from the requirements (26). Consider two elements of the form (28) and take their product

$$\tau(N\mathbf{a}_i|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_f)\tau(N\mathbf{a}_k|\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_g')$$
$$=\tau(N\mathbf{a}_i+N\mathbf{a}_k|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_f,\mathbf{R}_1',\mathbf{R}_2',\cdots,\mathbf{R}_g')\,. \quad (31)$$

[3] G. F. Koster, *Solid State Physics*, edited by F. Seitz and D. Turnbull (Academic Press Inc., New York, 1957), Vol. 5.

But since the elements on the left side of (31) should behave as constant factors, the additional factor on the right side of (31),

$$\exp\{\tfrac{1}{2}(N\mathbf{a}_i\times N\mathbf{a}_k\cdot\mathbf{h}\}\,, \quad (32)$$

should be equal to 1. We have thus

$$(N\mathbf{a}_i\times N\mathbf{a}_k)\cdot\mathbf{h}=4\pi m;\quad i,\,k=1,\,2,\,3\,, \quad (33)$$

for odd N [for even N there is no additional condition to the one expressed by (30)]. Combining (30) and (33) we get for odd N the condition

$$(N\mathbf{a}_k\times\mathbf{R}_n')\cdot\mathbf{h}=4\pi m;\quad k=1,\,2,\,3\,, \quad (34)$$

which is stronger than the requirement (30). We now write the conditions (30) and (34) in a more convenient form, using the fact that (30) and (34) will be satisfied for any vector $\mathbf{R}_n'$ if they hold for the unit cell vectors $\mathbf{a}_1$, $\mathbf{a}_2$, $\mathbf{a}_3$:

$$N(\mathbf{a}_k\times\mathbf{a}_l)\cdot\mathbf{h}=2\pi n_{kl}\quad\text{(for even } N)\,, \quad (35a)$$

$$N(\mathbf{a}_k\times\mathbf{a}_l)\cdot\mathbf{h}=4\pi n_{kl}\quad\text{(for odd } N)\,, \quad (35b)$$

where n_{kl} is an integer and $k,\,l=1,\,2,\,3$. By using the definition of the reciprocal lattice vectors

$$K_i=(2\pi/V)\mathbf{a}_j\times\mathbf{a}_k\,, \quad (36)$$

where $i,\,j,\,k$ form the cycle (123) and V is the volume of this unit cell, we can write the conditions (35a), (35b) as follows:

$$N(V/2\pi)\mathbf{K}_m\cdot\mathbf{h}=2\pi m\quad\text{(for even } N)\,, \quad (37a)$$

$$N(V/2\pi)\mathbf{K}_m\cdot\mathbf{h}=4\pi m\quad\text{(for odd } N)\,. \quad (37b)$$

Here m is an integer. Equations (37a) and (37b) show that

$$\mathbf{h}=(2\pi/V)(\mathbf{R}_n/N)\quad\text{(for even } N)\,, \quad (38a)$$

$$\mathbf{h}=(4\pi/V)(\mathbf{R}_n/N)\quad\text{(for odd } N)\,. \quad (38b)$$

The requirements (38a), (38b) which follow from (26) are limitations on both the possible directions and values of the magnetic field. Let us choose the magnetic field in the direction $\mathbf{a}_3$ [this can always be done when conditions (38a), (38b) hold] and let $\mathbf{R}_n=n\mathbf{a}_3$; then

$$\mathbf{h}=(2\pi/V)(n/N)\mathbf{a}_3\quad\text{(for even } N)\,, \quad (39a)$$

$$\mathbf{h}=(4\pi/V)(n/N)\mathbf{a}_3\quad\text{(for odd } N)\,. \quad (39b)$$

For N sufficiently large the limitations (39a), (39b) on the magnetic field $\mathbf{H}$ are not essential. It should, however, be noted that when the crystal has dimensions of the order of 1 cm ($N\approx10^8$), the fields satisfying conditions (39a), (39b) differ by quanta of the order of 10 G (i.e., the lowest nonzero magnetic field satisfying the above conditions is of the order of 10 G). Unlike the boundary conditions for the usual translation group (which lead to no physical consequences), in the case of the M.T.G. we have restrictions on the magnetic field

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

even for crystals of the dimensions of 1 cm on which bulk experiments have been carried out.

We now show that the Born-von Karman conditions (26) on the representations of H, which led to requirements (39a), (39b), turn the group G into a finite one $\bar{G}$. By using (39a), (39b), we find that the elements of $\bar{G}$ are of the form

$$\tau(\mathbf{R}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)=\exp\{(i/\hbar)\mathbf{R}_n\cdot(\mathbf{p}+(e/c)\mathbf{A})\}$$
$$\times\begin{cases}\exp\{2\pi im(n/N)\} & \text{(for odd } N), \quad (40a)\\ \exp\{\pi im(n/N)\} & \text{(for even } N), \quad (40b)\end{cases}$$

where m is the coefficient by the product $\mathbf{a}_1\times\mathbf{a}_2$ in the expression

$$\mathbf{R}_1\times\mathbf{R}_2+\mathbf{R}_1\times\mathbf{R}_3+\cdots+\mathbf{R}_{i-1}\times\mathbf{R}_i. \quad (41)$$

From Eqs. (40a), (40b), we see that the number of elements of $\bar{G}$ is finite. In order to count the number of elements of $\bar{G}$, we treat the cases for even and odd N separately. For odd N, condition (39b) is imposed and the elements of $\bar{G}$ are given by (40a). The number of different values of the vector $\mathbf{R}_n$ is N^3. For each $\mathbf{R}_n$ there are different elements in (40a) arising from the second exponential factor. We first show that the number m in (40a) [and also in (40b)] can take all integer values. This follows from the fact that we can add to the path joining the point O with point $\mathbf{R}_n$ a closed path which will change (41) by an elementary area $\mathbf{a}_1\times\mathbf{a}_2$ and will change m in the expressions (40a), (40b) by unity. Let us now assume that p is the largest common factor of n and N (when there is no common factor, $p=1$), and let $N/p=N'$, $n/p=n'$. In order to count the different elements of (40a) for a given $\mathbf{R}_n$, let us check that

$$\exp\{2\pi im(n/N)\}\neq\exp\{2\pi im'(n/N)\} \quad (42)$$

for $m'\neq m$ (we exclude here those cases for which m' differs from m by the number N'). By assuming the equality sign in (42) to hold, we get

$$\exp\{2\pi i(m-m')(n/N)\}=1. \quad (43)$$

Relation (43) holds only when

$$(m-m')(n/N)=(m-m')(n'/N')=\text{integer}. \quad (44)$$

But since n' and N' have no common factor, the relation (44) is possible only for $m-m'\geq N'$, which means that m' should differ from m at least by N' in order to get the equality sign in (42). The second exponential in (40a) thus takes on N' different values for a given $\mathbf{R}_n$. Since $\mathbf{R}_n$ itself has N^3 different values, there are N^3N' different elements in $\bar{G}$ in the case of odd N. In a similar way, it is easy to show that there are $N^3(2N')$ different elements in $\bar{G}$ for even N.

It is of interest to note that when the magnetic field $\mathbf{H}$ is very strong (of the order of 10^{10} G), we can have the case that

$$\mathbf{h}=(4\pi/V)\mathbf{a}_3, \quad (45)$$

in which case the group $\bar{G}$ consists of N^3 commutative elements of the form

$$\exp\{(i/\hbar)\mathbf{R}_n\cdot(\mathbf{p}+(e/c)\mathbf{A})\} \quad (46)$$

and is isomorphic to the usual translation group.

IV. CONCLUSION

We have defined here a magnetic translation group G which commutes with the Hamiltonian for a Bloch electron in a magnetic field. In a following paper, we construct the irreducible representations of this group and give the classification of the solutions of Schrödinger's equation for an electron in both a periodic electric potential and a constant magnetic field.

PHYSICAL REVIEW VOLUME 134, NUMBER 6A 15 JUNE 1964

Magnetic Translation Group. II. Irreducible Representations

J. ZAK*

National Magnet Laboratory,† Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received 13 January 1964)

The physical irreducible representations of the magnetic translation group (M.T.G.) defined previously have been found. From these a set of solutions of Schrödinger's equation for a Bloch electron in a magnetic field has been constructed. In general the M.T.G. is non-Abelian. However, when the magnetic flux through areas enclosed by any vectors of the Bravais lattice become multiples of an elementary "fluxon" hc/e, the M.T.G. becomes isomorphic to the usual translation group.

I. INTRODUCTION

IN a previous paper[1] a magnetic translation group was defined and its general properties were established. The elements of this group, which depend on both a point of the Bravais lattice and a path joining the origin of the lattice with this point, are given by

$$\tau(\mathbf{R}|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)=\exp\{(i/\hbar)\mathbf{R}_n\cdot[\mathbf{p}+(e/c)\mathbf{A}]\}\times\exp\{2\pi i(n/bN)m\}, \quad (1)$$

where $\mathbf{R}_n$ is a vector of the Bravais lattice, $\mathbf{A}$ is the vector potential of the magnetic field $\mathbf{H}$, m is the coefficient by the product $\mathbf{a}_1\times\mathbf{a}_2$ of the unit cell vectors $\mathbf{a}_1$, $\mathbf{a}_2$ in the sum of ordered products

$$\mathbf{R}_1\times\mathbf{R}_2+\mathbf{R}_1\times\mathbf{R}_3+\cdots+\mathbf{R}_1\times\mathbf{R}_i+\mathbf{R}_2\times\mathbf{R}_3+\cdots+\mathbf{R}_{i-1}\times\mathbf{R}_i, \quad (2)$$

n, N, and b appear from the Born-von Karman conditions which turn the magnetic translation group into a finite one and impose the following condition on the magnetic field:

$$\frac{e\mathbf{H}}{\hbar c}=\frac{4\pi}{V}\frac{\mathbf{R}_n}{bN}=\frac{4\pi}{V}\frac{n}{bN}\mathbf{a}_3, \quad (3)$$

V is the volume of the unit cell, $V=\mathbf{a}_1\times\mathbf{a}_2\cdot\mathbf{a}_3$, and b takes the values 1 or 2 for N odd or even, respectively.

The finite magnetic translation group $\bar{G}$ is of the order $b(N/p)N^3$, where p is the largest common factor of N and n. For constructing the irreducible representations of $\bar{G}$ we use the fact that it has an invariant subgroup $\bar{F}$ consisting of elements

$$\tau(\mathbf{r}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)=\exp\left\{\frac{i}{\hbar}\mathbf{r}_n\cdot\left(\mathbf{p}+\frac{e}{c}\mathbf{A}\right)\right\}\times\exp\left\{2\pi i\frac{n}{bN}m\right\}, \quad (4)$$

where

$$\mathbf{r}_n=n_1\mathbf{a}_1+n_3\mathbf{a}_3. \quad (5)$$

The group $\bar{G}$ can therefore be written as

$$\bar{G}=\tau(\mathbf{a}_2|\mathbf{a}_2)\bar{F}+\cdots+\tau(N\mathbf{a}_2|N\mathbf{a}_2)\bar{F}. \quad (6)$$

The invariant subgroup $\bar{F}$ is a commutative group and its irreducible representations are well known. In order to find the irreducible representations of $\bar{G}$ we use the method of Frobenius.[2,3] This method enables one to find all the irreducible representations of a group from the irreducible representations of its invariant subgroup.

In Sec. II the physical irreducible representations of the M.T.G. are constructed. They turn out to be the same in the case of the finite M.T.G. as the ray representations of the usual translation group that are given by Brown.[4] This result is not surprising because in the usual method for constructing ray representations of a finite group[5,6] one augments the group, finds the vector representations of the augmented group, and then chooses those representations which correspond to ray representations of the original group. It appears, however, more natural to define a group which commutes with the Hamiltonian for a Bloch electron in a magnetic field than to treat ray representations of a group (the usual translation group) which does *not* commute with this Hamiltonian. Moreover, by finding all the physical representations of the M.T.G., we are sure that we have all the possible symmetry types for the wave functions.[7]

For constructing the irreducible representations of the M.T.G., we first start with the finite group obtained by applying the boundary conditions. From the method of construction, it is possible to find a complete set of symmetry adapted functions for the problem under discussion.[8] These functions are presented in Sec. III. As shown in Ref. 1, the boundary conditions on the magnetic translation group lead to physical restrictions on the magnitude of the magnetic field. In Sec. IV we

[7] The statement used in Ref. 4 for showing the completeness of the irreducible representations, namely, that the sum of squares of the dimensions of nonequivalent irreducible ray representations equals the order of the group is, in general, not true. There are, for example, finite groups that have no ray representations at all.

[8] An alternative method for constructing symmetry adapted functions is discussed in Ref. 4.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

remove these restrictions by dealing with an infinite M.T.G. Finally, in the same section, the significance of the elementary fluxon hc/e for the magnetic translation group is discussed.

II. CONSTRUCTION OF THE IRREDUCIBLE REPRESENTATIONS OF G

The invariant subgroup $\bar{F}$ of $\bar{G}$ is a commutative group and its irreducible representations are

$$D^{(s,k_1,m_3)}\{\tau(\mathbf{r}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)\} = \exp\left\{2\pi i\left[\frac{n}{bN}ms+\frac{k_1n_1}{N}+\frac{m_3n_3}{N}\right]\right\}, \quad (7)$$

where s takes the values from 1 to bN/p, and k_1, m_3 the values from 1 to N. Relation (7) thus defines $(bN/p)N^2$ one-dimensional representations of $\bar{F}$. These are all the irreducible representations of $\bar{F}$ because the order of the latter is just $(bN/p)N^2$. However, some of the representations (7) are nonphysical as may be seen by setting $\mathbf{r}_n=\mathbf{o}$. The element $\tau(\mathbf{o}|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)$ is a constant factor which will be represented by different constants if we take different values of s in (7). When the operator $\tau(\mathbf{r}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)$ itself operates in the functional space, the only physical representations in (7) will be those for $s=1$. We therefore consider the representations of $\bar{F}$ only for $s=1$ and from these we construct the irreducible representations of $\bar{G}$.

Let us first consider the case $p=1$ (i.e., no common factor for N and n) and denote the vector that spans representation (7) (for $s=1$) by $|k_1, m_3\rangle$. Then

$$D^{(k_1,m_3)}\{\tau(\mathbf{r}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)\}|k_1,m_3\rangle = \exp\left\{2\pi i\left[\frac{n}{bN}m+\frac{2nk_1n_1}{bN}+\frac{m_3n_3}{N}\right]\right\}|k_1,m_3\rangle, \quad (8)$$

where a factor $2n/b$ was introduced for convenience in front of k_1n_1/N. (This is equivalent to an alternative numbering of the eigenvectors $|k_1,m_3\rangle$.) We now perform a similarity transformation:

$$\tau(-n_2\mathbf{a}_2|-n_2\mathbf{a}_2)\tau(\mathbf{r}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)\tau(n_2\mathbf{a}_2|n_2\mathbf{a}_2) = \tau(\mathbf{r}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)\exp\{4\pi i(n/bN)n_1n_2\}. \quad (9)$$

It follows from (9) that

$$D\{\tau(\mathbf{r}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i\}D\{\tau(n_2\mathbf{a}_2|n_2\mathbf{a}_2)\}|k_1,m_3\rangle = \exp\left\{2\pi i\left[\frac{n}{bN}m+\frac{2n(k_1+n_2)n_1}{bN}+\frac{m_3n_3}{N}\right]\right\} \times D\{\tau(n_2\mathbf{a}_2|n_2\mathbf{a}_2)\}|k_1,m_3\rangle. \quad (10)$$

It is seen that the vector $D\{\tau(n_2\mathbf{a}_2|n_2\mathbf{a}_2)\}|k_1,m_3\rangle$ is an eigenvector of $D\{\tau(\mathbf{r}_n|\mathbf{R}_1,\mathbf{R}_2,\cdots,\mathbf{R}_i)\}$ corresponding to the eigenvalues k_1+n_2, m_3 (D now denotes a representation of $\bar{G}$). Since we assumed that N and n have no common factor we get[2] N vectors $D\{\tau(n_2\mathbf{a}_2|n_2\mathbf{a}_2)\}|k_1,m_3\rangle$ for $n_2=1, 2, \cdots, N$:

$$D\{\tau(n_2\mathbf{a}_2|n_2\mathbf{a}_2)\}|k_1,m_3\rangle = |k_1+n_2, m_3\rangle. \quad (11)$$

Let us show that relations (10) and (11) for each m_3 define an irreducible representation of $\bar{G}$. According to (6) each operator $\tau(\mathbf{R}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i)$ can be written as follows:

$$\tau(\mathbf{R}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i) = \tau(n_2\mathbf{a}_2|n_2\mathbf{a}_2)\tau(\mathbf{r}_n|-n_2\mathbf{a}_2,\mathbf{R}_1,\cdots,\mathbf{R}_i), \quad (12)$$

where $\mathbf{R}_n=\mathbf{r}_n+n_2\mathbf{a}_2$, $\mathbf{r}_n=n_1\mathbf{a}_1+n_3\mathbf{a}_3$. Therefore,

$$D\{\tau(\mathbf{R}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i)\}|k_1,m_3\rangle = \exp\left\{2\pi i\left[\frac{n}{bN}g+\frac{2nk_1n_1}{bN}+\frac{m_3n_3}{N}\right]\right\}|k_1+n_2, m_3\rangle, \quad (13)$$

where g is the coefficient of the product $\mathbf{a}_1\times\mathbf{a}_2$ in

$$-n_2\mathbf{a}_2\times\mathbf{R}_n+\mathbf{R}_1\times\mathbf{R}_2+\mathbf{R}_1\times\mathbf{R}_3+\cdots+\mathbf{R}_{i-1}\times\mathbf{R}_i. \quad (14)$$

From (13) it follows that

$$D_{k'k}{}^{m_3}\{\tau(\mathbf{R}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i)\} = \langle m_3k'|\tau(\mathbf{R}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i)|k,m_3\rangle = \delta_{k',k+n_2}\exp\left\{2\pi i\left[\frac{n}{bN}g+\frac{2nkn_1}{bN}+\frac{m_3n_3}{N}\right]\right\}, \quad (15)$$

where $D_{k'k}{}^{m_3}$ denotes a matrix element $k'k$ of the operator $\tau(\mathbf{R}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i)$; k' and k take values from 1 to N, and $k+n_2$ is taken modulo N.

We next show that for each m_3 the matrices D^{m_3} form a representation of $\bar{G}$. To do this we first calculate the product of two matrices (15) corresponding to two elements $\tau(\mathbf{R}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i)$ and $\tau(\mathbf{R}_n'|\mathbf{R}_1',\cdots,\mathbf{R}_i')$ and then the matrix which corresponds to the product $\tau(\mathbf{R}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i)\tau(\mathbf{R}_n'|\mathbf{R}_1',\cdots,\mathbf{R}_i')$. The two results must be the same if (15) is to be a representation of $\bar{G}$. From (15) we have

$$\sum_{\alpha=1}^{N} D_{k'\alpha}{}^{m_3}\{\tau(\mathbf{R}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i)\}D_{\alpha k}{}^{m_3}\{\tau(\mathbf{R}_n'|\mathbf{R}_1',\cdots,\mathbf{R}_i')\} = \delta_{k',k+n_2+n_2'}\exp\left\{2\pi i\left[\frac{n}{bN}(g+g')+\frac{2nk(n_1+n_1')}{bN}+\frac{2nn_1n_2'}{bN}+\frac{m_3(n_3+n_3')}{N}\right]\right\}. \quad (16)$$

On the other hand, the matrix corresponding to the product of the two elements is

$$D_{k'k}{}^{m_3}\{\tau(\mathbf{R}_n+\mathbf{R}_n'|\mathbf{R}_1,\cdots,\mathbf{R}_i,\cdots,\mathbf{R}_i')\} = \delta_{k',k+n_2+n_2'}\exp\left\{2\pi i\left[\frac{n}{bN}g''+\frac{2nk(n_1+n_1')}{bN}+\frac{m_3(n_3+n_3')}{N}\right]\right\}, \quad (17)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

where g'' is the coefficient by the product $\mathbf{a}_1\times\mathbf{a}_2$ in the expression

$$-(n_2+n_2')\mathbf{a}_2\times(\mathbf{R}_n+\mathbf{R}_n')+\mathbf{R}_1\times\mathbf{R}_2+\cdots+\mathbf{R}_{i-1}\times\mathbf{R}_i+\mathbf{R}_1'\times\mathbf{R}_2'+\cdots+\mathbf{R}_{i-1}'\times\mathbf{R}_i'. \quad (18)$$

It is easily shown that

$$g''=g+g'+2n_1n_2'. \quad (19)$$

It therefore follows that expressions (16) and (17) are equal and thus that the matrices (15) for each m_3 form a representation of $\bar{G}$. These representations are irreducible because all the vectors $|km_3\rangle$ for a given m_3 and different $k(k=1, 2; \cdots, N)$ form a closed subspace. An alternative way to check the irreducibility of (15) is to calculate the character for a given m_3,

$$\chi^{m_3}\{\tau(\mathbf{R}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i)\}=\sum_{k=1}^{N}D_{kk}^{m_3}=N_{\delta n_1 0\delta n_2 0}\exp\left\{2\pi i\left[\frac{n}{bN}g+\frac{m_3n_3}{N}\right]\right\}, \quad (20)$$

and to find the sum

$$\sum_{\bar{G}}|\chi^{m_3}\{\tau(\mathbf{R}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i)\}|^2=N^4. \quad (21)$$

Result (21) shows that the representation (15) with the character (20) is irreducible [for reducible representations the sum (21) is greater than the number of elements in $\bar{G}$]. Note that the way of constructing irreducible representations here corresponds to the method of finding conjugate representations of the invariant subgroup $\bar{F}$ by means of the elements of $\bar{G}$ that do not belong[3] to $\bar{F}$. In the case when N and n have no common factor all the conjugate representations are nonequivalent and the representation of $\bar{G}$ which they induce is thus irreducible.

According to the method of Froebenius, relation (15) gives us all the irreducible representations of the group[2,3] corresponding to $s=1$. Since we are interested only in the physical representations of $\bar{G}$ these are all the representations of $\bar{G}$.

Let us now treat the case when the largest common factor of N and n is p. If we start with a vector $|k_1,m_3\rangle$ [see (8)] and apply all the operators $\tau(n_2\mathbf{a}_2|n_2\mathbf{a}_2)$ we shall get in general only $N'=N/p$ independent vectors $|k,m_3\rangle$ for $k=1, 2, \cdots, N'$. According to Ref. 2 it again follows that we may assume

$$D\{\tau(n_2\mathbf{a}_2|n_2\mathbf{a}_2)\}|k,m_3\rangle=\exp\{2\pi i(m_2n_2/N)\}|k+n_2, m_3\rangle \quad (22)$$

for $n_2=1, 2, \cdots, N'$ and $m_2=0, 1, \cdots, p-1$. The representations induced by the vectors (22) can be written as

$$D_{k'k}^{(m_1m_2m_3)}\{\tau(\mathbf{R}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i)\}=\delta_{k',k+n_2}\exp\left\{2\pi i\left[\frac{m_1n_1}{N}+\frac{m_2n_2}{N}+\frac{n}{bN}g+\frac{2nkn_1}{bN}+\frac{m_3n_3}{N}\right]\right\}, \quad (23)$$

where the values of m_1, m_2 range from 0 to $p-1$; k, k' assume values from 1 to N' ($k+n_2$ is defined modulo N'), and m_3 ranges from 1 to N. Relation (23) defines p^2N irreducible and nonequivalent $N'\times N'$ representations of the group $\bar{G}$ and again gives us all the physical representations of $\bar{G}$. Note that in this case when N and n have a common factor the conjugate representations of $\bar{F}$, constructed by means of elements of $\bar{G}$ that do not belong to $\bar{F}$, will in general no longer be nonequivalent. The representations of $\bar{G}$ induced by the conjugate representations of $\bar{F}$ will be reducible; the irreducible parts are given in (23). In the case when $p=1$, representations (23) go over into (15). Hence, relation (23) gives all the irreducible physical representations of $\bar{G}$.

III. SYMMETRY ADAPTED FUNCTIONS

We now use the irreducible representations of the magnetic translation group $\bar{G}$ to construct symmetry adapted solutions of Schrödinger's equation for a Bloch electron in a magnetic field. By using the gauge

$$\mathbf{A}=\tfrac{1}{2}[\mathbf{H}\times\mathbf{r}], \quad (24)$$

we can write the elements (1) of the magnetic translation group as

$$\tau(\mathbf{R}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i)=\exp\left\{\frac{i}{\hbar}\mathbf{R}_n\cdot\mathbf{p}+i\frac{n}{bN}(n_2\mathbf{K}_1-n_1\mathbf{K}_2)\cdot\mathbf{r}\right\}\times\exp\left\{2\pi i\frac{n}{bN}m\right\}, \quad (25)$$

where $\mathbf{K}_1$ and $\mathbf{K}_2$ are vectors of the unit cell of the reciprocal lattice. Let

$$\psi(\mathbf{r})=\exp\{i\mathbf{k}\cdot\mathbf{r}\}u(\mathbf{r}), \quad (26)$$

with

$$\mathbf{k}=\frac{1}{N}\left[\left(m_1+\frac{2nk_1}{b}\right)\mathbf{K}_1+m_3\mathbf{K}_2\right],$$

$$m_1=0, 1, \cdots, p-1; \quad k_1=1, \cdots, N'; \quad (27)$$

and

$$\tau(\mathbf{r}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i)u(\mathbf{r})=\exp\{2\pi i(n/bN)g\}u(\mathbf{r}).$$

The last condition on $u(\mathbf{r})$ means that

$$u(\mathbf{r}+\mathbf{r}_n)=\exp\left\{i\frac{n}{bN}\mathbf{n}_1\mathbf{K}_2\cdot\mathbf{r}\right\}u(\mathbf{r}), \quad (28)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

in which case

$$\tau(\mathbf{r}_n|\mathbf{R}_1,\cdots,\mathbf{R}_i)\psi(\mathbf{r}) = \exp\left\{2\pi i\left[\frac{n}{bN}g+\frac{m_1n_1}{N}+\frac{2nk_1n_1}{bN}+\frac{m_3n_3}{N}\right]\right\}\psi(\mathbf{r}). \quad (29)$$

In order to satisfy condition (28) and the boundary conditions, we choose $u(r)$ as follows:

$$u(\mathbf{r}) = \exp\left\{\frac{i}{2\pi}\frac{n}{bN}\mathbf{r}\cdot\mathbf{K}_1\mathbf{r}\cdot\mathbf{K}_2\right\}w(\mathbf{r}), \quad (30)$$

with

$$w(\mathbf{r}+\mathbf{r}_n) = w(\mathbf{r}), \qquad w(\mathbf{r}+N'\mathbf{a}_2) = \exp\{-iN'\mathbf{a}_2\times\mathbf{h}\cdot\mathbf{r}\}w(\mathbf{r}). \quad (31)$$

The function (26) will therefore be

$$\psi(\mathbf{r}) = \exp\{i\mathbf{k}\cdot\mathbf{r}\}\exp\left\{\frac{i}{2\pi}\frac{n}{bN}\mathbf{r}\cdot\mathbf{K}_1\mathbf{r}\cdot\mathbf{K}_2\right\}w(\mathbf{r}). \quad (32)$$

By using Eq. (32) and the relation (22) and by reintroducing the magnetic field according to Eq. (3) we get the functions

$$\psi_q^{(l,\mathbf{k})}(\mathbf{r}) = \exp\{i\mathbf{k}\cdot\mathbf{r}\} \times\exp\{i[q+(1/4\pi)\mathbf{K}_2\cdot\mathbf{r}](\mathbf{a}_2\times\mathbf{h})\cdot\mathbf{r}\}w_{lk}(\mathbf{r}+q\mathbf{a}_2), \quad (33)$$

where $\mathbf{k}=(1/N)(m_1\mathbf{K}_1+m_2\mathbf{K}_2+m_3\mathbf{K}_3)$, m_1, m_2 are integers which take values from 0 to $p-1$ (with p again the common factor of N and n), m_3 is an integer whose values range from 1 to N and the integer q has values from 0 to $N'-1$. The functions $w_{lk}(\mathbf{r})$ satisfy conditions (31). The meaning of l will be given later. For fixed $\mathbf{k}$ and l there are $N'(=N/p)$ functions in (33) which form a basis for an $N'\times N'$ irreducible representation (23) of the magnetic translation group $\bar{G}$. For different $\mathbf{k}$ we get nonequivalent representations of $\bar{G}$. The functions in (33) are thus the symmetry adapted functions for all the irreducible representations of $\bar{G}$. The physical picture connected with this description is the following. All the functions (33) with fixed l and $\mathbf{k}$ (and varying q) belong to the same energy. When $\mathbf{k}$ also varies the energy will be in general varying and one obtains an energy band for each l. The number l was thus introduced to distinguish between different energy bands in the same way in which it is done in the case of the usual translation group.

From the fact that the function (33) form bases for irreducible unitary representations (23) of the magnetic translation group, it follows that functions (33) are orthogonal for different $\mathbf{k}$ and q. [Note that the functions $w_{lk}(\mathbf{r})$ also depend on the vector $\mathbf{k}$. This dependence is obtained by substituting functions (33) into Schrödinger's equation.] By assuming (as is usual) the orthogonality of $w_{lk}(\mathbf{r})$ for different l

$$\int w_{l'k}^*(\mathbf{r})w_{lk}(\mathbf{r})dV = \delta_{ll'}, \quad (34)$$

where the integration is over the volume of the crystal, we get

$$\int\psi_{q'}^{*(l'k')}(\mathbf{r})\psi_q^{(l,k)}(\mathbf{r})dV = \delta_{qq'}\delta_{kk'}\delta_{ll'}. \quad (35)$$

Hence, the functions (33) form a complete orthonormal set.

IV. INFINITE MAGNETIC TRANSLATION GROUP

The construction of the representations of (23) of $\bar{G}$ and of the symmetry adapted functions (33) was made possible by imposing the Born-von Karman boundary conditions. We know, however, that in the case of the usual translation group it is possible to write down the representations without using the boundary conditions, in which case the wave vector $\mathbf{k}$ describing the representations varies continuously in the first Brillouin zone. One may expect the same to be valid also in the case of the magnetic translation group. The crucial point in deriving the irreducible representations of $\bar{G}$ was the existence of an invariant Abelian subgroup $\bar{F}$ of the group $\bar{G}$. The infinite magnetic translation group G always has an invariant commutative subgroup F [Eq. (23), Ref. 1] when the magnetic field $\mathbf{H}$ is in a direction of a lattice vector. The restriction imposed on the direction of the magnetic field only is a much weaker one and it leaves the group $\bar{G}$ infinite. Since the Born-von Karman boundary conditions do not appear explicitly in the functions (33), it is easy to obtain a generalization of the functions in the case of an infinite M.T.G. (with the restriction that the magnetic field is in a direction of a lattice vector, say, again in the direction of $\mathbf{a}_3$). We have, however, to distinguish the case

$$\mathbf{h}\neq(4\pi/V)(n/N)\mathbf{a}_3 \quad (36)$$

from the case

$$\mathbf{h}=(4\pi/V)(n/N)\mathbf{a}_3, \quad (37)$$

where n and N have no common factor. The integers n and N are no longer connected with the boundary conditions. In the case when (36) holds the symmetry adapted functions will be

$$\psi_q^{(l_1m_3)}(\mathbf{r}) = \exp\{im_3\mathbf{K}_3\cdot\mathbf{r}\}\exp\{i[q+(1/4\pi)\mathbf{K}_2\cdot\mathbf{r}] \times(\mathbf{a}_2\times\mathbf{h}\cdot\mathbf{r})\}w_{lm_3}(\mathbf{r}+q\mathbf{a}_2), \quad (38)$$

where $0\leq m_3<1$ (continuously) and q takes on integer values from 0 to infinity. For the case (37) we get as in (33):

$$\psi_q^{(l,\mathbf{k})}(\mathbf{r}) = \exp\{i\mathbf{k}\cdot\mathbf{r}\}\exp\{i[q+(1/4\pi)\mathbf{K}_2\cdot\mathbf{r}] \times(\mathbf{a}_2\times\mathbf{h})\cdot\mathbf{r}\}w_{lk}(\mathbf{r}+q\mathbf{a}_2), \quad (39)$$

where

$$q=0,\ 1,\ \cdots,\ N-1\ [(N/2)-1] \text{ for odd (even) } N,$$

$$\mathbf{k}=\frac{m_1}{N}\mathbf{K}_1+\frac{m_2}{N}\mathbf{K}_2+m_3\mathbf{K}_3, \quad (40)$$

$$0\leq m_1,\ m_2<1\ (2) \text{ for odd (even) } N,\quad 0\leq m_3<1,$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and

$$w_{lk}(\mathbf{r}+N\mathbf{a}_2)=\exp\{-iN\mathbf{a}_2\times\mathbf{h}\cdot\mathbf{r}\}w_{lk}(\mathbf{r}) \quad \text{for odd } N, \quad (41)$$

$$w_{lk}[\mathbf{r}+(N/2)\mathbf{a}_2]=\exp\{-i(N/2)\mathbf{a}_2\times\mathbf{h}\cdot\mathbf{r}\}w_{lk}(\mathbf{r}) \quad \text{for even } N.$$

One should note that the appearance of $N/2$ for even N is in agreement with the distinction between even and odd N in the construction of the irreducible representations (23).

There are two interesting points connected with the generalization for an infinite M.T.G. The first point is that by changing the magnetic field *continuously* we can pass from case (37) to case (36). This means that by changing the magnetic field by an amount which can be as small as we like we change the degeneracy from a finite one (given by the number N) to an infinite one. We thus see that the representations are very sensitive to the magnitude of the magnetic field. The relation (37) can also be written in a different way by multiplying both sides by $\mathbf{a}_1\times\mathbf{a}_2$. We get (by using the definition of $\mathbf{h}$):

$$\frac{\mathbf{H}\cdot\frac{1}{2}(\mathbf{a}_1\times\mathbf{a}_2)}{hc/e}=\frac{n}{N}, \quad (42)$$

where h is Planck's constant. In the numerator on the left of (42) we have the flux of the magnetic field through an elementary area enclosed by the vectors $\mathbf{a}_1$, $\mathbf{a}_2$ and $-(\mathbf{a}_1+\mathbf{a}_2)$. The quantity hc/e is the elementary quantum of magnetic flux (fluxon) which is of great importance in superconductivity[9] and may have an influence on the significance of potentials in quantum mechanics.[10] From Eq. (42) it follows that the representations of the magnetic group are finite when the ratio of magnetic flux through areas enclosed by any vectors of the Bravais lattice to the elementary fluxon are given by rational numbers. Through Eq. (42) we come also to the second point, namely, when the ratio given by this equation is an integer, all the constant factors in the definition of the elements of the M.T.G. [Eq. (1)] will be unity. In this case the magnetic translation group will be isomorphic to the usual translation group and all the irreducible representations of the first will become one dimensional, and one has an energy band picture as in the Bloch case. In this connection, it is interesting to refer to the work of Azbel[11] who shows that for a special Hamiltonian all physical properties of electrons in a magnetic field are periodic in the magnetic field with a period

$$\mathbf{h}=(4\pi/V)\mathbf{a}_3. \quad (43)$$

The relation (43) expressed in the form (42) is just a requirement on the magnetic flux through areas enclosed by any Bravais lattice vectors to be multiples of the fluxon hc/e. The fields satisfying condition (43) must be of the order of 10^{10} G for $a\approx10^{-8}$ cm, and cannot be practically achieved. The fundamental significance of flux quantization in the problem under discussion is, however, of great interest and requires further investigation.

V. CONCLUSION

We have indicated the usefulness of the magnetic translation group for investigating the dynamics of a Bloch electron in a magnetic field. From the irreducible representations of the M.T.G. a set of orthonormal functions was constructed. It turns out that when a magnetic field is present the imposition of boundary conditions leads to quantization of the field, i.e., by imposition of boundary conditions on crystals, even of dimensions of the order of 1 cm, the magnetic field can only take values which differ by about 10 G. (It has been usual to assume that the Born-von Karman boundary conditions have no influence on the physical description of an electron in a periodic potential.[12]) It was therefore important for us to remove the boundary conditions. By doing so, we found the irreducible representation of the M.T.G. (and the symmetry adapted functions) when the magnetic field is required to be along a lattice vector—without any restrictions on the magnitude of the magnetic field. It turns out that the representations are very sensitive to whether or not condition (42) holds.

It would be interesting to find the representations of the M.T.G. without any requirements on the magnetic field at all.

ACKNOWLEDGMENTS

The author would like to thank the National Magnet Laboratory for its very kind hospitality and especially Dr. Arthur J. Freeman for helpful discussions and valuable suggestions in preparing the manuscript. The author would also like to thank Professor G. F. Koster for reading the manuscript and for his encouragement.

PHYSICAL REVIEW VOLUME 134, NUMBER 6A 15 JUNE 1964

Nuclear Magnetic Relaxation of the Impurity Nucleus in Dilute Ferromagnetic Alloys

R. L. STREEVER
National Bureau of Standards, Washington, D. C.
(Received 27 January 1964)

We have measured the nuclear relaxation times T_1 and T_2 for 1% Ni^{61} in 99% iron, 1% Ni^{61} in 99% cobalt, and 0.5% Co^{59} in 99.5% nickel at several temperatures using the pulsed-free precession method. The relaxation curves are generally nonexponential and power-dependent. The signals at low-power levels are from nuclei in domain walls and T_1 is due to thermal fluctuations of the domain walls. At high-power levels, where the signal is mainly from nuclei in domains, the longest measured relaxation times T_1 are lower limits for relaxation times for nuclei in domains. The longest T_1's are found to be inversely proportional to temperature with $T_1T=1.0$ sec °K for 1% Ni^{61} in cobalt, $T_1T=1.2$ sec °K for 1% Ni^{61} in iron, and $T_1T=0.3$ sec °K for 0.5% Co^{59} in nickel, and are believed to be due to conduction electron relaxation. The quantity $1/\gamma_n^2T_1T$ (where γ_n is the nuclear gyromagnetic ratio) is a normalized measure of the strength of the conduction electron relaxation mechanism and is found to be smaller for the impurity nuclei than for the nuclei of the solvent atoms in the pure solvent metal. This is believed to show that the relaxation of the nuclei by the conduction electrons (which is enhanced in the pure metals by spin waves) is slower for the nuclei on the solute atoms in the alloys due to a reduction of the spin wave enhancement. T_2 for Ni^{61} in cobalt is 0.15 msec at room temperature and is believed to be due to a coupling of Ni^{61} and Co^{59} nuclei by the Ruderman-Kittel interaction.

I. INTRODUCTION

In the pure metals, iron, cobalt, and nickel, the nuclear relaxation times T_1 and T_2 have been measured by Weger[1–3] by the free precession method. The decay of the longitudinal and transverse magnetization in the ferromagnetic metals is found to be nonexponential and a function of the rf power level. Nuclei in the domain walls experience a large enhancement of the applied rf level due to the domain wall motion. Thermal fluctuations of the domain walls also provide a relaxation mechanism; consequently, at low rf pulse levels, the nuclear signals are from nuclei near the center of the domain walls which have the largest rf enhancement and shortest relaxation times. At higher rf pulse amplitudes signals come from nuclei farther out from the centers of domain walls, which have lower enhancements of rf fields and longer relaxation times. Finally, at very high rf pulse levels, signals come primarily from nuclei in the domains which see a much smaller rf enhancement than those in the domain walls. For these nuclei, relaxation times T_1 are longer, being determined by conduction electrons now and no longer by domain wall motions. For T_2, the experimental situation is more complicated. For low abundance of nuclear spins and at high temperatures the nuclear spin-spin interactions can generally be neglected. In this case, T_2 is found to be of the same order as T_1. For cases in which nuclear spin-spin interactions are important, as in pure cobalt, these determine T_2.

In the present work we have used the free precession method to measure T_1 and T_2 for Ni^{61} in dilute alloys of 1% Ni^{61} in cobalt[4] and iron,[5] and for Co^{59} in a 0.5% Co^{59} in nickel alloy.[6] Preliminary to studying relaxation times of the impurity nuclei in the alloys, some measurements were also made of T_1 and T_2 for Ni^{61} in pure unenriched nickel powders to determine the effect of annealing on the relaxation times. The Ni^{61} relaxation times were also measured in the 0.5% cobalt in nickel alloy to determine the effect of the cobalt impurity on the Ni^{61} relaxation.

In Sec. II the experimental methods and techniques are discussed. In Sec. III we review briefly the theory of relaxation, both in domain walls and in the domains. In Sec. IV we give the experimental results, and compare them with the theory.

II. EXPERIMENTAL METHOD AND TECHNIQUE

A. Equipment

We have used the free precession method to measure the inhomogeneous linewidth and the longitudinal and transverse relaxation times T_1 and T_2. A pulsed push-pull rf oscillator (Arenberg Ultrasonic Laboratories Model 650-C) was used to supply the rf pulses. The widths of the rf pulses used were about 1 μsec and the maximum rf voltage level was about 300 V peak-to-peak rf. The metal powder was inserted in the rf coil of the oscillator. A second coil coaxial to the first was used to detect the free precession signal. It was convenient to heterodyne the nuclear signal with a mixing frequency differing by about 20 Mc/sec, using a television tuner. The television tuner was followed by a wide-band rf

amplifier and detector. The video signal was then amplified and observed directly on the oscilloscope. The dc pulses necessary to gate the pulsed oscillator were supplied by appropriate combinations of Tektronix Nos. 162 and 163 units.

B. Measuring Methods

To measure T_1 and T_2, one usually employs a method in which one makes use of 90° and 180° pulses. In a ferromagnetic metal as a result of the skin depth and the distribution in enhancement factors, different nuclei see different rf fields. Consequently, 90° and 180° pulses are impossible to obtain. The decay of the magnetization in the transverse direction with time constant T_2 is, however, independent of pulse adjustments and T_2 can be obtained from the echo decay envelope. To measure T_1, we saturated the nuclear signal with one or more closely spaced rf pulses, and then monitored the recovery of the magnetization by observation of the echo following two closely spaced pulses applied some time after the saturating pulses. An echo rather than a single pulse was used to sample the recovery of the magnetization because for the broad resonance lines where the echo width is a few μsec, the receiver blocking after the rf pulse makes the decay itself impossible to observe. Weger[1] has shown that the above method is subject to some error due to diffusion of magnetization in space out of the domain walls. By applying a large number of saturating pulses whose separation is much less than T_2, this effect can to a large extent be overcome.

The relaxation times T_1 and T_2 were measured as a function of rf pulse amplitude. The echo signal following two pulses of equal width goes from zero through a maximum at low rf pulse amplitudes as the pulse amplitude is increased from zero, then slowly decreases again as the pulse amplitude is further increased, as discussed in Ref. 1. The variation in the echo signal intensity results from the distribution in rf fields due to skin depth and a distribution in enhancement factors, and the signal reaches a maximum when $\gamma_n\eta_1 H_1 t_w \sim \pi/2$. Here η_1 is an *average effective* enhancement factor, $2H_1$ is the linearly applied rf field, t_w is the pulse width, and γ_n is the nuclear gyromagnetic ratio. The relaxation curves were in general nonexponential, and a function of the amplitude of the rf pulses for a given pulse width, which was usually about one μsec. T_2 and T_1 can in the case of a nonexponential decay be defined for any point on the relaxation curves from the slope. That is,

$$1/T_2 = -d\ln M(t)/dt,$$

where $M(t)$ is the amplitude of the echo signal at a time t after the first pulse and

$$1/T_1 = -d\ln[M(\infty)-M(t)]/dt,$$

where $M(t)$ is the value of the sampling signal at a time t after the last saturating pulse.

C. Samples

The majority of the relaxation time studies were made on alloy powders of 1% Ni^{61} and 99% cobalt,[4] 1% Ni^{61} and 99% iron,[5] and 0.5% Co^{59} and 99.5% nickel[6] (all atomic percents). The Ni^{61} in cobalt was annealed for $\frac{1}{2}$ h at 600°C. The Ni^{61} in iron sample was annealed for $\frac{1}{2}$ h at 680°C. The Co^{59} in nickel sample was annealed for 1 h at 1100°C, but some measurements were also made on an unannealed sample. The relaxation times for nuclei in the domain walls is expected to depend somewhat on the degree of particle annealing and will be discussed in Sec. III.A. The average particle size was about 10 μ. More details of sample preparation have been previously discussed.[4–6]

Some studies were also made on the Ni^{61} resonance in pure unenriched nickel samples with various degrees of annealing to investigate the effects of strains on the relaxation times. These samples were all 10 μ powders. The preparation of the pure nickel samples has been discussed previously.[7]

III. THEORY

A. Relaxation in the Domain Walls

Nuclear relaxation in the domain walls has been studied both theoretically and experimentally by several authors.[1,3,8–10] For the pure metals Weger[3] gives for $1/T_1$

$$1/T_1 = (kT\tau_c\omega^2/\delta^2\pi M_s^2)(1+\omega^2\tau_c^2)^{-1}. \quad (1)$$

Here k=Boltzmann constant, T=absolute temperature, τ_c=correlation time for wall motion due to thermal fluctuations, δ=wall thickness, M_s=saturation magnetization, and ω=resonance frequency. For cobalt at room temperature Eq. (1) gives good agreement with experiment.[3] For the pure metals and the alloys studied in this paper, $\omega\tau_c<1$ is a good approximation. In this limit

$$1/T_1 = kT\tau_c\omega^2/\pi\delta^2 M_s^2. \quad (2)$$

The weak temperature dependence of T_1 in the pure metals is believed to arise because while kT enters directly into Eq. (2), τ_c probably increases with decreasing temperature due to greater eddy current damping of the domain wall motion.[3]

Equation (2) was derived for the pure metals; however, quite generally in the limit $\omega\tau<1$ the relaxation time will be given by (see Ref. 11)

$$1/T_1 = \langle H_f^2\rangle\gamma_n^2\tau_c. \quad (3)$$

Here H_f is the fluctuating field perpendicular to the hyperfine field H_n resulting from thermal fluctuations

of the domain wall. Equation (3) can be rewritten

$$1/T_1=\langle\theta^2\rangle\gamma_n^2H_n^2\tau_c=\langle\theta^2\rangle\tau_c\omega^2, \quad (4)$$

where θ is the angular displacement of the electron spin in the domain wall.

At a given temperature Eq. (4) shows that either an increase in the amplitude of the wall motion or the correlation time of the motion will shorten T_1. These parameters should be sensitive to the degree of anneal of the metal. Hence, in the pure metals, for example, in pure nickel, we might expect the Ni^{61} relaxation times T_1 to depend on the degree of annealing of the sample. Also, for the same annealing time we might expect the parameters $\langle\theta^2\rangle$ and τ_c to depend on the concentration of impurities so that the relaxation times T_1 of the solvent nuclei might be expected to depend on the impurity concentration. We also see from Eq. (4) that samples with the highest rf enhancements (due to domain wall motion) will be expected to have the shortest relaxation times for the nuclei in domain walls, a result previously noted.[10]

Consider now the relaxation time of the nuclear spin of the solute atom. From Eq. (4) we see that if the impurity spin in the domain wall moves with the same correlation time and angular displacement as the solvent atom spin in the dilute alloy, then the value of $T_1\omega^2$ for the nuclei of the solute and solvent atoms should be equal. This relation is used in Sec. IV.C to discuss values of T_1 measured for the nuclei of the solute atoms in the domain walls.

B. Relaxation in the Domains

The spin-lattice relaxation time for nuclei in the domains has been considered by Weger.[3] The relaxation time T_1 for nuclei in domains due to conduction electron relaxation is given by the expression

$$1/T_1=(kT\omega^2a^2\Sigma)(h\omega_d^2 32\pi^3S^2)^{-1}, \quad (5)$$

where a=lattice constant, ω_s=parameter describing spin-wave spectra, S=average spin/atom, Σ=area of Fermi surface, ω=nuclear resonance frequency, k=Boltzmann constant, and T=absolute temperature.

Equation (5) applies to the pure metals and the T_1 mechanism is a second-order process which involves the coupling of the nuclei to the unpaired electron spins through the hyperfine interaction ($A\mathbf{I}\cdot\mathbf{S}$) and the coupling of the electron spins to the conduction electrons through the *sd* coupling. The intermediate states involve the excitation of spin waves.

In the cases where hyperfine fields are proportional to local atomic moments (this is, at least, roughly true for the cases of concern here),[5] the factor (ω^2/S^2) appearing in Eq. (5) is just proportional to γ_n^2, where γ_n is the nuclear gyromagnetic ratio. Quite generally, the quantity $1/\gamma_n^2T_1T$ is a normalized measure of the strength of the conduction electron relaxation mechanism. If the mechanism in which the nuclear relaxation is enhanced by the spin waves applies to the solute nuclei in the dilute alloys, as well as to the pure metals, then the quantity $\gamma_n^2T_1T$ would be expected to be of the same order of magnitude for the nucleus of the solute atom in the dilute alloy as for the nuclei of the solvent atoms in the same alloy or in the pure solvent metal. One might expect that the creation of spin waves by a spin flip of the solute atom will in general involve a higher energy than in the case of the same process in the pure metal and that the enhanced conduction electron relaxation mechanism will be weaker for the solute nuclei. In this case the quantity $\gamma_n^2T_1T$ will be longer for the solute nuclei and closer to its value in the nonferromagnetic materials.

C. Transverse Relaxation

Weger has measured T_2 as well as T_1 in the pure metals; iron, cobalt, and nickel.[1–3] In the case of Ni^{61} or Fe^{57} in the pure unenriched metals, where nuclear spin-spin interactions are weak, T_2, at least at higher temperatures and in the domain walls, is of the order of T_1 and the transverse relaxation is related to the T_1 mechanism. In the case of Co^{59} in pure cobalt where the abundance of active nuclei is high, T_2 is determined by nuclear spin-spin interactions.

At low temperatures in the domains where T_1 is long, T_2 may be determined by a mechanism of the type discussed by Moriya.[12] He considers in detail nuclear relaxation in antiferromagnets; however, similar considerations would apply to ferromagnets as well. Fluctuations in S_z can arise from the interference of two spin waves and might be particularly important in the alloys. These fluctuations would be very effective for relaxation since they occur at lower frequencies than the spin waves. Hence, at low temperatures in the domains, we might expect $T_2<T_1$, even in cases where the nuclear spin-spin coupling can be neglected.

IV. RESULTS AND DISCUSSION

A. T_1 and T_2 for Ni^{61} in Pure Nickel and in the Dilute Alloys

Preliminary to studying relaxation times of the solute nuclei in the dilute alloys, measurements were made of T_1 and T_2 for Ni^{61} in pure unenriched nickel powder with a particle size of 10 μ or less to determine the effect of annealing. The measurements were made at 77°K and the initial relaxation rates were measured at low pulse levels to determine T_1 and T_2 appropriate to the nuclei in domain walls. We found for unannealed samples or for samples annealed for 1 h at 300 and 500°C that T_1 was roughly independent of annealing and about 1.2 msec with T_2 about 0.3 msec. In nickel annealed at 1100°C for 1 h, however, T_1 decreased to 0.5 msec and T_2 to 0.06 msec. The Ni^{61} relaxation time

[12] T. Moriya, Progr. Theoret. Phys. (Kyoto) 16, 641 (1956).

appropriate to nuclei in domain walls was also measured at 77°K in a sample of 99.5% nickel and 0.5% cobalt, which was annealed at 1100°C for 1 h. T_1 was found to be 1.3 msec, which is about the same as the T_1 in the pure nickel which was not well annealed.

The decrease in T_1 in the well-annealed samples can be explained as follows: In the well-annealed nickel, the initial permeability is high and we expect a larger amplitude for the domain wall motion (for a given excitation). This is in agreement with previous continuous-wave studies,[7] where the large dispersion signals in the well-annealed samples were explained partly by the larger rf enhancements in these samples. The decrease in T_2 is partly related to the T_1 decrease; however, the ratio of T_1 to T_2 is even greater in the well-annealed sample, indicating that fluctuations in S_z along the direction of the nuclear hyperfine field may be more important here. We also see that in the well-annealed sample of 0.5% cobalt in nickel the Ni^{61} relaxation time T_1 is about the same as in the unannealed pure nickel. Both strains as well as impurities seem to have the effect of limiting the displacement of the domain walls and lengthening the relaxation time. For the same annealing time at least the relaxation time is longer in the 0.5% cobalt sample than in the pure nickel.

B. T_1 and T_2 of the Solute Nuclei in the Alloys

The longitudinal and transverse relaxation curves were obtained as a function of pulse level at various temperatures, as discussed in Sec. II.B, for the solute nuclei in annealed samples of 1% Ni^{61} in cobalt, 1% Ni^{61} in iron and 0.5% Co^{59} in nickel. The relaxation curves were, in general, nonexponential and dependent on the pulse level. The longest and shortest times are given in Table I. The shortest times T_{10} and T_{20} were determined from the initial slopes of the respective relaxation curves obtained at a low pulse amplitude below that at which the echo signal went through a maximum, and are believed to approach the shortest relaxation times appropriate to nuclei near the center of the domain walls. The longest times T_{1M} and T_{2M} were measured at the highest pulse level from the slope of the respective relaxation curves at the farthest time out, and are believed to approach the values for nuclei in the domains. The highest rf pulse level which was roughly 12 times that at which the echo signal went through a maximum corresponded to an H_1 of roughly 6 G for Ni^{61} in cobalt and Ni^{61} in iron and about 3 G for Co^{59} in nickel.

TABLE I. Relaxation times for the impurity nuclei in the dilute alloys, T_{10} and T_{20} are the relaxation times appropriate to nuclei in domain walls, while T_{1M} and T_{2M} approach the relaxation times in domains as discussed in the text.

Temp. (°K)	T_{10} (msec)	T_{1M} (msec)	T_{20} (msec)	T_{2M} (msec)
		1% Ni^{61} in Cobalt		
300	1.4	3.5	0.15	0.15
77	2.0	13	0.18	0.18
4	3.5	250	0.19	0.22
		1% Ni^{61} in Iron		
300	0.7	4	0.17	2.0
77	1.7	15	0.6	2.4
4	6.0		1.0	3.0
		0.5% Co^{59} in Nickel		
300	0.05	1	0.03	0.12
77	0.13	4	0.04	0.18
4	1.4		0.15	0.34

The longitudinal relaxation curves were dependent on the rf pulse level, nonexponential at low pulse levels and more nearly exponential at higher pulse levels, where the signal was mainly from nuclei in domains. For the case of Ni^{61} in iron and Co^{59} in nickel, the transverse decay curves at the higher temperatures were also dependent on the pulse level and nonexponential and T_2 in the domain walls was of the same order as T_1, indicating it was related to the T_1 mechanism. At lower temperatures, particularly in the domains, T_2 is seen from Table I to be much less than T_1 and less dependent on pulse level. In the case of Ni^{61} in cobalt, the transverse decay curves are nearly exponential and T_2 was nearly independent of pulse level. The nearly unique value of T_2 for this case indicates it is being determined by nuclear spin-spin interactions, a similar result having been observed for the case of Co^{59} in pure cobalt metal.[1]

The inhomogeneous linewidths at room temperature obtained from the width of the echo (assuming an exponential decay) and measured by the quantity $1/\pi T_2^*$ were about 240 kc/sec for 1% Ni^{61} in cobalt and 190 kc/sec for 0.5% Co^{59} in nickel and were in approximate agreement with continuous wave measurements. The 1% Ni^{61} in iron width (~700 kc/sec) was too broad to estimate accurately from the width of the echo.

C. Discussion of T_1 in Domain Walls

In Table II we have compared the value of T_{10} (the T_1 appropriate to nuclei in domain walls) for the nuclei in the dilute alloys with the shortest T_1's measured in the pure solvent metals by Weger[2] which correspond to our T_{10}'s. In view of Eq. (4), if the angular displacement and the correlation time associated with the thermal fluctuations of the solute electron spin in the domain wall were the same as for the electron spin in the pure solvent metal, then the quantity $T_{10}\nu^2$ (where ν is the resonance frequency) should be the same for the solute nucleus as for the nucleus in the pure solvent metal. In the last two columns of Table II we compare the quantity $\nu^2 T_{10}$ for the solute nuclei in the alloys and the nuclei in the pure solvent metal. We see that in all cases this quantity is longer for the solute nuclei. This can probably be understood as due to the fact that the thermal fluctuations of the domain wall in the dilute

alloy tend to be decreased compared with those in the pure solvent metal.

Although in Table II the T_{10} for the solute nuclei is compared with the T_{10} in the pure host nickel, it would be better to actually compare the relaxation times for the nuclei of the solute and solvent atoms in the same sample. In the case of 0.5% cobalt in nickel at 77°K we have done this. As already discussed (see Sec. IV.A), T_{10} for the Ni^{61} in a sample annealed for one hour at 1100°C was 1.3 msec, while for Co^{59} the value of T_{10} in the same sample was 0.13 msec. From Eq. (4) we see then that $\langle\theta^2\rangle\tau_c$ is about one-half as large for the Co^{59} as for the Ni^{61}, and this probably represents a somewhat smaller angular displacement of the cobalt spin in the domain wall.

In the 0.5% cobalt in nickel sample, the Co^{59} relaxation times in domain walls were found to be nearly independent of annealing time. This seems to indicate that in this sample the solute atoms themselves rather than the degree of anneal are limiting the wall motion.

D. Discussion of T_1 in the Domains

The longer times T_{1M} given in Table I are nearly inversely proportional to temperature and are believed to approach the limiting value of T_1 appropriate to the nuclei in domains and to be determined by relaxation through the conduction electrons. The quantity $1/\gamma_n^2T_{1M}T$ is a measure of the strength of the conduction electron relaxation mechanism normalized for the difference in nuclear gyromagnetic ratios. In Table III we compare $\gamma_n^2T_{1M}T$ for the nuclei on the impurity atoms with the corresponding quantity for the nuclei of the pure host metal using the value of T_1T measured in the pure metals by Weger.[3] We also list in the same table the atomic magnetic moments measured by neutron diffraction.[13,14]

The quantity $\gamma_n^2T_{1M}T$ is seen in all cases to be greater for the impurity nucleus than for the nucleus of the corresponding pure host metal and this is particularly true for the case of 0.5% Co^{59} in nickel. Also, especially in the case of Ni^{61} in iron where the signal at high power levels was weak and the dependence of T_1 on the power level was quite strong, we cannot be sure we have measured the longest time so that the T_{1M} is only a lower limit for the value of T_1 in the domains.

The longer relaxation times for the impurity nuclei can probably be understood qualitatively as representing a partial decoupling of the spin on the impurity

TABLE III. A comparison of the quantity $T_{1M}T$ for the impurity nuclei in the dilute alloys (from Table I) with the corresponding quantity in the pure host metal, as measured by Weger.[a] The quantities $\gamma_n^2T_{1M}T$ are also compared.[b] The atomic moments[c] in Bohr magnetons (bm) are also given.

Nucleus	μ (bm)	$T_{1M}T$ (sec°K)	γ_n (cps G^{-1})	$\gamma_n^2T_{1M}T$
Co^{59} in Co	1.7	0.08	6.27×10^3	3.1×10^6

atom from the spin-wave spectrum; that is, a spin flip of the impurity atom spin, which is different from that of the host (see Table III), will probably in general require a higher energy than for the case of the pure metal. This probably reduces the enhancement of the conduction electron relaxation by the spin waves.

Note also that while $\gamma^2T_{1M}T$ for Ni^{61} in cobalt and iron is longer than in pure nickel, it is still shorter than γ^2T_1T for the case of a nonferromagnetic metal like Cu^{63} in copper where γ^2T_1T is about 45×10^6 (with γ in cpsG^{-1} and T_1T in sec °K).[15] Similarly, while $\gamma^2T_{1M}T$ for Co^{59} in nickel is longer than for Co^{59} in pure cobalt, it is still less than γ^2T_1T for V^{51} in vanadium, where γ^2T_1T is about 39×10^6.[16]

E. Discussion of T_2

In the case of Ni^{61} in cobalt, T_2 is being determined by nuclear spin-spin interactions. We will discuss various coupling mechanisms. The Suhl-Nakamura interaction[17,18] involving virtual excitation of spin waves is a nuclear spin-spin coupling mechanism for Co^{59} in pure cobalt.[1] This mechanism, however, at least in the pure ferromagnets and at low temperatures (well below the Curie point), couples nuclear spins according to $I_1^+I_2^-+I_2^+I_1^-$ and this would not be a broadening mechanism for unlike nuclear spins which would not be precessing at the same Larmour frequency.[18] This would probably to a large extent be true also for the case of 1% Ni^{61} in cobalt, where the spin-wave excitations are still mainly transverse.

The Ruderman-Kittel[19] interaction involving a scalar coupling between nuclear spins would be a broadening mechanism for unlike spins. One might argue that the same mechanism which leads to the short values of T_1T for both Co^{59} and Ni^{61} in the 1% Ni^{61} in cobalt alloy would also lead to an enhanced Ruderman-Kittel interaction. However, an enhanced interaction of this sort involving spin-wave excitations would at low temperatures be anisotropic in the same way as the Suhl interaction and would not be effective in broadening unlike spins. However, the ordinary Ruderman-Kittel interaction is about the right value to explain the observed T_2. This can be seen as follows: In the case of Cu^{63} in copper metal, the experimental results could be explained by taking the scalar indirect exchange coupling A/h between two nearest Cu^{63} neighbors to be about 420 cycles or three times the calculated value.[15] Assuming a similar coupling between the nickel and cobalt nuclei leads to an exchange coupling between neighbors of

$$420\gamma(Co^{59})\gamma(Ni^{61})/[\gamma(Cu^{63})]^2=120 \text{ cycles}.$$

The nearest-neighbor contribution to the Van Vleck second moment is then given by

$$\langle\Delta\nu^2\rangle=4I(I+1)(A/h)^2.$$

This gives a width $[\langle\Delta\nu^2\rangle]^{1/2}$ of about 1 kc/sec or T_2 about 0.2 msec. Although the above is the order of magnitude of the T_2 observed, the fast spin exchange of the Co^{59} nuclei would tend to narrow the line and make the shape more nearly Lorentzian so that an exact calculation of T_2 is difficult.

In the case of Ni^{61} in iron and Co^{59} in nickel (where we believe we can neglect nuclear spin-spin interaction) the T_2 relaxation mechanism is evidently related to T_1 at high temperatures in the domain walls. At low temperatures, particularly in the domains, T_2 may be due to the mechanism discussed by Moriya. However, the situation is not completely understood.

V. CONCLUSION

The longitudinal relaxation times for the nuclei at the solute atoms in the domain walls in these alloys can be understood as due to the motion of the domain walls. However, it appears that the relaxation time for the solute nuclei will generally be somewhat longer than the relaxation time for the nucleus at the host atom due to the pinning of the domain wall near the solute atom. In the domains it appears that the coupling of the nucleus to the conduction electron which determines T_1 at high power levels is weaker for the solute atom than for the host atom in these materials. In the case of Ni^{61} in cobalt, T_2 is being determined by nuclear spin-spin interaction. A Ruderman-Kittel indirect coupling of nuclei by conduction electrons seems to account for the observed value of T_2.

Further Results on the Fermi Surface of Beryllium*

T. L. Loucks†
North American Aviation, Tulsa, Oklahoma
(Received 3 January 1964)

Following the methods presented in an earlier paper, the conduction eigenvalues for beryllium at the equivalent of over 80 000 points in the first Brillouin zone (all in the immediate vicinity of the Fermi surface) were calculated. The constant energy surfaces were constructed for several values of the energy near the Fermi energy. The hole and electron volumes were calculated for each case, and the Fermi energy was determined by the requirement that the two volumes be equal. This is the first time that this well-known result has actually been used to determine the Fermi energy in a band calculation. The corresponding Fermi surface was defined by about ten cross sections perpendicular to the [0001] direction. The agreement between these results and experiment is generally good and slightly improved over the previous results.

INTRODUCTION

IN a previous article[1] the Fermi surface of beryllium was determined theoretically and compared with the experimental results of Watts.[2] The surface was constructed from conduction electron eigenvalues at the equivalent of 5184 general points in the first Brillouin zone (BZ). These eigenvalues were calculated by expanding the wave functions in a linear combination of 23 orthogonalized plane waves (OPW's). The crystal potential used in these calculations was self-consistent and its construction was fully described in the original article.

The same program which was developed for the earlier calculations has been used to calculate the conduction electron eigenvalues at the equivalent of over 80 000 points in the first BZ. All of these points were in the immediate vicinity of the Fermi surface. From these eigenvalues the Fermi energy was determined for the first time by the well-known requirement that the hole and electron volumes be equal. The Fermi surface corresponding to this Fermi energy was constructed and is presented in this report. It differs only slightly from the previous results, but tends to bring the theoretical and experimental results into closer agreement. The interesting feature here is not the new results, but rather the reminder that there is available, through the application of a well-known conservation requirement, a method of determining the Fermi energy which requires the calculation of energy eigenvalues only in the vicinity of the Fermi surface.

DETERMINING THE FERMI ENERGY

In the work of Loucks and Cutler[1] the Fermi energy was determined in the usual way by arranging in increasing value the energy eigenvalues which were calculated for representative points throughout the BZ. The energy corresponding to the highest occupied state was taken to be the Fermi energy. This method, although correct in principle, suffers in that it is difficult to get a representative sample of points (particularly near the zone edges) without calculating the eigenvalues at an extremely large number of points throughout the zone. Many of these points are not near the Fermi surface and hence are of little value except in the counting procedure for the determination of the Fermi energy.

The method proposed here has the advantage that all eigenvalues are calculated at points in the immediate vicinity of the Fermi surface. Thus, they serve not only to determine the Fermi energy but also to define more accurately the surface itself. In addition it provides enough information about the other energy surfaces near the Fermi surface to enable one to calculate first and second derivatives for use in determining such parameters as the density of states at the Fermi energy and the effective mass.

Essentially, the method employed is based on the obvious conservation requirement that the hole volume in the first double zone must equal the volume of the electron pockets in the second double zone. Since the electrons spill out of one zone into the next in order to

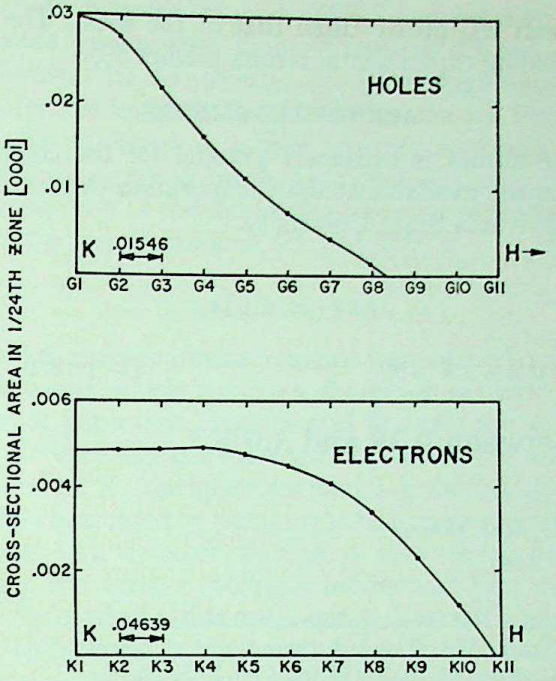

FIG. 2. Cross-sectional area of electron and hole surfaces in 1/24th zone for planes perpendicular to the [0001] direction.

minimize the energy, the vacated volume must be exactly equal to the volume occupied by the electrons. This is an admittedly obvious fact. However, it has never been used in practice to determine a theoretical value of the Fermi energy from a band calculation. The reason it has been avoided is perhaps because of the large number of calculations necessary to determine the electron and hole volumes. In this work they were determined for each of several constant energy surfaces near the Fermi surface. The results are plotted in Fig. 1. The curves of the hole volume and electron volume were found to intersect at $E_F=0.909$ Ry. The Fermi energy presented in the original paper was $E_F=0.901$ Ry.

FERMI SURFACE OF BERYLLIUM

The constant energy surface was constructed at $E_F=0.91$, as well as at other points, in constructing the curves shown in Fig. 1. Since we have found that the true Fermi energy is $E_F=0.909$, it is within the accuracy of the procedure used in constructing the surfaces to consider the one for $E_F=0.91$ to be the Fermi surface. These results are presented in Figs. 2, 3, and 4. In Fig. 2 the cross-sectional area perpendicular to the [0001] direction is shown for the holes and the electrons. In both drawings the left-hand side represents the symmetry point K, and the abscissa corresponds to distances measured along the symmetry edge KH. The identifications such as G1, G2, etc., correspond to the cross sections shown in Fig. 4. It should be noticed that in the lower curve of Fig. 2, corresponding to the electron cigars, the abscissa extends from K to H. However, in the upper curve, corresponding to the hole coronet, the distance between G1 and G11 extends only $\frac{1}{3}$ of the distance from K to H. Figures 3 shows the intersection of the Fermi surface with the 1/24th zone faces.

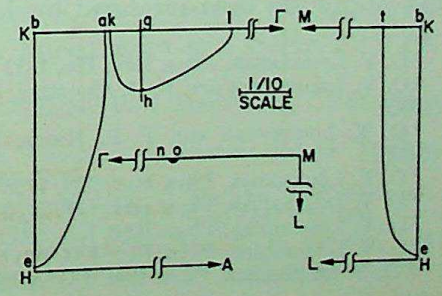

FIG. 3. Intersections of Fermi surface with faces of the 1/24th zone.

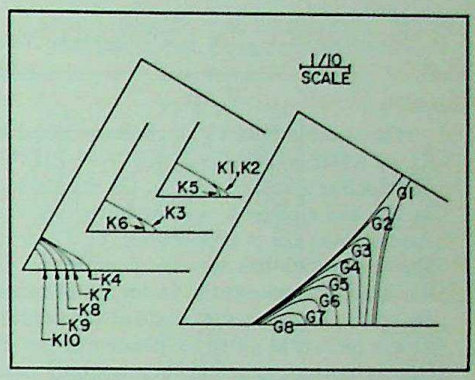

FIG. 4. Intersections of Fermi surface with planes perpendicular to the [0001] direction.

DISCUSSION

The Fermi surface which corresponds to the Fermi energy determined by the above method is compared to the previous theoretical results and the experimental results in Table I. It is seen that the agreement between the present theory and experiment is very good, especially for the bottom four entries which correspond to the coronet. However, the theoretical cigar is still shorter than the experimental one and almost triangular, rather than circular in cross section. This almost triangular shape also yields extremal cross-sectional areas

which are consistent with the observed de Haas–van Alphen frequencies. Further experiments or calculations which can distinguish between this model and the circular one proposed by Watts are necessary. It should be noticed in Fig. 2 that there is a waist on the almost triangular cigar. This is also consistent with the de Haas–van Alphen data. The larger cross-sectional area is about 2% greater than that of the waist. The corresponding experimental results predict 3%.

Specific Heat of Thulium Metal Between 0.38 and 3.9°K*

O. V. LOUNASMAA†
Argonne National Laboratory, Argonne, Illinois
(Received 20 January 1964)

The specific heat C_p of thulium metal has been measured in a He^3 cryostat. Between 0.38 and 3.9°K $C_p=2.839T^3+17.94T+23.43T^{-2}-1.79T^{-3}-0.066T^{-4}$ (in mJ/mole °K). The last three terms represent the nuclear specific heat C_N. On the basis of earlier estimates, we put $C_L=0.243T^3$ and $C_E=10.5T$ for the lattice and electronic specific heats, respectively. According to the simple spin-wave theory, the magnetic specific heat C_M is proportional to T^3 for a ferrimagnetic metal; experimentally one finds $C_M=6.2T^{5/2}$ for thulium, which has a rather complicated ferrimagnetic structure. Further, there seems to be no evidence in C_M for an exponential factor, to be expected because of magnetic anisotropy. All conclusions on C_M are tentative, however, until data at temperatures between 4 and 20°K become available. C_N does not fit to the simple picture as given by Bleaney either. Since $I=\frac{1}{2}$ for the only stable thulium isotope Tm^{169}, quadrupole interactions are zero and there are only two nuclear energy levels, their separation being determined by the magnetic hyperfine constant a'. This would give a nuclear specific heat with even powers of T only, with a' determining the values of the coefficients. The observed C_N cannot be fitted into an equation of this type which indicates that other interactions, probably nuclear exchange interactions, are present. Formally, the experimental situation may be expressed by writing $a'=a_0-b/T$, instead of treating a' as a constant. Our results are in good agreement with recent Mössbauer data by Kalvius *et al.* who found 22.9 for the coefficient of the T^{-2} term.

I. INTRODUCTION

At low temperatures, the specific heat of rare-earth metals has four components which, depending on circumstances, can be separated totally or partially from each other. These are the lattice specific heat $C_L=AT^3$, the electronic specific heat $C_E=BT$, the magnetic specific heat C_M, and the nuclear specific heat C_N. In the higher lanthanides, C_M is primarily caused by exchange interaction between the $4f$ electronic spins. At 4.2°K and below, thulium has a unique ferrimagnetic structure, to be described in some detail later (cf. Sec. IV.B).[1] It is interesting to see how well the magnetic specific heat follows the prediction, $C_M=CT^3$, of the simple spin-wave theory.[2]

C_N is due to splitting of the nuclear spin states by interaction with the $4f$ electrons. By far the largest contribution to C_N comes from the magnetic field produced by the orbital angular momentum of the $4f$ electrons. The resulting nuclear specific heat has the familiar appearance of a Schottky curve with its maximum somewhere below 0.1°K. Above the maximum, C_N may be expressed in inverse powers of T, the leading term being proportional to T^{-2}.

According to the above discussion the total specific heat of thulium becomes

$$C_p=AT^3+BT+C_M+C_N, \qquad (1)$$

where A and B are constants.

The present measurements on thulium are a part of our research program for studying the heat capacities of rare-earth metals between 0.4 and 4°K,[3–10] with particular emphasis on C_N. The specific heat of thulium has previously been measured by Jennings, Hill, and

Spedding[11] between 15 and 360°K and by Dreyfus, Goodman, Lacaze, and Trolliet[12] between 0.5 and 4°K. The former data do not extend to low enough temperatures for determining C_N. Measurements by Dreyfus *et al.* are published as a brief research note only and detailed comparisons are thus impossible; this is unfortunate in view of the interesting behavior observed for C_N in the present research (cf. Sec. IV.C).

II. EXPERIMENTAL

The heat capacity measurements were carried out in a He^3 cryostat which has been described earlier[4]; only the most important experimental features are related here. He^4 exchange gas was used for cooling the sample down to 4.2°K; the space surrounding the calorimeter was then evacuated by pumping until a mass-spectrometer-type leak detector showed a very small helium reading. For further cooling a mechanical heat switch was employed. In this way, good thermal insulation was achieved when the heat switch was opened and desorption of helium gas from the sample during heat capacity measurements was prevented. By pumping on He^3, a temperature of about 0.33°K was reached and maintained in the He^3 pot for 48 h without recondensing. With the heat switch closed, the sample was cooled from 4.2 to 0.35°K in about 24 h.

For the heat capacity measurements, a colloidal graphite (Aquadag) thermometer was employed; its construction has been described elsewhere.[4,8] The thermometer was calibrated against the vapor pressure of He^4 between 4.15 and 2.2°K, against the vapor pressure of He^3 between 2.2 and 0.75°K, and against a magnetic thermometer (chrominum methylamine alum salt) between 0.75 and 0.35°K. He^4 temperatures were determined according to the T_{58} scale.[13] For He^3 the 1962 Los Alamos scale[14] was employed; a correction was made for the 0.6% of He^4 in our He^3 gas. The constants in the susceptibility versus temperature curve for the magnetic thermometer were determined from calibration points between 2.2 and 0.75°K. Altogether about 30 points were measured for the carbon thermometer between 4.15 and 0.35°K.

III. RESULTS

Our thulium metal was purchased from Research Chemicals, Inc. (Division of Nuclear Corporation of America). It was vacuum distilled by the manufacturer, then remelted in a vacuum and cast into a tantalum crucible. Next, the tantalum was machined off and the sample turned down to a cylinder 0.9 cm long and 2.7 cm in diameter; its weight was 49.902 g (=0.29539 mole). The spectrographic laboratory at Argonne found the following metallic impurities (weight %): Al, 0.03%; Cr, 0.003%; Fe, 0.01%; K, 0.01%; Mg, 0.005%; Mn, 0.01%; Na, 0.02%, Ta, 0.12%; Ti, 0.01%. These analyses are uncertain by a factor of 2 except in the case of Ta for which the precision is ±10%. The Ta result was obtained by a very careful densitometric analysis. Of nonmetallic impurities, the Argonne chemical laboratory found: H, 0.0006%; N, 0.20%; O, 0.10%; F, 0.024%; C, 0.014%. The accuracy is about 10%.

The experimental specific heat results are listed in Table I and the points are also plotted into Fig. 1. All calculations were performed by an IBM-704 digital computer.[15] The results have been corrected for curvature due to finite temperature increments when measuring C_p. The size of these increments may be computed from the separation of successive points in Table I.

After a heating period (about 1 min), the sample came to equilibrium in less than 2 sec at all temperatures. The heat leak to the calorimeter was always less than 0.2% of the corresponding heat input during heating periods. A correction for this was made in the customary manner by assuming linear drifts. The scatter of the points belonging to the same run from a smooth curve is about 0.3% (cf. Fig. 2). The heating current was measured with a Rubicon No. 2781 potentiometer and timed with an electronic timer using a tuning fork frequency standard. The potentiometer was cross checked against a Rubicon No. 2773 double potentiometer, the timer compared with radio signals over a 24-h period, and standard cells and standard resistors cali-

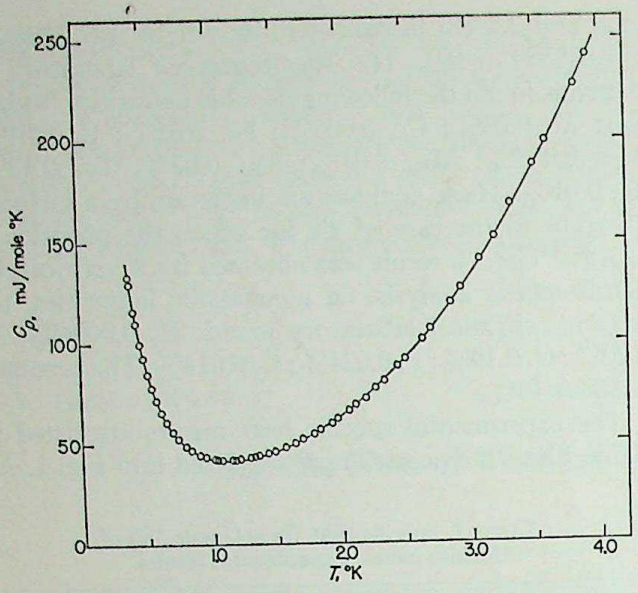

FIG. 1. The specific heat of thulium metal. Solid curve corresponds to equation $C_p=2.839T^3+17.94T+23.43T^{-2}-1.79T^{-3}-0.066T^{-4}$ (C_p in mJ/mole °K).

brated against NBS certified equipment. Possible systematic errors here are thus negligible. The electrical leads between the He^4 bath and the calorimeter were made of lead-covered constantan and were superconducting below 7°K. As described in another paper,[8] it is likely that the coating had tiny cracks at which a small amount of heat was generated. Due to this, there might be an error of 0.1% in the effective heater resistance ($R_H=362.13+0.03T$ Ω).

The heat capacity of the empty calorimeter ($C_{cal}=0.0090T^3+0.116T$ mJ/°K) was known from an earlier experiment; it was never more than 1.2% of the heat capacity of the sample. Possible uncertainties here can cause only errors smaller than 0.1% in the final results.

As is usual in low-temperature calorimetry, the largest errors in C_p are probably due to calibration of the carbon thermometer. The scatter of the calibration points was, with a few exceptions, less than 1 mdeg. The calculated temperature is thus probably within 1 mdeg of the temperature defined by the He^4 and He^3 scales.[13,14] Uncertainties of about 2 mdeg may arise from the extrapolation of the magnetic thermometer calibration below 0.75°K.

The three runs and the thermomenter calibrations were made during the same experiment without warming the sample above 4.2°K in the meantime. Largest discrepancies between runs occur in C_p at 2.0°K where they are about 0.5%.

After considering all the sources of errors and the discrepancies mentioned above, the accuracy of the present results is estimated as 0.6% between 1 and 4°K and 2% at 0.4°K.

The observed specific heat points from Table I, over the entire temperature range from 0.38 to 3.9°K, were fitted, after assuming $C_N=DT^{-2}-FT^{-4}(F=D^2/R$, cf. Sec. IV.C) and $C_M=CT^3$, to Eq. (1) by the method of least squares. The result was (C_p in mJ/mole °K):

$$C_p=2.74T^3+19.2T+19.15T^{-2}-0.044T^{-4}. \quad (2)$$

However, as may be seen from Fig. 2, deviations of the measured points from this curve are fairly large at low temperatures. This indicates that a term proportional to T^{-3} must be taken into account when expressing C_N (for a discussion on the temperature dependence of C_N, see Sec. IV.C). By writing $C_N=DT^{-2}-ET^{-3}-FT^{-4}$ the least-squares result was

$$C_p=2.839T^3+17.94T+23.43T^{-2}-1.79T^{-3}-0.066T^{-4}. \quad (3)$$

Standard deviations of the first four coefficients are 0.012, 0.12, 0.26, and 0.11. Equation (3) gives a reasonably good fit to the experimental points over the entire temperature range from 0.38 to 3.9°K (cf. Fig. 1); maximum deviations in $\Delta C/C$ are 1.9% at 1.3°K. Figure 2 shows that the fit is much better than with Eq. (2).

IV. DISCUSSION

A. The Lattice and Electronic Heat Capacities

Since the temperature dependence of C_M is uncertain, we must assume that the first term in (3) is due to C_L and C_M, the second term to C_E and C_M, and the last three terms to C_N. It is thus impossible to separate C_L and C_E from C_M without additional information.

On the basis of considerations described in an earlier paper,[8] we estimate that the lattice heat capacity of thulium should correspond to a Debye characteristic temperature $\theta=200$°K giving $C_L=0.243T^3$, and that $C_E=10.5T$ (C_L and C_E in mJ/mole °K). The major contribution to the first term in Eq. (3) thus comes

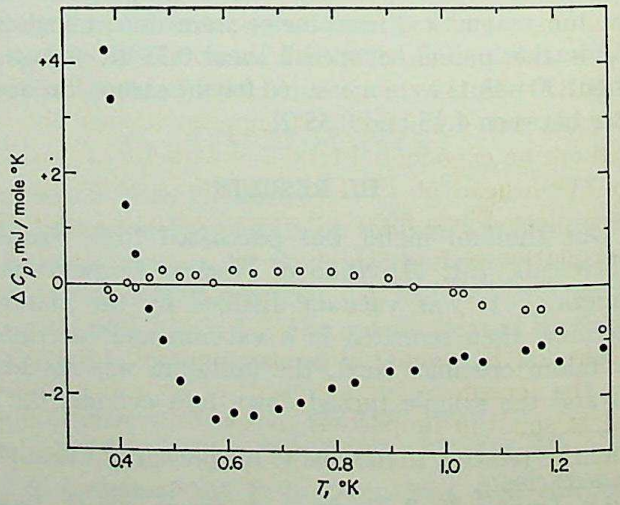

FIG. 2. Deviations ΔC_p of the experimental specific heat points from the expressions $C_p=2.74T^3+19.2T+19.15T^{-2}-0.044T^{-4}$ [filled circles, Eq. (2)] and $C_p=2.839T^3+17.94T+23.43T^{-2}-1.79T^{-3}-0.066T^{-4}$ [open circles, Eq. (3)]. $\Delta C_p=C_p$(calc.) $-C_p$(exp) (in mJ/mole °K).

from C_M. The precision of these values is estimated as 5% for θ and 7% for C_E.[8]

B. The Magnetic Heat Capacity

The magnetic susceptibility of polycrystalline thulium has been studied by Rhodes, Legvold, and Spedding[16] and by Davis and Bozorth.[17] A Néel point was observed at about 56°K and a Curie point at 22°K. According to Jennings, Hill, and Spedding[11] the heat capacity shows a pronounced peak at the Néel point but no anomalous behavior was noted at the Curie point.

The magnetic structure of thulium has been determined by Koehler, Cable, Wollan, and Wilkinson[1] by using neutron diffraction techniques. At 4.2°K, where saturation has very nearly been reached, thulium has an antiphase domain-type structure in which four layers of atoms with their magnetic moments pointing in the direction of the positive c axis are followed by three layers of atoms with their moments in the opposite direction. The low-temperature magnetic structure of thulium is thus ferrimagnetic. Each atom has an ordered magnetic moment of 7 μ_B, and the ferrimagnetic structure has thus a net moment of 1 μ_B per atom.

According to the simple spin-wave theory,[2] the magnetic specific heat of a ferrimagnetic metal, at temperatures well below the Curie point, may be written $C_M=CT^3$, where C is a constant. Niira[18] and Cooper[19] have shown, however, that in metals with magnetic anisotropy there is an energy gap E_g at the bottom of the spin-wave spectrum. Due to this, $C_M=CT^{3/2}\exp(-E_g/kT)$ for a ferromagnetic metal and $C_M=CT^3\exp(-E_g/kT)$ for a ferri- or antiferromagnetic metal.[20] More complicated formulas have also been proposed.[19] The physical reason for E_g is that it always takes a finite energy to turn a spin against the anisotropy field. Energy gaps of the order of $E_g/k=20-30$°K have been predicted for dysprosium[19] and for terbium.[5]

We have tried to fit the magnetic specific heat of thulium, calculated from the relation (in mJ/mole °K; C_p is the measured specific heat) $C_M=C_p-0.243T^3-10.5T-23.43T^{-2}+1.79T^{-3}+0.066T^{-4}$, to the above formula for C_M. The best agreement was obtained without an exponential term and with C_M proportional to $T^{5/2}$ instead of T^3. The magnetic specific heat has been plotted into Fig. 3; the straingth line corresponds to equation (C_M in mJ/mole °K).

$$C_M=6.2T^{5/2}. \tag{4}$$

Above 2.2°K, where C_M is more than 60% of the total C_p, the agreement is quite good; at lower temperatures C_M is small in proportion to the other contributions and the relative precision with which it can be determined becomes poor. Of course, the weak points in our calculation are the assumptions made about the size of C_L and C_E. By writing $C_E=17.94T$ [cf. Eq. (3)], C_M would be proportional to T^3. It seems unlikely, however, that the electronic specific heat is much larger for thulium than for the other trivalent lanthanides.[8] Of course, by subtracting C_L, C_E, and C_N from C_p in Eq. (3), we get $C_M=2.596T^3+7.44T$. This relation for C_M has, however, no theoretical basis.

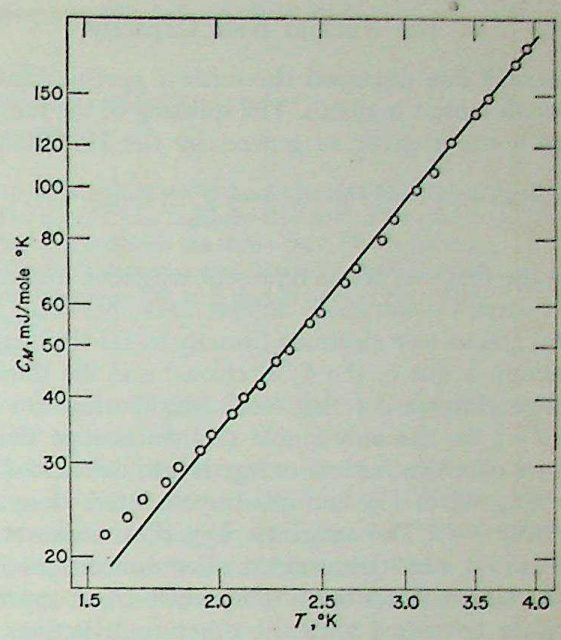

FIG. 3. The magnetic specific heat of thulium. The straight line corresponds to equation $C_M=6.2T^{5/2}$ (C_M in mJ/mole °K).

Before drawing any definite conclusions about the temperature dependence of C_M, measurements of C_p should be made at higher temperatures, especially between 4 and 20°K. This would allow us to decide whether or not an exponential factor is necessary in expressing C_M. At the moment one can only say that such a factor does not seem to be very important.

Measurements by Dreyfus *et al.*[12] gave $C_p=0.949T^3+21.5T+27T^{-2}$ (C_p in mJ/mole °K). Their data agree with ours at 1.5°K, are higher at lower temperatures and lower above 1.5°K; at 4°K the difference is 40%. Large discrepencies between specific heat results of different investigators are quite common between 2 and 4°K for rare-earth metals.[3–5,9] The disagreement is usually attributed to impurities which, even in small concentrations, might significantly alter the energy gap E_g at the bottom of the spin-wave spectrum.[4,5,19] There is some difficulty with this explanation here since the exponential factor in C_M seems to be absent or its effect is small in thulium. Another possibility is magnetic ordering in an impurity which, even in quantities of 0.1% of the sample, will cause large contributions to the observed specific heat, provided a magnetic transformation occurs in the impurity in or near the temperature range under investigation.[7]

C. The Nuclear Heat Capacity

Bleaney[21] has discussed the nuclear specific heat of rare-earth metals in detail. The splitting of the nuclear energy levels is given in general by the Hamiltonian

$$\mathcal{H}=a'i+P[i^2-\tfrac{1}{3}I(I+1)]-\tfrac{1}{2}\sum_{j\neq k}2(\mathbf{I}_j\cdot\mathbf{K}_{jk}\cdot\mathbf{I}_k), \quad (5)$$

where the first two terms represent magnetic hyperfine and electric quadrupole interactions between the nucleus and its own electrons (usually by far the biggest interaction is due to the $4f$ electrons) and the third is exchange interaction between neighboring nuclei. Since $I=\frac{1}{2}$ for the only stable thulium isotope Tm^{169}, there are only two nuclear energy levels, corresponding to $i=+\frac{1}{2}$, $-\frac{1}{2}$ in (5), and quadrupole interactions are identically $=0$. The magnetic hyperfine constant a' varies as $\langle J_z\rangle$, which measures the electronic magnetization. At temperatures below 2°K, where C_N is appreciable when compared with the other contributions to C_p, complete electronic magnetization is usually assumed and $\langle J_z\rangle$ is replaced by $J(=6$ for Tm^{3+} ions) and thus $a'=$const.

Once the nuclear energy levels are known, C_N can be calculated from the partition function in the usual way and, by expanding the nuclear specific heat in inverse powers of T, we obtain [cf. Eq. (3)]

$$C_N=DT^{-2}-ET^{-3}-FT^{-4}+\cdots, \quad (6)$$

where

$$D/R=\tfrac{1}{3}(a')^2I(I+1)+(4/9)I^2(I+1)^2\sum_{jk}(K_x^2+K_y^2+K_z^2)_{jk}, \quad (7)$$

$$E/R=(4/9)(a')^2\sum_{jk}(K_{jk})_zI^2(I+1)^2, \quad (8)$$

$$F/R=(1/30)(a')^4I(I+1)(2I^2+2I+1) \quad (9)$$

($P=0$, R is the gas constant, magnetic field is assumed in z direction, some higher terms in $\mathbf{K}$ have been ignored).

According to Bleaney's[21] estimates, contributions from the nuclear exchange interaction should be relatively small. However, if we put $\mathbf{K}=0$ only even powers of T appear in (6) and ($I=\frac{1}{2}$)

$$F=(3D^2/10R)(2I^2+2I+1)/(I^2+I)=D^2/R. \quad (10)$$

By assuming $D=19.15$ mJ °K/mole [cf. Eq. (2)], we get $F=0.044$ mJ °K³/mole. Even at 0.4°K, the T^{-4} term accounts only for 1.5% of the total C_N. By ignoring relation (10) and by letting all the coefficients in (2) be free in the least-squares analysis, we obtain a considerably larger value of F (C_p in mJ/mole °K):

$$C_p=2.82T^3+18.2T+21.6T^{-2}-0.49T^{-4}. \quad (11)$$

This equation fits to the measured points almost as well as (3). Our experimental accuracy is not sufficient to decide whether the "residual" C_N is proportional to T^{-3} or to T^{-4}.

In any case, the observed C_p below 1°K forces us to assume that other interactions, besides the magnetic hyperfine term, have a fairly large effect in the value of C_N. Due to the peculiar magnetic structure of thulium, the nuclear exchange interaction, acting through the spin waves, might be unusually large in this metal. We shall adopt Eq. (3) for representing the specific heat of thulium; this choice was made since it is impossible to explain the large T^{-4} term in (11) on theoretical grounds. In these two relations the coefficient of the T^{-2} term differs by 8%. On the basis of this and our earlier error estimates (cf. Sec. III), we put $D=23.4\pm1$ mJ °K/mole. If the temperature dependence of C_N in Eq. (3) and the ratio $F/D=D/R$ [cf. Eq. (10)] can be assumed correct, the limits of error in D would be ±0.5 mJ °K/mole.

Dreyfus *et al.*[12] have calculated from their specific heat data $D=27\pm3$ mJ °K/mole without taking higher terms in C_N into account. Since their measurements have been published as a smoothed curve only, it is impossible to reanalyze them. However, inclusion of higher terms would tend to increase D. From atomic beam experiments on neutral thulium atoms by Ritter,[22] Bleaney[21] has derived $D=26.9$ mJ °K/mole, which is in good agreement with the result by Dreyfus *et al.* However, recent Mössbauer measurements by Kalvius, Kienle, Eicher, Wiedemann, and Schüler[23] on thulium metal gave, at 5°K, the splitting of the ground state as $9.04\cdot10^{-6}$ eV, which corresponds to $D=22.9$ mJ °K/mole. If electronic magnetization was not complete at 5°K, this value would tend to increase towards lower temperatures; this effect cannot be larger than about 0.5%.[23]

The present specific heat measurements are thus in good agreement with the Mössbauer data.[23] The observed temperature dependence of C_N remains a puzzle. Formally one can write for thulium, in the temperature range studied, $a'=a_0-b/T$, whatever the reason may be. Here a_0 and b are constants. By extending the measurements to still lower temperatures, more would be learned about the nature of the interactions, in particular, one could see whether cooperative effects are present.

Collective Strain Splitting of Acceptor States in Silicon*

CALVIN S. KOONCE†
Department of Physics, University of California, Berkeley, California
(Received 27 January 1964)

A splitting of the ground acceptor state in silicon due to equilibrium homogeneous strains and a corresponding transition temperature have been calculated. The equilibrium homogeneous strains are due to linear terms in the strain Hamiltonian which couple the acceptor states with the strain field. The transition temperature was found to be $N_A \times 5.6 \times 10^{-20}$ °K, where N_A is the acceptor concentration in acceptors per cubic centimeter. For indium, concentrations as high as 10^{20} acceptors per cc should be possible before Coulomb and exchange effects between acceptors are dominant.

I. INTRODUCTION

THE acceptor state in silicon having the lowest energy transforms like Γ_8 of the tetrahedral double group. That is, the lowest acceptor state possesses the same fourfold degeneracy as the $P_{3/2}$ valence band edge at $k=0$.[1] At temperatures sufficiently low, all holes can be considered to be in the ground acceptor state.

It has been found[2,3] that the valence band edge of silicon and germanium at $k=0$ is split under the application of a homogeneous uniaxial stress. These stresses also split the degeneracy of the ground acceptor state.[4]

If there are two acceptor states in the crystal, they should be able to interact through the strain, or phonon, field. If there are a great many acceptor states, they should collectively produce a strain in a manner analogous to the way in which a lattice of magnetic dipoles interact to produce ferromagnetism.

In this paper the lowering of the energy corresponding to this collective equilibrium strain and a corresponding transition temperature are calculated.

II. DIAGONALIZATION OF THE HAMILTONIAN

In this section a Hamiltonian density will be set up and diagonalized, yielding the energy density associated with various equilibrium strains in the crystal. The strains associated with the minimum energy density and the maximum lowering of the energy density are obtained.

Although the strain Hamiltonian for silicon doped with acceptor atoms contains strains of all wavelengths, and the equilibrium strain in the neighborhood of an acceptor state will contain strains having wavelengths comparable to the dimensions of the acceptor state and even shorter, the strains responsible for the collective effect of all acceptor states are homogeneous strains. Therefore, in all that follows, only homogeneous strains will be considered.

If an individual acceptor is considered, it can strain in one of the normal-mode strains. However, the zero-point motion is large enough to average over all of the possible normal-mode strains and their negatives, so that on the average no strain exists. The only effect is to increase the amplitude of the zero-point motion. A homogeneous strain, however, induces a splitting even after averaging over the zero-point motions. Only the states split by the homogeneous strain are considered to be strain states of the system. This is in contrast with treatments of Jahn-Teller phase transformations of ordered impurities in which the individual atomic strain states are considered.[5]

In the strain Hamiltonian there are two types of terms. First, there are the terms independent of strain, quadratic in the strain and of higher order in the strain which are present when the acceptor concentration, and hence the hole concentration, is zero. All powers of the strain higher than the second will be neglected.

Second, there are terms which depend on the acceptor concentration. Because the acceptor concentration will always be much less than the atomic concentration of silicon, strain terms quadratic and higher in the strain which depend on acceptor concentration will be neglected. The change in elastic constants with acceptor concentration has been computed only for quite high acceptor concentrations[6] and will be neglected here. The linear terms in the Hamiltonian exist because the acceptor state is a wave packet of states taken from the top of the valence band, and exhibits the degeneracy in the valence band. The Jahn-Teller effect[7] states that, if a nonlinear symmetric arrangement of atoms has a degenerate ground state (not including spin degeneracy), there will exist in the Hamiltonian nonvanishing terms linear in the displacement of the atoms which destroy the symmetry and split the degeneracy.

The most general form for these linear terms for a crystal with cubic symmetry has been given by Kleiner

and Roth[2] and can be obtained from symmetry considerations alone. The values of the deformation potential coefficients D_u and D_u' for states in the valence-band edge of silicon at $k=0$ have been determined by Hensel and Feher.[3] Because the ground acceptor state has the same symmetry as the valence-band edge, the linear terms caused by the acceptor state will have exactly the same form as those for the valence-band edge, except for a change in the deformation potential coefficients.

If the binding energy of the acceptor state were much less than the energy lowering due to the equilibrium strain, the deformation potential coefficients obtained for the valence band edge by Hensel and Feher could be used for the acceptor state. Although this condition is not satisfied, these deformation potential coefficients will be used. The Hamiltonian density due to acceptor states is taken to be the acceptor concentration times the energy per hole given by Kleiner and Roth.[2]

The Hamiltonian density is then

$$\begin{aligned}\mathcal{H}=\mathcal{H}_0+(\tfrac{1}{2}c_{11})\sum_i e_{ii}^2+c_{12}\sum_{i>j}e_{ii}e_{jj}+(\tfrac{1}{2}c_{44})\sum_{i>j}e_{ij}^2\\ +N_A\{D_d^v\sum_i e_{ii}+(\tfrac{2}{3}D_u)\sum_i(J_i^2-\tfrac{1}{2}J^2)e_{ii}\\ +(\tfrac{2}{3}D_u')\sum_{i>j}[(J_iJ_j+J_jJ_i)/2]e_{ij}\}\,,\end{aligned}\quad(1)$$

where c_{ii} and c_{ij} are the elastic stiffness constants, e_{ii} and e_{ij} are the conventional strain components,[3] D_d^v, D_u, and D_u' are the deformation potential coefficients appropriate to the various types of strain, $\mathcal{H}_0$ is the Hamiltonian density with no strain, N_A is the acceptor concentration, J_i is an angular momentum matrix for angular momentum $\frac{3}{2}$, and the sums over i and j run from one to three over the Cartesian components. Where no angular momentum matrix is indicated, the identity matrix should be taken, because the terms independent of acceptor concentration do not split the acceptor states.

If a conventional phase for our angular momentum matrices is chosen,[8] we can write our Hamiltonian in matrix form.

$$\mathcal{H}=\begin{pmatrix}\epsilon+Q_1+Q_2 & Q_5-iQ_6 & Q_3-iQ_4 & 0\\ Q_5+iQ_6 & \epsilon+Q_1-Q_2 & 0 & Q_3-iQ_4\\ Q_3+iQ_4 & 0 & \epsilon+Q_1-Q_2 & -Q_5+iQ_6\\ 0 & Q_3+iQ_4 & -Q_5-iQ_6 & \epsilon+Q_1+Q_2\end{pmatrix},\quad(2)$$

where

$$\begin{aligned}Q_1&=N_AD_d^v(e_{xx}+e_{yy}+e_{zz});\\ Q_2&=N_A(\tfrac{2}{3}D_\mu)[e_{zz}-\tfrac{1}{2}(e_{xx}+e_{yy})];\\ Q_3&=N_A(\tfrac{2}{3}D_u)(\tfrac{1}{2}\sqrt{3})(e_{xx}-e_{yy});\\ Q_4&=N_A(\tfrac{2}{3}D_u')(\tfrac{1}{2}\sqrt{3})e_{xy};\\ Q_5&=N_A(\tfrac{2}{3}D_u')(\tfrac{1}{2}\sqrt{3})e_{xz};\\ Q_6&=N_A(\tfrac{2}{3}D_u')(\tfrac{1}{2}\sqrt{3})e_{yz},\end{aligned}\quad(3)$$

and

$$\epsilon=E_0+(\tfrac{1}{2}c_{11})\sum_i e_{ii}^2+c_{12}\sum_{i>j}e_{ii}e_{jj}+(\tfrac{1}{2}c_{44})\sum_{i>j}e_{ij}^2;\quad(4)$$

or, in terms of the Q_i,

$$\begin{aligned}\epsilon=E_0+\frac{c_{11}+2c_{12}}{6(D_d^vN_A)^2}Q_1^2+\frac{c_{11}-c_{12}}{3(\frac{2}{3}N_AD_u)^2}(Q_2^2+Q_3^2)\\ +\frac{2c_{44}}{3(\frac{2}{3}N_AD_u')^2}(Q_4^2+Q_5^2+Q_6^2).\end{aligned}\quad(5)$$

This matrix can be diagonalized to give eigenvalues for the energy density,

$$\lambda=\epsilon+Q_1\pm(Q_2^2+Q_3^2+Q_4^2+Q_5^2+Q_6^2)^{1/2}.\quad(6)$$

The minimum for the energy density cannot depend on the particular choice of Q_2 and Q_3 as long as $Q_2^2+Q_3^2$ is equal to a constant. The same degeneracy holds for Q_4, Q_5, and Q_6. Also, strains of the type Q_1 are separated from the other types and cause no energy splitting. Minimizing the energy density λ with respect to Q_1, one obtains an equilibrium value for Q_1. Terms in Q_1 can be included with the terms independent of strain to form the arbitrary zero of our energy.

The energy density change due to the other strains is

$$\lambda'=Ax^2+By^2\pm(x^2+y^2)^{1/2},\quad(7)$$

where

$$\begin{aligned}A&=\tfrac{1}{3}(c_{11}-c_{12})(\tfrac{2}{3}N_AD_u)^2;\quad B=\tfrac{1}{3}2c_{44}(\tfrac{2}{3}N_AD_u')^2;\\ x^2&=Q_2^2+Q_3^2;\qquad y^2=Q_4^2+Q_5^2+Q_6^2.\end{aligned}\quad(8)$$

The energy density can be minimized with respect to x and y by finding the values for x and y for which the first derivative of λ' with respect to both x and y is equal to zero. For $A\neq B$, as is usually the case, either x or y must be zero at equilibrium. However, $x=y=0$ gives $\lambda'=0$ and is not a minimum for λ'. If $A>B$, as is true for silicon, the minimum energy density is

$$\lambda_{\min}'=-1/4B=-N_A^2D_u'^2/6c_{44},\quad(9)$$

and the corresponding distortions are

$$\begin{aligned}e_{xy}^2+e_{xz}^2+e_{yz}^2&=N_A^2D_\mu'^2/3c_{44}^2;\\ e_{xx}=e_{yy}&=e_{zz}=Q_1/3N_AD_d^v.\end{aligned}\quad(10)$$

The strains e_{xx}, e_{yy}, and e_{zz} are chosen so that Q_2 and Q_3 are zero, and their value is determined by the value of Q_1 at equilibrium.

III. THE WEISS FIELD METHOD

The analogy with ferromagnetism will now be pursued, letting the strain field play the part of the magnetic field, and the average value of the angular momentum components of the acceptor state play the part of the magnetization. It will be found that the ratio of the average angular momentum components

[8] L. I. Schiff, *Quantum Mechanics* (McGraw-Hill Book Company, Inc., New York, 1955), 2nd ed., p. 146.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

to the applied strains obeys a "Curie-Weiss law," and the transition temperature can be computed.

The response of the crystal to an applied strain must be determined. If the applied strain is of the form e_{xy}, then a "Weiss field" of the same form is assumed.

$$e_0=e_{xy}|_0;\quad e_{xx}|_0=e_{yy}|_0=e_{zz}|_0=e_{xz}|_0=e_{yz}|_0=0. \quad (11)$$

The notation $|_0$ means to evaluate the strain with no external strain fields applied.

$$e_{xy}=e_0+e_{xy}';\quad e_{xx}=e_{xx}';\quad \text{etc.}, \quad (12)$$

where e_{xy}' is the applied strain.

The Hamiltonian for the splitting of the acceptor state due to the total strain field e_{xy} is

$$\mathcal{H}_S=\tfrac{2}{3}D_\mu'[(J_xJ_y+J_yJ_x)/2]e_{xy}. \quad (13)$$

After diagonalizing (13), one finds that the acceptor level is split into two states, each twofold degenerate, with an energy difference

$$\Delta E=|(2/\sqrt{3})D_u'e_{xy}|. \quad (14)$$

For the higher energy state, the eigenfunctions are $(\psi_{1/2}+i\psi_{-3/2})/\sqrt{2}$; $(\psi_{3/2}+i\psi_{-1/2})/\sqrt{2}$. This state will be denoted by $+$. The lower energy state has eigenfunctions $(\psi_{1/2}-i\psi_{-3/2})\sqrt{2}$; $(\psi_{3/2}-i\psi_{-1/2})/\sqrt{2}$. This state will be denoted by $-$.

The density of states at each level is

$$N_+=\frac{N_A\exp(-D_u'e_{xy}/\sqrt{3}kT)}{\exp(D_u'e_{xy}/\sqrt{3}kT)+\exp(-D_u'e_{xy}/\sqrt{3}kT)};$$
$$N_-=\frac{N_A\exp(D_u'e_{xy}/\sqrt{3}kT)}{\exp(D_u'e_{xy}/\sqrt{3}kT)+\exp(-D_u'e_{xy}/\sqrt{3}kT)}. \quad (15)$$

The density of the angular momentum coefficient is

$$\tfrac{1}{2}\langle J_xJ_y+J_yJ_x\rangle_{\rm av}=\tfrac{1}{2}\langle+|J_xJ_y+J_yJ_x|+\rangle N_+ +\tfrac{1}{2}\langle-|J_xJ_y+J_yJ_x|-\rangle N_-. \quad (16)$$

Here $\langle+||+\rangle$ indicates that the expectation value between the upper states should be taken. This gives the upper eigenvalue $+\sqrt{3}/2$.

Substituting (15) into (16), one obtains

$$\tfrac{1}{2}\langle J_xJ_y+J_yJ_x\rangle_{\rm av}=-N_A(\sqrt{3}/2)\tanh(D_u'e_{xy}/\sqrt{3}kT), \quad (17)$$

This form of strain dependence has been experimentally verified for the case of O_2 centers in alkali halides.[9] Equation (17) becomes, for $D_u'e_{xy}\ll kT$,

$$\tfrac{1}{2}\langle J_xJ_y+J_yJ_x\rangle_{\rm av}=-(N_AD_u'/2k)(e_{xy}/T)=C(e_{xy}/T). \quad (18)$$

The expectation values between $+$ or $-$ states for all other angular momentum combinations in our Hamiltonian (1) vanish, so that the assumed strain gives an average value for only its coefficient.

This average splitting of the acceptor states in turn leads to an equilibrium strain in the crystal. The energy density is

$$\mathcal{E}=\tfrac{2}{3}D_u'[\tfrac{1}{2}\langle J_xJ_y+J_yJ_x\rangle_{\rm av}]e_{xy} +\tfrac{1}{2}c_{11}\sum_i e_{ii}^2+c_{12}\sum_{i>j}e_{ii}e_{jj} +\tfrac{1}{2}c_{44}\sum_{i>j}e_{ij}^2. \quad (19)$$

The energy density is then minimized with respect to the possible strains to obtain the equilibrium strains

$$e_{xx}|_0=e_{yy}|_0=e_{zz}|_0=e_{xz}|_0=e_{yz}|_0=0;$$
$$e_{xy}|_0=e_0=-\tfrac{2}{3}D_u'[\tfrac{1}{2}\langle J_xJ_y+J_yJ_x\rangle_{\rm av}] =\gamma[\tfrac{1}{2}\langle J_xJ_y+J_yJ_x\rangle_{\rm av}]. \quad (20)$$

Equations (12), (18), and (20) yield

$$\frac{\tfrac{1}{2}\langle J_xJ_y+J_yJ_x\rangle_{\rm av}}{e_{xy}'}=\frac{C}{T-C\gamma}. \quad (21)$$

$C\gamma$, the transition temperature, is given by

$$T_c=C\gamma=N_AD_u'^2/3kc_{44}. \quad (22)$$

Comparing (9) and (22), one obtains for the lowering of the energy density

$$\lambda_{\rm min}'=-\tfrac{1}{2}N_AkT_c. \quad (23)$$

The splitting of the lowest acceptor level is then

$$\Delta E=kT_c, \quad (24)$$

which might have been expected.

Using $D_u'=2.68\pm0.25$ eV, determined by Hensel and Feher,[3] and a value for $c_{44}=8.007\times10^{11}$ dyn/cm^2, which it has at low temperatures and which varies little with temperature at low temperatures,[6,10] one obtains

$$T_c=N_A\times5.6\times10^{-20}\text{°K}=n_A\times2800\text{°K}, \quad (25)$$

where n_A is the fractional number of acceptors and N_A is the acceptor concentration in acceptors per cc.

Feher, Hensel, and Gere[4] found that a stress of about 300 kg/cm^2 in the (100) direction was necessary to split the ground acceptor state enough for paramagnetic resonance absorption transitions to be observed over the broadening due to the background of random strains in the crystal. The energy splitting due to an applied stress in the [100] direction[3] is

$$\Delta E_S=\tfrac{4}{3}D_uT/(c_{11}-c_{12}), \quad (26)$$

where T is the applied stress. The splitting necessary for transitions to be observed is roughly 8×10^{-5} eV, or 0.9°K.

In order to observe the effect of the equilibrium strain, one would like to increase the concentration to a value which would allow the energy splitting of (24) to be greater than the energy splitting necessary to overcome the random strains in the crystal. However,

at very high concentrations, the acceptor states gain more energy by binding into hydrogen-like molecules and finally bands than they gain due to the Jahn-Teller effect. The energy of binding into hydrogen-like molecules comes from both direct Coulomb and exchange interactions. For concentrations in the range of interest, this binding energy is much larger than the energy due to Van der Waals forces between acceptor states and the direct magnetic coupling between acceptor states.

Therefore, one must know at what concentration the molecular binding energy exceeds the energy lowering computed from (9). Table I gives the approximate concentrations at which this occurs, and the transition temperatures associated with these concentrations.

ACKNOWLEDGMENT

The author would like to thank Professor J. J. Hopfield for proposing the problem and for many helpful suggestions and discussions.

Band Structure of Gallium Phosphide from Optical Experiments at High Pressure*

RICHARD ZALLEN AND WILLIAM PAUL
Division of Engineering and Applied Physics, Harvard University, Cambridge, Massachusetts

(Received 22 January 1964)

The effect of hydrostatic pressure on the following optical properties of GaP has been measured at room temperature: the fundamental absorption edge region from 2.2 to 2.7 eV, an infrared absorption band appearing in n-type material at 0.3–0.5 eV, peaks in the reflectivity spectrum at 2.8 and 3.7 eV, and recombination radiation in forward-biased p-n junctions at 1.7–2.3 eV. The results have been interpreted by means of a proposed energy band structure in which the conduction band states X_1^c, X_3^c, Γ_1^c, Γ_{15}^c are located at energies of 2.2, 2.5, 2.8, 3.7 eV, respectively, above the valence band maximum at Γ_{15}^v. The following pressure coefficients have been measured (the transition involved is given in parenthesis), where energy is expressed in eV and pressure in 10^6 bars: $E_G(\Gamma_{15}^v \rightarrow X_1^c) = 2.22 - 1.1P$; $E_0(\Gamma_{15}^v \rightarrow \Gamma_1^c) = 2.78 + 10.7P$; $E_0'(\Gamma_{15}^v \rightarrow \Gamma_{15}^c) = 3.71 + 5.8P$; $\Delta E_2(X_1^c \rightarrow X_3^c) = 0.3 + 1P$. The coefficients of E_G and E_0' are close to those for the corresponding transitions in Si; that of E_0 is close to the corresponding coefficient in Ge. The weak reflectivity peak at 2.8 eV, the direct gap, shifts with temperature at a rate of about -4.6×10^{-4} eV/°K, compared to a value of about -5.2×10^{-4} eV/°K for the 2.2 eV indirect gap.

1. INTRODUCTION

THIS paper describes an experimental investigation of the electronic energy band structure of GaP. The approach taken in this study was to measure the effect of hydrostatic pressure on certain optical properties in the infrared, visible, and near ultraviolet regions of the spectrum. Included in these were absorption near the fundamental absorption edge, extrinsic absorption, reflectivity, and recombination radiation. Several features of the lowest conduction bands have been elucidated in the energy range from 2 to 4 eV above the valence band maximum.

Part of the basis for this work is a systematic correlation inferred from earlier work on pressure effects in group 4 and group 3–5 semiconductors.[1–8] It has been observed that corresponding energy separations in these materials have similar pressure coefficients. In other words, the effect of pressure on the energy of an electronic transition depends primarily on the particular type of final and initial states involved (each specified by a band index n, a reduced wave vector k, and a group-theoretic classification), and is relatively insensitive to choice of material from among this class of simple semiconductors. We have listed some pressure

(1) The $k=0$ vertical transition in germanium, responsible for the "direct" edge in optical absorption at 0.8 eV, takes place between a $\Gamma_{25'}$ valence band maximum and a $\Gamma_{2'}$ conduction band minimum. The transition in the zincblende structure 3–5 compounds which corresponds to $\Gamma_{25'}{}^v \rightarrow \Gamma_{2'}{}^c$ in the diamond structure group 4 elements is $\Gamma_{15}{}^v \rightarrow \Gamma_1{}^c$.[9] The pressure shift of the energy of this $\Gamma_{25'}{}^v \rightarrow \Gamma_{2'}{}^c(\Gamma_{15}{}^v \rightarrow \Gamma_1{}^c)$ transition is within the range $(10-15)\times 10^{-6}$ eV/bar for Ge,[10] GaAs,[11] InSb,[12] and GaSb.[13]

(2) Germanium and many of the 3–5's exhibit doublet peaks in reflectivity in the 2–3 eV range.[14,15] These are due to $\Lambda_3{}^v \rightarrow \Lambda_1{}^c$ vertical transitions along [111] axes in the Brillouin zone.[16] The pressure coefficient of these reflectivity peaks in Ge, GaSb, and InAs is $(7-8)\times 10^{-6}$ eV/bar.[7]

The results for GaP obtained in this study are consistent with this idea of correlation between pressure coefficient and transition assignment.

Comparatively little is known of the band structure of GaP. The valence band maximum is assumed to be a Γ_{15} state at the zone center, in analogy with the other 3–5 compounds.[17–19] The energy gap observed in optical absorption is 2.2 eV at room temperature, 2.33 eV at 0°K.[20–22] Measurements on GaAs–GaP alloys reveal a nonlinear variation of energy gap with composition,[23] indicating that the conduction band minimum in GaP is not the same as in GaAs, i.e., is not a Γ_1 state. This conclusion is supported by the large electron effective mass obtained from mobility and Faraday rotation experiments.[24] That the fundamental absorption edge involves indirect transitions can be seen from the functional form of the dependence of absorption coefficient upon photon energy above threshold,[21] especially the distinct phonon-derived structure observed at low temperatures.[22] The effect of pressure on the band gap is to shift it, slowly, to lower energies,[25] an unusual behavior seen also in silicon.[2,26] This suggests that the conduction band minima, as in silicon, lie along [100] directions in k space. Recent work by Spitzer and Mead on the photoresponse of surface barriers on GaAs-GaP alloys places the direct energy gap at 2.65 eV.[27] Our experiments indicate a somewhat higher estimate for this energy, closer to 2.8 eV, as will be seen in Secs. 3 and 5. Information available from ultraviolet reflectivity measurements and from measurements on an infrared absorption band in n-type material are discussed in later sections, along with our pressure experiments on these properties.

The discussion of our experimental results in Secs. 3–6 is presented in four parts. In Sec. 3 we describe the effect of pressure on the absorption edge between 2.2 and 2.7 eV, showing how the shape of the edge and its pressure dependence implies the presence of indirect transitions of the type $\Gamma_{15}{}^v \rightarrow X_1{}^c$ near 2.2 eV, and direct transitions of the type $\Gamma_{15}{}^v \rightarrow \Gamma_1{}^c$ near 2.8 eV. In Sec. 4 we discuss the 0.3-eV absorption band observed in n-type GaP, its pressure shift, and its interpretation as a direct inter-conduction band transition of the type $X_1{}^c \rightarrow X_3{}^c$. In Sec. 5 we describe the pressure shift of the strong reflectivity peak at 3.7 eV, as well as that of a weak peak at 2.8 eV not hitherto reported. We present evidence for attributing the former to $\Gamma_{15}{}^v \rightarrow \Gamma_{15}{}^c$ and the latter to $\Gamma_{15}{}^v \rightarrow \Gamma_1{}^c$ direct interband transitions. In Sec. 6 we discuss the results obtained for the effect

TABLE II. Optical components used for the various experiments.

Measurement	Spectral region (eV)	Dispersing element	Spectral slit-width (eV)	Source	Detector	Fluid surrounding sample
Fundamental absorption edge	2.2–2.8	glass prism	0.004	W lamp	9526B photomultiplier or 1P21 photomultiplier	isopentane
Infrared absorption band	0.3–0.7	LiF prism	0.003	globar	thermocouple	CS_2
Reflectivity under pressure	2.3–4.5	NaCl prism	0.01	D_2 lamp	9526B photomultiplier	isopentane
Reflectivity at 80°K	1.9–3.2	glass prism	0.004	W lamp	9526B photomultiplier	vacuum
Radiative recombination at 300°K and 80°K	1.7–2.3	glass prism or 7500-Å grating	0.02 0.006	GaP diode	9526B or 7102 photomultiplier	isopentane or He gas

of pressure upon recombination radiation emitted from forward-biased p-n junctions of GaP. The sharp edge emission lines at 2.1–2.3 eV, observed at 80°K, serve as accurate markers for monitoring the shift of the indirect edge. The results obtained in this fashion are compared to the results of Sec. 3.

2. EXPERIMENTAL TECHNIQUES

The spectrometer used in this work was a Perkin-Elmer model 12G unit used as a prism instrument or as a grating instrument in different experiments. Usually, the prism used was glass for the visible region of the spectrum, LiF for the infrared, and NaCl for the ultraviolet. Table II lists the prisms, sources, and detectors used for the various measurements, along with the spectral resolution available in each instance. In some of the low-temperature radiative recombination work, a grating blazed at 7500 Å provided somewhat higher resolution for studying the relatively narrow (0.02-eV half-width) edge emission lines and their small pressure shift. The radiation was chopped mechanically at 13 cps and phase-detected. The resultant ac signal was then amplified, rectified, and recorded on a Leeds & Northrup type G recorder. Data were taken by continuous recording of the signal while scanning photon energy over the region of interest, rather than by a point-by-point method. Optical transmissions down to 10^{-4} were measurable before reaching the limit set by scattered light within the monochromator.

The technique of optical experiments performed at high hydrostatic pressure has been well documented elsewhere.[2,28,29] The pressure fluid was transmitted between the Bridgman press and the sample chamber by means of flexible, stainless-steel tubing.[30] Pressure was measured by means of manganin gauges,[31] calibrated by observing the freezing pressure of mercury

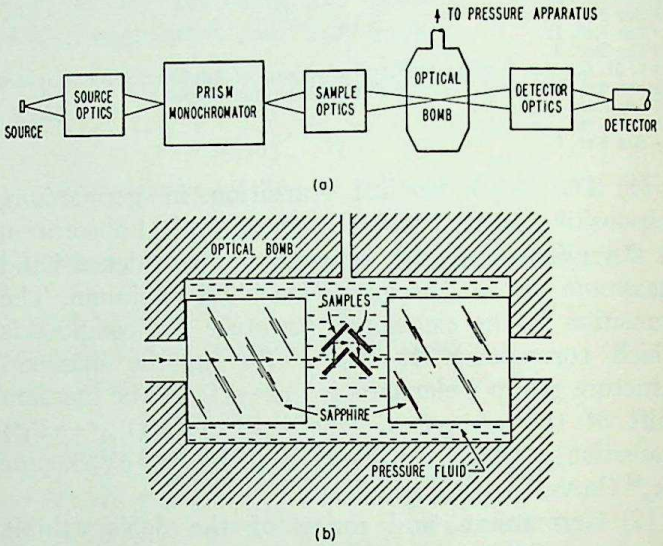

FIG. 1. Experimental arrangement for the measurement of optical absorption or reflectivity as a function of pressure: (a) block diagram of the optical system; (b) schematic diagram of the sample chamber with reflectivity samples in place. For the absorption measurements, the sample was the usual plane-parallel slab.

at 0°C, 7566 bars.[32] Our experiments were conducted at pressures up to 9 kbars.[33]

For the absorption and reflectivity pressure experiments, all performed at room temperature, the pressure fluids used were liquids; isopentane for the visible and ultraviolet measurements, carbon disulfide for the infrared measurements. The sample was placed in an optical high pressure vessel[34] between two $\frac{1}{2}$-in.-thick sapphire windows. A system of plane and spherical mirrors formed a real image of the monochromator exit slit at the sample position. The experimental layout is schematically shown in Fig. 1. For the measurements of absorption coefficient, the sample was a plane-parallel slab with polished surfaces normal to the direction of the light beam. For the measurements of reflectivity, four etched samples were arranged in a periscope-like reflectivity capsule. The transmission of

this capsule, proportional to R^4, exhibits peaks at photon energies at which the reflectivity peaks occur. Since we were interested in the position in energy of reflectivity peaks, rather than the absolute magnitude of reflectivity, the use of 45° angle of incidence rather than normal incidence does not present any difficulties. This is supported by measurements made with this technique on Ge, InAs, and GaSb,[7] as well as on Si,[8] which yielded values of peak positions in good agreement with values obtained at normal incidence.[35,36] One feature omitted, for reasons of clarity, from Fig. 1, is a set of mirrors which sampled a small fraction of the beam from the monochromator for the purpose of monitoring the stability of the spectral distribution of the energy available in the source-monochromator-detector system.

For the low-temperature measurement of the 2.8-eV reflectivity peak discussed in Sec. 5C, the reflectivity capsule was mounted in the vacuum chamber of a conventional metal cryostat, in thermal contact with a copper block connected to the liquid nitrogen bath.

For the experiments on the emission from GaP diodes, some of which were performed at 80°K, the pressure fluid used was helium gas. This entailed the use of a second pressure system and sample chamber designed for use with gas. The diode was mounted on a combination electrical and optical plug in which a central sapphire window was encircled by electrical lead-in wires. For the low-temperature measurements, the pressure vessel was immersed in liquid nitrogen inside a stainless-steel Dewar. The radiation, emitted through the sapphire window, was conveyed by means of glass fiber optics to the source position of the spectrometer. This arrangement is schematically shown in Fig. 2.

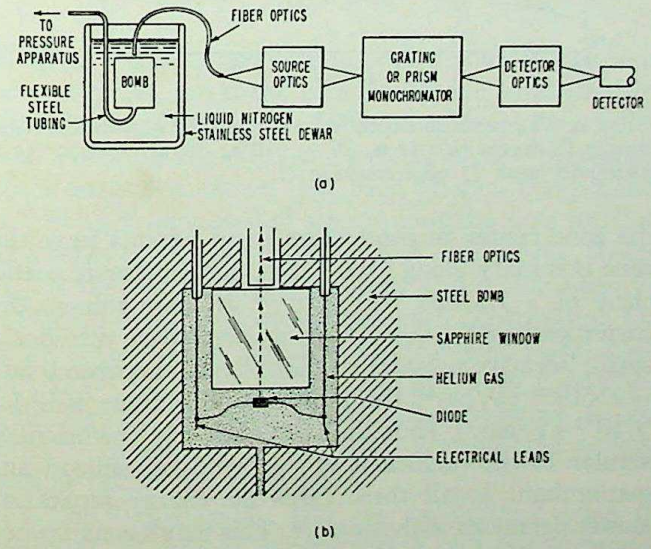

FIG. 2. Experimental arrangement for the measurement of radiative recombination as a function of pressure: (a) block diagram of the optical system; (b) schematic diagram of the sample chamber.

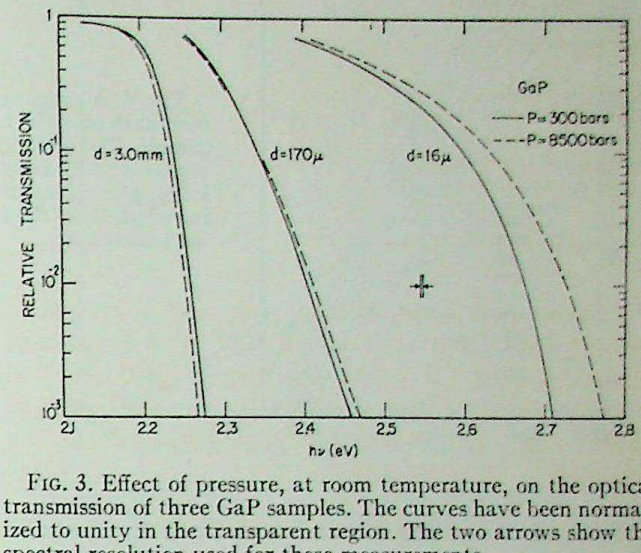

FIG. 3. Effect of pressure, at room temperature, on the optical transmission of three GaP samples. The curves have been normalized to unity in the transparent region. The two arrows show the spectral resolution used for these measurements.

3. EFFECT OF PRESSURE ON THE ABSORPTION EDGE: 2.2–2.7 eV

Transmission samples were prepared by polishing down bulk material. The range of absorption coefficient α covered in our measurements was from 5 to 5000 cm^{-1}. Figure 3 displays representative data taken at room temperature on three samples of different thickness. Relative transmission, t/t_0, where t_0 is the transmission in the transparent region at low energy, is plotted against photon energy for each sample at a low and a high pressure. Pressure shifts the transmission curves in opposite directions for the two extreme samples: There is a small shift toward lower energy for the thick sample, which spans the region of low α for $h\nu$ near 2.2 eV; and a large shift toward higher energy for the thin sample, which spans the region of high α from 2.5 to 2.7 eV. The pressure effect reverses sign within the range covered by the intermediate sample, near 2.33 eV.

Figures 4 and 5 show sets of transmission curves taken during two pressure runs. Figure 4 corresponds to absorption coefficients of the order of 10 cm^{-1}, at photon energies just above the energy gap E_G near the beginning of the absorption edge. Later we will show that the pressure shift of the curves in this region approaches the value of $\partial E_G/\partial P$, the pressure coefficient of the band gap. Figure 5 corresponds to absorption coefficients of the order of 10^3 cm^{-1}, at photon energies well into the fundamental absorption region. The change of shape with pressure is readily apparent; the large positive shift increases rapidly with $h\nu$. The large difference between the ranges of photon energy covered in Figs. 4 and 5 illustrates the difference in magnitude between the small, negative shift with pressure near 2.2 eV, and the large, positive shift with pressure near 2.7 eV.

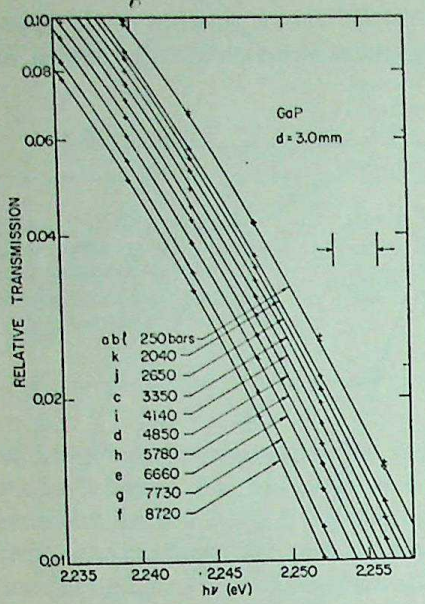

FIG. 4. A pressure run taken on a thick sample. The letters, arranged alphabetically, give the order in which the data were taken.

Plots such as Figs. 4 and 5 were used to construct isoabsorption curves, $h\nu_\alpha = h\nu_\alpha(P)$, in which photon energy for a given relative transmission (i.e., for a given α) is plotted against pressure. These were linear, within our 0–9 kbar pressure range. In Fig. 6 the slopes of these lines, $(\partial h\nu/\partial P)_\alpha$, are shown as a function of their zero-pressure intercepts $h\nu(0)$. The two extreme points, at 2.78 and 2.23 eV, are obtained from other experiments to be discussed in Secs. 5 and 6, respectively. All that need be noted now is that they are consistent with the isoabsorption data spanning the range from 2.24 to 2.72 eV. Figure 6 essentially summarizes the effect of hydrostatic pressure on the room temperature absorption edge of GaP.

To obtain $\partial E_G/\partial P$ from Fig. 6, it is necessary to know the room temperature value of E_G. One method of studying an indirect edge is a high-resolution analysis of phonon-absorption and phonon-emission components of $\alpha(h\nu)$ at low α, as has been successfully performed for Ge and Si.[37] Gershenzon, Thomas, and Dietz[22] have made such a study on GaP at low temperatures, observing phonon-emission components consistent with previous work on phonon combination bands in GaP. Their work is the most direct evidence thus far reported that the energy gap is indirect, and provides the best estimate available for E_G. Although unable to observe phonon structure at room temperature, they extrapolate their low-temperature data to a room-temperature energy gap of 2.22 eV.

Using $E_G = 2.22$ eV, we find from Fig. 6 that

$$\partial E_G/\partial P = -1.2\times10^{-6}\ \text{eV/bar}. \qquad (1)$$

This pressure coefficient is in fairly good agreement with previously reported values, less accurately determined than the present one, although it is somewhat smaller in magnitude.[25] The band gap of silicon, a $\Gamma_{25'}{}^v \rightarrow \Delta_1{}^c$ indirect transition from the valence band maximum at the zone center to conduction band minima near the zone boundary along [100] axes, has a pressure coefficient of -1.5×10^{-6} eV/bar.[2,26] In germanium, the corresponding $\Gamma_{25'}{}^v \rightarrow \Delta_1{}^c$ energy separation also has a small, negative pressure coefficient lying between 0 and -2×10^{-6} eV/bar[3]; the most accurate value is -1.5×10^{-6} eV/bar.[38] Thus the GaP band gap coefficient is similar to the coefficient of $\Gamma_{25'}{}^v \rightarrow \Delta_1{}^c$ in silicon and germanium. In all three cases the energy separation slowly decreases with pressure. This may be contrasted to the behavior of the band gap of germanium, a $\Gamma_{25'}{}^v \rightarrow L_1{}^c$ indirect transition, which increases with pressure at a rate of $+5\times10^{-6}$ eV/bar.[3]

We conclude then that the indirect transition responsible for the energy gap in GaP is that which corresponds to the $\Gamma_{25'}{}^{v} \rightarrow \Delta_1{}^{c}$ transition in Ge and Si, namely, $\Gamma_{15}{}^{v} \rightarrow \Delta_1{}^{c}$. Since the degeneracy at the X point in the diamond structure is split in the zincblende structure, it is likely that the conduction-band minima in GaP are at the X point on the zone boundary, rather than along the Δ axis in the interior of the zone. Thus we assign the band gap to the transition $\Gamma_{15}{}^{v} \rightarrow X_1{}^{c}$.

Figure 6 clearly shows that the absorption edge does not simply translate rigidly in energy along with E_G when pressure is applied, since for that situation $(\partial h\nu/\partial P)_\alpha$ would be equal to $\partial E_G/\partial P$ for all $h\nu$. Instead, $(\partial h\nu/\partial P)_\alpha$ varies linearly with $h\nu$ between 2.2 and 2.45 eV, beyond which energy it increases progressively more rapidly. Thus, for example, the photon energy corresponding to $\alpha = 5000$ cm^{-1} increases with pressure at a rate of 8×10^{-6} eV/bar, even though E_G itself decreases with pressure.

To account for the variation of $(\partial h\nu/\partial P)_\alpha$ with $h\nu$, we must first discuss the theoretically calculated and the experimentally measured shape of the absorption edge, $\alpha = \alpha(h\nu)$. The simplest theory[37] predicts that for indirect, allowed transitions, α is given by a sum of terms corresponding to phonon emission and absorption processes, and that each term varies quadratically with energy above threshold. Thus,

$$\alpha = \sum_i (\alpha_i{}^{+} + \alpha_i{}^{-}), \tag{2}$$

where:

$$\alpha_i{}^{\pm} = \begin{cases} 0, & \Delta E_i{}^{\pm} < 0 \\ C_i{}^{\pm}(\Delta E_i{}^{\pm})^2, & \Delta E_i{}^{\pm} > 0 \end{cases} \quad \begin{aligned} &\Delta E_i{}^{\pm} = h\nu - E_G{}^{i\pm}, \\ &E_G{}^{i\pm} = E_G \pm k\theta_i. \end{aligned}$$

Here $\alpha_i{}^{+}$ is the component due to emission of a phonon of energy $k\theta_i$, $\alpha_i{}^{-}$ is the component due to absorption of a phonon of energy $k\theta_i$. In the more exact theory,[37,39] which includes the effect of the electron-hole interaction (excitons), it is shown that each phonon component, $\alpha_i{}^{\pm}$, is itself composed of several contributions starting at a series of energies given by $E_G{}^{i\pm} - (1/n^2)E_{ex}$, where E_{ex} is the exciton binding energy and n is a positive integer. For allowed transitions, each contribution for finite n (formation of bound electron-hole pairs) goes as $(\Delta E)^{1/2}$ for small ΔE, the energy above threshold. The highest threshold contribution, starting at $h\nu = E_G{}^{i\pm}$ (formation of unbound electron-hole pairs), goes as $(\Delta E)^{3/2}$ for small ΔE.

When experimental data on an indirect edge is analyzed, it is usual to construct a plot of $\alpha^{1/2}$ versus $h\nu$. From the above it is clear that $\alpha^{1/2}$ versus $h\nu$ would not be expected to reveal simple linear behavior in the complex region near $h\nu \approx E_G$. However, in the region in which $h\nu$ greatly exceeds the highest phonon-emission threshold ($h\nu - E_G{}^{i} \gg E_{ex}$ for all i), the simple theory and the theory including excitons both give the same result:

$$\alpha = C[(h\nu - E_G')^2/h\nu]. \tag{3}$$

The quantity E_G' results from a weighted average of the phonon components and may differ from E_G by an amount of the order of a phonon energy. This expression holds provided that the assumption of parabolic energy bands, used in the theories, is valid to these energies. The factor $(h\nu)^{1/2}$ usually does not vary by more than 10% over the range of interest, so that we might expect $\alpha^{1/2}$ versus $h\nu$ to exhibit a region of linearity at photon energies exceeding $E_G + 0.05$ eV.

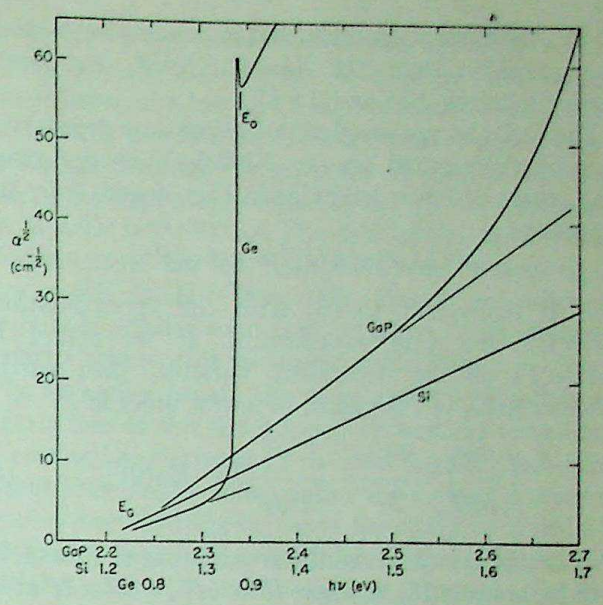

FIG. 7. A comparison of the absorption edges of Ge, Si, and GaP. The curves have been shifted horizontally so that the indirect energy gaps coincide. The Ge data (which are for 20°K) and the Si data (which are for 77°K) are from T. P. McLean, Progr. Semiconductors 5, 53 (1960). The GaP curve is our room-temperature, zero-pressure data.

Our results on the room temperature, atmospheric pressure absorption edge of GaP are in quite good agreement with the data of Spitzer, Gershenzon, Frosch, and Gibbs[21] (henceforth referred to as SGFG). Figure 7 presents a comparison of the absorption edge of GaP with those of Ge and Si. The scales of photon energy have been shifted so that the indirect energy gaps roughly coincide. The vertical scale is the square root of the absorption coefficient $\alpha^{1/2}$. The germanium and silicon data, for 20° and 77°K, respectively, are from the work of Macfarlane *et al.* quoted in Ref. 37. The silicon edge is accurately linear over the range shown, extrapolating to $\alpha^{1/2} = 0$ at a photon energy of 1.19 eV, 0.03 eV higher than the actual band gap at 77°K. The germanium edge is linear over a small range of energy until the onset of direct transitions at E_0, the direct energy gap. The extrapolated energy is 0.74 eV, in agreement with E_G (to the nearest 0.01 eV). The GaP edge is linear below about 2.5 eV, extrapolating to zero absorption at 2.20 eV, 0.02 eV lower than the band gap as estimated by Gershenzon *et al.* Above

2.5 eV, the absorption coefficient increases progressively more rapidly than the $(h\nu-2.2\text{ eV})^2$ dependence obeyed between 2.25 and 2.5 eV.

The GaP absorption edge and its pressure dependence may be represented, in the 2.2–2.5-eV energy range (the region of linear behavior in Figs. 6 and 7) by the expression

$$\alpha^{1/2}(h\nu,P)=A(P)[h\nu-E_G(P)]. \quad (4)$$

This is equivalent to (3) with the approximations $E_G'=E_G$ and $(h\nu)^{-1/2}=$constant. If we regard $h\nu=h\nu(\alpha,P)$ as the dependent variable, then partial differentiation of (4) yields, to lowest order in P,

$$\left(\frac{\partial h\nu}{\partial P}\right)_\alpha=\frac{\partial E_G}{\partial P}-\frac{1}{A}\frac{\partial A}{\partial P}[h\nu-E_G(0)]. \quad (5)$$

This is just the observed linear variation of $(\partial h\nu/\partial P)_\alpha$ with $h\nu$ shown in Fig. 6, where $(\partial h\nu/\partial P)_\alpha=\partial E_G/\partial P$ at $h\nu=E_G(0)$, and where the slope of the linear region, $(d/dh\nu)(\partial h\nu/\partial P)_\alpha\equiv\beta$, is given by $-(1/A)(\partial A/\partial P)$. In Sec. 7, the quantity β is estimated theoretically from the proposed pressure-dependent band structure of GaP. The result is in satisfactory agreement with the measured value of 1.15×10^{-5} bar^{-1} obtained from Fig. 6.

In the region of photon energy above 2.5 eV, the curves of Figs. 6 and 7 deviate from their linear behavior at lower energy. Both $\alpha^{1/2}$ and $(\partial h\nu/\partial P)_\alpha$ increase, gradually at first and then more and more rapidly, above the line extrapolated from low energies. The suggestion which immediately comes to mind is that a new mechanism, strongly pressure-dependent, is beginning to contribute to the absorption above 2.5 eV.

Several possible explanations for the rise in absorption are listed below:

(a) the breakdown of the validity of the theory behind (3), due to such considerations as the k dependence of matrix elements, energy denominators, and especially, effective masses (nonparabolic energy bands away from the extrema);

(b) the onset of a new indirect transition process at 2.5 eV, involving, for example, a set of higher conduction band minima;

(c) the low-energy "tail" of a direct edge occurring at a higher energy not reached in our absorption measurements;

(d) the onset of direct transitions at 2.5 eV.

Both (a) and (b) are plausible possibilities. The valence and conduction band masses may increase at k vectors away from the extrema, thereby providing a joint density of states for indirect transitions exceeding that predicted on the basis of parabolic bands. Also, regarding (b), it will be seen in Sec. 4 that there is evidence for a higher conduction band lying, at the X point, about 0.3 eV above the lowest conduction band. However, our calculations indicate that these two mechanisms are probably too weak to account for the observed increase in α above 2.5 eV. Note, for example, that (a) is apparently unimportant in the case of silicon, for which $\alpha^{1/2}$ versus $h\nu$ is linear over the 0.5-eV range of photon energy shown in Fig. 7. If the additional contribution to the absorption of GaP is analyzed by constructing $\alpha_2\equiv\alpha-\alpha_1$, where α_1 is extrapolated from the low-energy region where $\alpha=\alpha_1=A(h\nu-2.2\text{ eV})^2$, then it is found that α_2 does not at all resemble the $(h\nu-2.5\text{ eV})^2$ dependence expected of an indirect transition beginning at 2.5 eV, but increases much more rapidly than this. Thus, neither (a) nor (b) accounts for the observed shape of the edge. Moreover, neither mechanism readily accounts for the more rapid increase of $(\partial h\nu/\partial P)_\alpha$ with $h\nu$ above 2.5 eV.

If the minimum "vertical" separation between the valence and conduction bands in GaP occurs at $k=0$ and the transition involved is of the type $\Gamma_{15}^v\rightarrow\Gamma_1^c$, as is the case in several other 3–5 compounds, then the pressure coefficient of the direct gap, $\partial E_0/\partial P$, is expected to have a value in the range of $+10$ to $+15\times10^{-6}$ eV/bar. Mechanisms (c) and (d) would then predict an increase of $(\partial h\nu/\partial P)_\alpha$ toward the value of $\partial E_0/\partial P$. In germanium it is found that $(\partial h\nu/\partial P)_\alpha$ reaches the value of the direct gap coefficient at an energy somewhat less than E_0, and then levels off.[10] For GaP we see that $(\partial h\nu/\partial P)_\alpha$ is still below the expected value of $\partial E_0/\partial P$ at $h\nu=2.7$ eV, indicating that E_0 occurs at a higher energy. Thus, only (c) is consistent with the variation of $(\partial h\nu/\partial P)_\alpha$ of Fig. 6. SGFG proposed (d) to account for the increase in α above 2.5 eV, and to account for an infrared absorption band observed in n-type material. Our discussion in this section favors (c) as the explanation for the increase in α; the actual origin of the infrared absorption band will be discussed in Sec. 4.

In a direct absorption edge, the absorption coefficient rises rapidly to a high value at E_0, and then increases more slowly with $h\nu$.[37,40] The direct edge of Ge is shown in Fig. 7, and clearly exhibits the characteristic "knee" at E_0. This curve is for 20°K and shows the exciton peak at an energy just under E_0. At room temperature the exciton peak is washed out but the marked knee at E_0 persists. No indication of such a knee appears in the GaP absorption edge of Fig. 7. This also demonstrates that E_0 does not fall within the range shown, and that it thus exceeds 2.7 eV.

From these arguments we therefore propose that (c) is the dominant mechanism responsible for the deviation from linearity above 2.5 eV in Figs. 6 and 7. The presence of a $\Gamma_{15}^v\rightarrow\Gamma_1^c$ direct transition is indicated at an energy E_0 greater than 2.7 eV. The momentum matrix element for this transition, p_{cv}, which governs the optical absorption, is nearly equal for several 3–5 compounds.[41] Assuming that the same value holds also

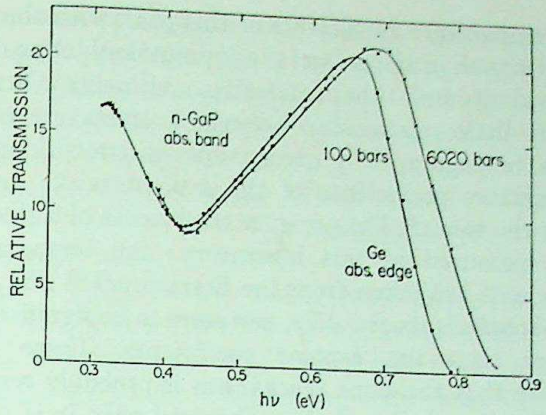

FIG. 8. Effect of pressure on the infrared absorption band in n-type GaP. The trough at 0.4 eV is due to the GaP absorption band. The cutoff at 0.7–0.8 eV is due to the absorption edge of a Ge sample which was included along with the GaP sample in order to provide a comparison of pressure shifts.

for GaP, we can obtain a rough estimate for $\alpha(E_0)$, the absorption level at the knee of the absorption curve. This quantity is proportional to $p_{cv}^2 m_c^2/n^3 E_0$,[37,39] where n is the refractive index, and where it is assumed thta both the density-of-states effective mass and the exciton reduced mass are determined primarily by m_c, the conduction band effective mass. In first approximation, m_c is proportional to E_0,[41] so that $\alpha(E_0)$ becomes proportional to $p_{cv}^2 E_0/n^3$. For GaAs, $\alpha(E_0)$ is equal to 0.9×10^4 cm^{-1}.[40] Using the values of n and E_0 for GaAs and GaP, where a trial value of $E_0=3$ eV is assumed for GaP, we obtain $\alpha(E_0)\approx2\times10^4$ cm^{-1} for GaP. The absorption curve of Fig. 7 extrapolates to this level at a photon energy of about 2.75–2.80 eV. In Sec. 5C we shall discuss a weak peak appearing in the reflectivity spectrum of GaP at about 2.78 eV, which we attribute to the $\Gamma_{15}^v \rightarrow \Gamma_1^c$ direct edge.

4. EFFECT OF PRESSURE ON AN INFRARED ABSORPTION BAND IN n-TYPE GaP

SGFG reported an absorption band in n-type GaP, in excess of the normal free carrier absorption, with a strength proportional to the electron concentration.[21] At room temperature, the band peaks at 0.41 eV and its low-energy threshold is at 0.31 eV; at low temperatures the threshold shifts to higher energy by about 0.05 eV. Since the absorption is proportional to the concentration of electrons, the initial states of the transitions responsible are probably either at the conduction band minima, or at shallow impurity states derived from these minima.

Spitzer *et al.* suggested that the mechanism responsible is an indirect transition from the conduction band minima to a higher minimum at $k=0$, i.e., $X_1^c \rightarrow \Gamma_1^c$. As a test of this hypothesis, which is inconsistent with our previously discussed estimate of the energy of Γ_1^c, we measured the effect of pressure on the absorption band in samples kindly provided us by Dr. Spitzer. Since $\partial E_0/\partial P$ exceeds $+10\times10^{-6}$ eV/bar, and $\partial E_G/\partial P$ is negative, the pressure shift of E_0-E_G (the energy of the $X_1^c \rightarrow \Gamma_1^c$ transition) should definitely exceed $+10\times10^{-6}$ eV/bar. Figure 8 displays the optical transmission, at a low and a high pressure, of an n-type GaP sample ($n=10^{18}$ cm^{-3}, $d=0.1$ mm) in series with a Ge sample included for purposes of comparison. The shift of the high-energy cutoff near 0.75 eV, due to the Ge, is $+9\times10^{-6}$ eV/bar. The shift of the dip in transmission caused by the absorption band is seen to be very much smaller than this, almost an order of magnitude smaller than that expected. This is strong evidence against this particular mechanism.

In an earlier paper, one of us (W.P.) presented an explanation of this band based on vertical transitions of conduction electrons to the next higher conduction band.[4] This simple model, unlike the indirect scattering process discussed above, leads naturally to a definite low-energy threshold, especially if the electrons are initially weakly bound to shallow impurities. It also explains reasonably well the magnitude of the absorption band and its relative insensitivity to temperature, as no phonons are involved. The model is consistent with a small pressure coefficient. Recently, Allen and Hodby[42] have studied this absorption band in n-type GaAs-GaP alloys. They found that it appears only in the alloys which have the (100) minima lowest, strong evidence in favor of our model.

The higher conduction band providing the final states for these direct transitions is logically X_3^c, which is degenerate with X_1^c in diamond-structure materials like Ge and Si. Thus the $X_1^c \rightarrow X_3^c$ energy separation in GaP is about 0.3 eV. Values for this quantity for some of the other 3–5's have been estimated by Greenaway[43] from structure observed at low temperatures in the strong X-point reflectivity peak in the ultraviolet. He obtains values in the range of 0.4–0.5 eV, close to the GaP value. The interconduction band absorption in n-type GaP which has been discussed here is the analog of the intervalence band infrared absorption found in p-type Ge,[44] GaAs,[45] and InAs;[46] the shape of the absorption curve is similar in all of these materials.

5. THE EFFECT OF PRESSURE ON THE REFLECTIVITY SPECTRUM: 2.5–4.5 eV

A. Reflectivity Spectra

Reflectivity spectra of semiconductors exhibit peaks in the 1–10-eV range of photon energies, due to corners (peaks or edges) in dN/dE, the joint density-of-states for direct interband transitions.[14–16] Corners in dN/dE are correlated with critical points in k space of $E^{cv}(k)$

$=E^c(k)-E^v(k)$, the vertical separation of the conduction and valence bands. The critical points are of four types; minima, maxima, and two types of saddle points. The saddle points produce the strongest singularities in dN/dE, and it is their identifications with particular reflectivity peaks which are the most certain. The strongest reflectivity peak in Ge, Si, and the 3–5 compounds appears at about 4 or 5 eV and is due to saddle point singularities at X and Σ points[47] in the zone.[14,16] Doublet peaks appearing in the 2–3 eV range in Ge and some of the 3–5's are due to saddle points at Λ points[47] in the zone,[16] the doublet structure being due to the spin-orbit splitting of the valence band.

Reflectivity peaks have been reported for GaP at 3.7, 5.3, 6.9, and 10 eV.[15] The dominant 5.3-eV peak is supposed due to the X, Σ critical point transition.[14,16] The $L_3^v \rightarrow L_3^c$ (or $\Lambda_3^v \rightarrow \Lambda_3^c$) transition has been suggested for the 6.9-eV peak. No transition has been associated with the peak at 10 eV. The 3.7-eV peak may be due to $\Lambda_3^v \rightarrow \Lambda_1^c$ transitions, in analogy with the 2–3-eV peaks in Ge and some of the 3–5's; or it may be due to $\Gamma_{15}^v \rightarrow \Gamma_{15}^c$ transitions, in analogy with the $\Gamma_{25'} \rightarrow \Gamma_{15}^c$ transitions believed responsible for the first peak in Si at 3.4 eV.[14,36]

In this section we shall discuss measurements which we have made on the reflectivity between 2.5 and 4.5 eV. We have measured the effect of pressure on the peak at 3.7 eV, as well as on a weak peak at 2.8 eV which has not been reported previously.

B. The Reflectivity Peak at 3.7 eV

Figure 9 shows the effect of pressure on the 3.7-eV peak. The vertical scale is the transmission of a reflectivity capsule (four successive 45° reflections from etched surfaces) of GaP immersed in isopentane, and is proportional to R^4. The peak position shifts toward higher energies at the rate of $+(5.8\pm15\%)\times10^{-6}$ eV/bar. In Table III we have compared the pressure and temperature coefficients of this peak with those of the first peak in silicon and the Λ-point doublet peaks in germanium and other materials. Although there is usually little relationship between temperature coefficients belonging to a given type of transition, the temperature coefficients of the Λ-point peaks are all about the same.[48] The pressure coefficients of Table III were measured in this laboratory; the temperature coefficients are taken from the literature.[36,48] The GaP and Si coefficients are alike, and seem to be significantly smaller than the Λ-point coefficients. These data indicate that the same mechanism is probably responsible for the GaP and Si peaks, and that it is not a Λ-point transition.[49]

That the Si 3.4-eV peak is other than a Λ-point transition has already been conclusively established by work of Tauc and Abraham[50] on Ge-Si alloys, in which it was shown that the variation of the energy of the first reflectivity peak (followed as a function of composition) shows a definite break at about 79% silicon. It now remains to identify this peak, and thereby the GaP 3.7-eV peak. There is a burgeoning body of evidence that the $\Gamma_{25'}^v \rightarrow \Gamma_{15}^c$ energy separation in silicon is

TABLE III. Comparison of the behavior of the 3.7-eV reflectivity peak in GaP with that of some other reflectivity peaks.

Coefficient	$\Lambda_3 \rightarrow \Lambda_1$ peaks at 2–3 eV in Ge, GaAs, GaSb, etc.	Peak at 3.7 eV in GaP	Peak at 3.4 eV in Si
$(\partial E/\partial P)_T$ in 10^{-6} eV/bar (±10%)	+7.2[a]	+5.8	+5.2[b]
$(\partial E/\partial T)_P$ in 10^{-4} eV/°K (±20%)	−4.7[c,d]	−2.5[c]	−2.6[c,d]

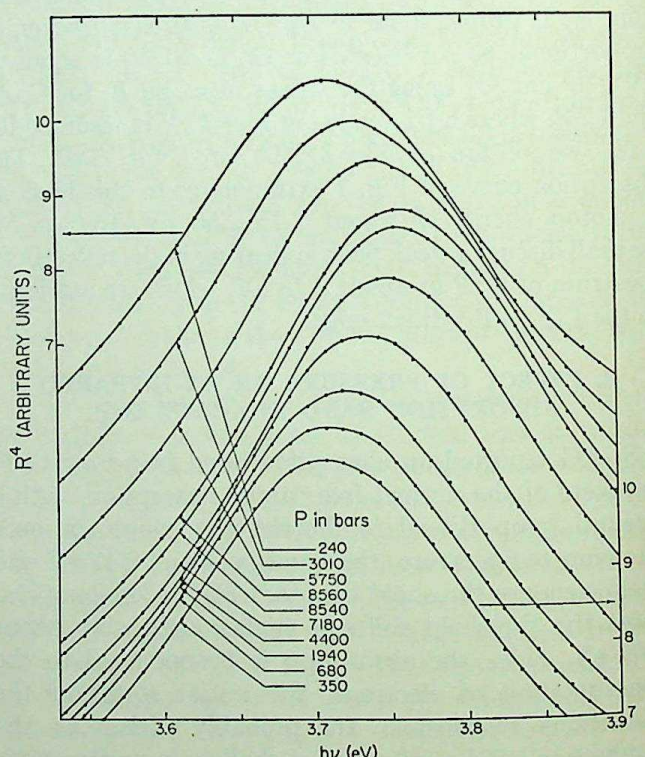

FIG. 9. Effect of pressure on the GaP reflectivity peak at 3.7 eV. The curves have been shifted vertically in order to separate them. The pressures are listed in the order in which the data were taken.

[47] We are using the accepted notation for various positions of high symmetry in the Brillouin zone of a face-centered cubic lattice: Γ, (000); Δ, along [100] axes; X, (100) at the zone boundary; Σ, along [110] axes; K, (110) at the zone boundary; Λ, along [111] axes; L, (111) at the zone boundary.

[48] F. Lukes and E. Schmidt, *Proceedings of the International Conference on the Physics of Semiconductors, Exeter* (Institute of Physics and the Physical Society, London, 1962), p. 389.

[49] It is worth noting that the lack of observed doublet structure in the Si and GaP peaks does not, by itself, make the Λ-point explanation unlikely, since the expected spin-orbit splitting in these materials is small, less than 0.1 eV (Ref. 18).

3.4 eV.[51–54] The band calculations for silicon seem to have successfully accounted for the reflectivity spectrum,[52] photoemission experiments on silicon surfaces,[52,53] and the alloy experiments mentioned above. We therefore assign the 3.4-eV Si peak to $\Gamma_{25'}{}^{v} \rightarrow \Gamma_{15}{}^{c}$. We conclude then that the 3.71-eV reflectivity peak in GaP is due to $\Gamma_{15}{}^{v} \rightarrow \Gamma_{15}{}^{c}$ transitions ($\Gamma_{25'}{}^{v}$ in Si corresponds to $\Gamma_{15}{}^{v}$ in GaP).

GaP belongs to the isoelectronic sequence GeSi, GaP, ZnS, CuCl. All of these materials exhibit very similar reflectivity spectra,[15,50,55,56] each peak occurring at an energy which is higher the more polar the compound. The data of Tauc and Abraham[50] indicate that the energies of the $\Gamma_{25'}{}^{v} \rightarrow \Gamma_{15}{}^{c}$ and $\Lambda_3{}^{v} \rightarrow \Lambda_1{}^{c}$ transitions in GeSi are 3.1 and 2.9 eV, respectively. Cardona,[56] from work on CuBr-CuCl alloys, puts the corresponding energies in CuCl at 6.8 and 6.5 eV. In both materials only a single reflectivity peak is observed, the weaker peak apparently being hidden under the stronger (which is less than 0.3 eV away). Cardona suggests that this is likely also the case in the other two members of the series. This would place the $\Lambda_3{}^{v} \rightarrow \Lambda_1{}^{c}$ energy separation in GaP in the 3.5–4.0-eV range where, in reflectivity, it is hidden under the (in this case) stronger $\Gamma_{15}{}^{v} \rightarrow \Gamma_{15}{}^{c}$ peak at 3.7 eV. A study of reflectivity in the alloy system GaAs-GaP would determine whether or not this is the correct picture. Finally, corroborating evidence for the Γ-point assignment to the 3.7-eV peak in GaP comes from the corresponding peak in ZnS which shows no splitting under the use of polarized light, and is therefore due to transitions at $k=0$.[57]

C. The Reflectivity Peak at 2.8 eV

In Sec. 3 we estimated a value of about 2.8 eV for E_0, the $\Gamma_{15}{}^{v} \rightarrow \Gamma_1{}^{c}$ direct gap. This type of direct edge, at which there is a sharp rise (edge) in dN/dE due to a minimum in $E^{cv}(k)$, is much weaker than other direct transitions: Typical values of α for this edge are of the order of 10^4 cm^{-1},[37,40] while typical values of α in the region of (for example) the $\Lambda_3{}^{v} \rightarrow \Lambda_1{}^{c}$ and the $X_4 \rightarrow X_1$ transitions are of the order of 10^6 cm^{-1}.[15,58] It is therefore not surprising that for Ge, no structure has yet been reported in the reflectivity spectrum near $E_0=0.8$ eV. For GaAs, there is some evidence of weak structure near $E_0=1.5$ eV.[46] Structure near 2.8 eV has not been present in published reflectivity spectra of GaP.

We have examined the transmission of a reflectivity capsule of GaP in the vicinity of 2.8 eV. Figure 10 shows the transmission (proportional to R^4) of the capsule in vacuum at 300 and 80°K. [It was found that the arrangement of the samples accidentally placed a small transmission sample (thickness about 1 mm) effectively in parallel with the R^4 samples. This is responsible for the small additional contribution to the transmission below about 2.3 eV. The shift of the cutoff of this added component yields a value of $-(5.2\pm15\%)\times10^{-4}$ eV/°K for $\partial E_G/\partial T$, the temperature coefficient of the indirect gap, in agreement with a previously reported value[20] of -5.4×10^{-4} eV/°K.] Superimposed upon the rapid rise of R^4 toward the 3.7-eV peak, there is very weak structure near 2.8 eV. This takes the form of a peak having a height of the order of $\Delta R^4/R^4\approx1/30$, and a width at half-maximum of about 0.2 eV. The temperature coefficient of the peak position is $-(4.6\pm15\%)\times10^{-4}$ eV/°K.

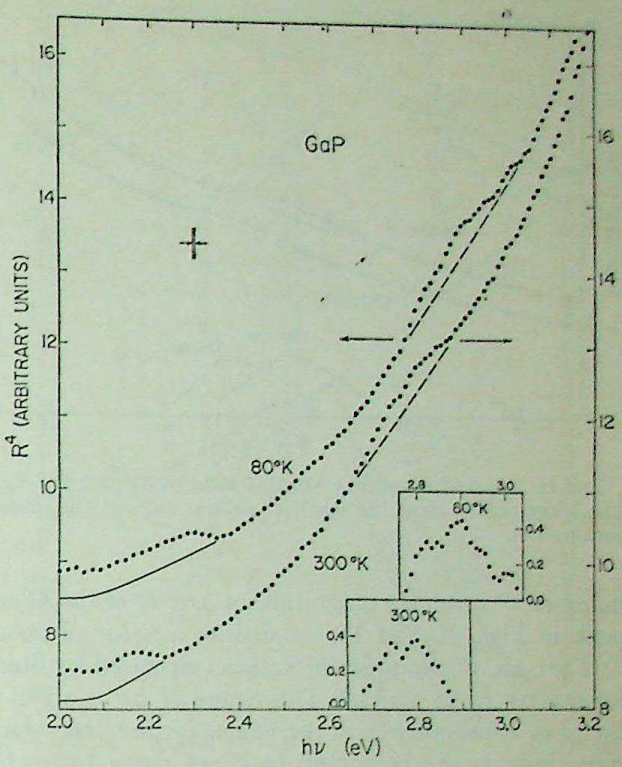

FIG. 10. Effect of temperature on the GaP reflectivity peak at 2.8 eV. The inserts show the data obtained by subtracting out the smooth background.

Figure 11 shows the effect of pressure on the 2.8-eV "peak," measured at room temperature, with the samples immersed in isopentane. Its pressure coefficient is $+(10.7\pm15\%)\times10^{-6}$ eV/bar. This large coefficient is appropriate for a $\Gamma_{15}{}^{v} \rightarrow \Gamma_1{}^{c}$ direct transition.[3–6] It has been plotted as the high-energy point in Fig. 6 (at 2.78 eV, the zero-pressure photon energy of the peak), where it is seen to be consistent with the absorption edge data obtained at lower energies.

Structure in reflectivity in this region (where the extinction coefficient, $K\equiv(C/2\omega)\alpha\approx10^{-5}$ cm$\times\alpha$, is less than unity) closely follows structure in the refractive

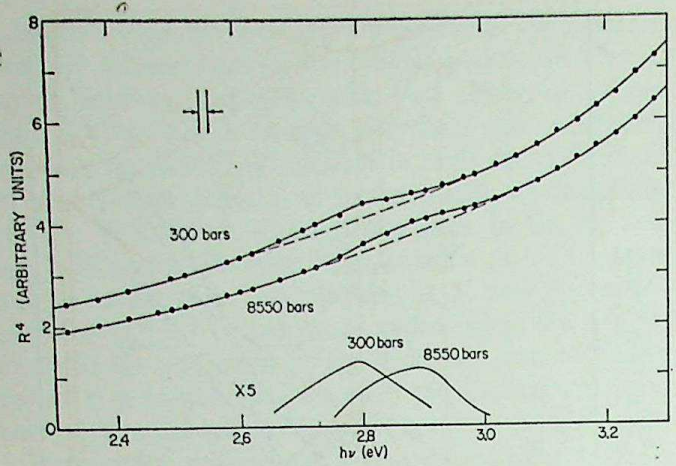

FIG. 11. Effect of pressure on the GaP reflectivity peak at 2.8 eV. The lower curves show the result of subtracting out the smooth background.

index n.[58,59] From the magnitude of $\Delta R^4/R^4$ of the 2.8-eV peak in Figs. 10 and 11, we deduce a value of about 0.02 for Δn, of the order of values calculated by Stern for n near E_0 in GaAs.[60] This value of Δn is about a factor of 10^2 smaller than the values for the first strong reflectivity peaks belonging to edges rising to $\alpha \approx 10^6$ cm^{-1},[58] implying that the edge involved has a strength of about 10^4 cm^{-1}.

From this evidence we conclude that this weak reflectivity peak is due to the onset of direct transitions of the type $\Gamma_{15}^v \rightarrow \Gamma_1^c$ at the center of the zone. The pressure and temperature dependence of the direct gap is then given by

$$E_0 = 2.78 + (10.7 \pm 15\%) \times 10^{-6} P - (4.6 \pm 15\%) \times 10^{-4} (T - 300), \quad (6)$$

where E_0 is in electron volts, P is in bars, T is in degrees Kelvin. Recently, Spitzer and Mead have estimated a value for E_0 of 2.65 eV based on measurements of the photoresponse of metal-semiconductor surface barriers on GaAs-GaP alloys.[27] We do not know the reason for the difference between our two results.

The photoconductivity of GaP shows a sharp drop at about 2.8 eV.[61] Similar effects have been observed in other materials,[62] and have been accounted for by the production of photoelectrons at $k=0$, where they contribute little to the current because of rapid direct recombination.[63] This is consistent with our estimate of E_0.

Note added in proof. D. F. Nelson, L. F. Johnson, and M. Gershenzon [Bull. Am. Phys. Soc. 9, 236 (1964)] have recently observed structure in the photoconductivity spectra of GaP samples which they attribute to direct exciton formation. Their room-temperature estimate of E_0, 2.79 eV, is in excellent agreement with our result, as is the temperature dependence which they obtain for E_0. The agreement between these two independent determinations of the direct gap is strong evidence for the correctness of our interpretation of this reflectivity peak, as discussed above.

6. EFFECT OF PRESSURE ON RADIATIVE RECOMBINATION IN FORWARD-BIASED p–n JUNCTIONS

Diodes formed from GaP p-n junctions exhibit carrier-injection electroluminescence (EL) emission of low efficiency when biased in the forward direction.[64,65] At low temperatures the emission in the green, at or near E_G, reveals a great deal of very complicated and interesting fine structure[65–67] due to such effects as associated shallow donor-acceptor pairs[66] and bound exciton states.[67] There is also a broad emission in the red involving levels well inside the forbidden zone.[64]

We have measured the effect of pressure on some of the EL lines observed in GaP diodes. A reason for doing this is that sharp lines emitted with nearly the band-gap energy serve as accurate and convenient markers for monitoring the pressure shift of the band gap, as has been demonstrated for GaAs.[11] We can thus obtain in straightforward fashion an independent measurement of $\partial E_G/\partial P$ to compare with the result of the analysis given in Sec. 3 of the pressure dependence of $\alpha(h\nu)$.

Table IV summarizes our data on two green-emitting diodes fabricated at Bell laboratories by diffusing Zn into nonintentionally doped, epitaxially grown, n-type material. The diodes were provided to us by Dr. M.

Gershenzon, who, along with co-workers, has carefully studied the EL spectra of such units and compared them with photoluminescence spectra.[65] The labeling of the various lines given in Table IV follows the discussion of Gershenzon, Mikulyak, Logan, and Foy,[65] and was obtained by comparison of our spectra with the similar 78°K spectra of their Fig. 8.

The notation for the 80°K lines of Table IV is as follows: EE signifies edge emission and is ascribed to recombination at widely separated donor-acceptor pairs.[65,66] It is associated with the sharp-line pair-spectra which appear at higher energies. The A line has been ascribed to annihilation of an exciton bound to an impurity.[65,67] The other four low-temperature lines are replications of the EE and A emissions at lower energies due to the simultaneous emission of phonons, acoustic (Ac), or longitudinal optical (LO). The edge emission lines saturate at higher currents while the A lines do not. The room temperature emission is either band-to-band or involves very shallow states.

Although the results for the weakest lines listed in Table IV are relatively less certain than the others, all yield about the same pressure coefficient. The consensus value for $\partial h\nu/\partial P$ is $-(1.1\pm0.1)\times10^{-6}$ eV/bar, in agreement with the band gap coefficient obtained in Sec. 3 from the absorption edge data. The room temperature datum of Table IV provided the lowest energy point shown in Fig. 6. We found no appreciable effect of pressure on the intensity of any of the lines.

The validity of equating the pressure coefficients of these emission lines with $\partial E_G/\partial P$ depends only on the assumption that the transitions involved are between shallow states derived from the band edges, which seems reasonable since their energies lie so close to E_G. However, it has been suggested that the A lines are due to a direct exciton (derived from the valence and conduction band states at $k=0$) strongly bound to an impurity, and that they accidentally occur at an energy near E_G because of a large binding energy. If this were so, then their pressure coefficient should be close to $\partial E_0/\partial P = +11\times10^{-6}$ eV/bar, rather than to $\partial E_G/\partial P = -1\times10^{-6}$ eV/bar. Table IV shows that the reverse is true. Thus, provided that we have correctly identified these lines as belonging to the A complex of Refs. 65 and 67, the mechanism for the A lines more probably involves an ordinary indirect exciton.

We have also measured, at room temperature, the effect of pressure on the broad emission band (width about 0.2 eV) appearing at 1.8 eV. This red emission has been attributed to radiative transitions from a deep donor level, associated with the presence of oxygen in the crystal,[56] to the valence band. The pressure coefficient is $+(1.0\pm0.5)\times10^{-6}$ eV/bar. This coefficient is slightly surprising; it is opposite in sign to $\partial E_G/\partial P$. [In silicon it was found that the pressure coefficient of the energy separation between a deep level and either band edge was a fraction of the (negative) band gap coefficient.[26]] This result implies that the donor binding energy decreases more rapidly with pressure than the band gap.

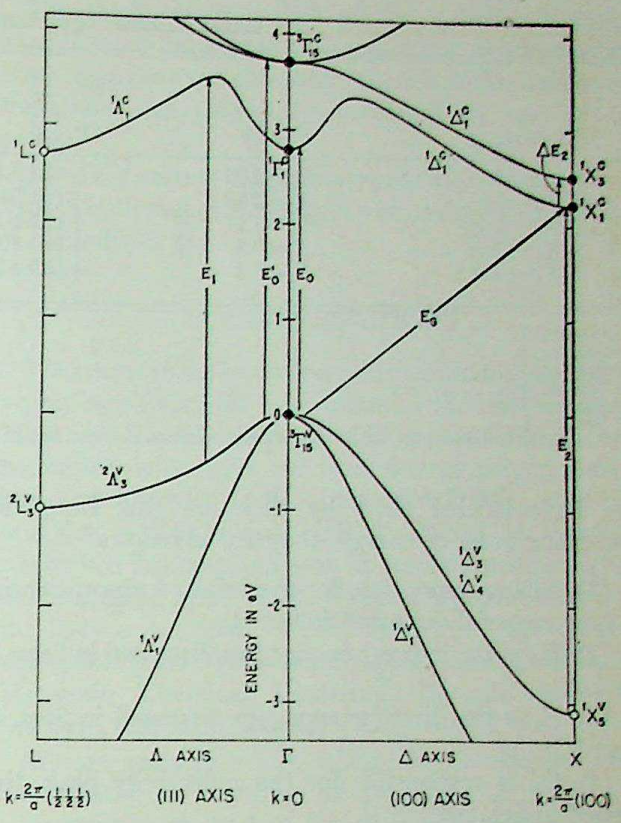

FIG. 12. Band structure of GaP. The states are labeled using the notation for the irreducible representations of the single group of the zincblende lattice. The left-hand superscript appended to each symbol gives the orbital degeneracy of the state. The arrows represent transitions observed in optical experiments. The five energy levels marked by solid circles were those studied by means of our pressure experiments.

7. THE BAND STRUCTURE AND ITS PRESSURE DEPENDENCE

In Fig. 12 we have constructed an electronic energy band diagram for GaP based upon available experimental information. The five energy levels marked by the solid circles are those upon which our pressure experiments bear. The three marked by open circles are from other data discussed below, the L-point levels being relatively uncertain. The levels at the symmetry points have been connected by plausible smooth curves which, although somewhat arbitrary, are consistent with various band structure calculations on similar semiconductors, as well as such considerations as crossing or noncrossing of bands and relative magnitudes of effective masses. We have neglected the spin-orbit splitting of valence band levels, which for GaP is about 0.1 eV. Since we do not consider effects of the electron spin, we have labeled the states with the irreducible representations for the single group, rather than for the double group, of the zincblende structure.[6]

The arrows shown in the figure represent the transitions which have been observed in optical experiments.

TABLE V. Effect of pressure on the band structure of GaP.

Transition	E in eV	$\frac{\partial E}{\partial P}$ in 10^{-6} eV/bar	Measurement
$\Gamma_{15}^v \rightarrow X_1^c$	$E_G=2.22$	$-(1.1\pm10\%)$	absorption edge,[a] recombination radiation[b]
$\Gamma_{15}^v \rightarrow \Gamma_1^c$	$E_0=2.78$	$+(10.7\pm10\%)$	absorption edge,[c] reflectivity peak[d]
$\Gamma_{15}^v \rightarrow \Gamma_{15}^c$	$E_0'=3.71$	$+(5.8\pm10\%)$	reflectivity peak[e]
$X_1^c \rightarrow X_3^c$	$\Delta E_2=0.3$	$+(1\pm50\%)$	absorption band[f]
$X_5^v \rightarrow X_1^c$	$E_2=5.3$	$+(2.9\pm20\%)$[g]	...

[a] See Sec. 3.
[b] See Sec. 6.
[c] See Sec. 3.
[d] See Sec. 5C.
[e] See Sec. 5B.
[f] See Sec. 4.
[g] This is the coefficient for the corresponding transition is silicon, as measured by means of the 4.3 eV silicon reflectivity peak (see Ref. 8).

We have labeled them by their energies. Listed in ascending order of energy, they are as follows:

(1) ΔE_2 is responsible for the infrared absorption in n-type material discussed in Sec. 4;

(2) E_G is the indirect energy gap discussed in Secs. 3 and 6;

(3) E_0 is the direct energy gap discussed in Secs. 3 and 5C;

(4) E_0' is responsible for the reflectivity peak discussed in Sec. 5B;

(5) E_1 is the Λ-point transition, hidden under E_0', discussed in Sec. 5B;

(6) E_2 is responsible for the 5.3-eV reflectivity peak mentioned in Sec. 5A.

In this work, we have studied the effect of pressure on (1) through (4).

The values of E_G, E_0, E_0', E_2, and ΔE_2, are sufficient to fix the energies (relative to ${}^3\Gamma_{15}^v$, the valence band maximum) of ${}^1X_1^c$, ${}^1\Gamma_1^c$, ${}^3\Gamma_{15}^c$, ${}^2X_5^v$, and ${}^1X_3^c$, respectively. To estimate the energies of ${}^1L_1^c$ and ${}^2L_3^v$, we made use of the following assumptions:

(1) E_1 is equal to E_0' (E_0' is the stronger transition which prevents E_1 from being seen);

(2) the separation of the two bands at L is not very different from E_1 (true for Ge[16]);

(3) ${}^2L_3^v$ is about 1 eV lower than ${}^3\Gamma_{15}^v$. (The known values of E_0, E_1, and the relative energy of the Γ and X conduction band minima, put the $\Gamma-L$ valence band width at 1.1 eV in GaSb, 1.5 eV in Ge.[7])

The two L-point energies shown in Fig. 12 are then specified. In view of the assumptions needed for their computation, they are clearly much less certain than the other levels.

The right-hand side of Fig. 12 is very similar to a band structure which has been calculated for AlP.[17] AlP is the 3–5 compound which is isoelectronic with Si. This points up the fact that GaP more closely resembles Si than it does Ge. Calculations on Ge-Si alloys[68] show that it is the silicon-rich alloys which most closely correspond to the GaP band structure of Fig. 12.

[68] F. Bassani and D. Brust, Phys. Rev. 131, 1524 (1963).

Our experiments determined the effect of pressure on E_G (Secs. 3, 6), E_0 (Secs. 3, 5C), E_0' (Sec. 5B), and ΔE_2 (Sec. 4). The pressure coefficients are listed in Table V. We have also listed a value for $\partial E_2/\partial P$. This is the pressure coefficient, as measured by us, for the corresponding peak in Si (at 4.3 eV).[8]

In the discussion of Sec. 3 on the pressure dependence of the indirect edge, we defined a quantity $(d/dh\nu)(\partial h\nu/\partial P)_\alpha=\beta$. The measured value of β, obtained from the slope of the linear, low-energy region of Fig. 6, was 1.15×10^{-5} bar^{-1}. We can now compare this experimental result with a theoretical estimate of β based, under certain assumptions, upon the information given in Table V.

In Sec. 3, we showed that β is equal to $-(1/A)\times(\partial A/\partial P)$, where A is the proportionality factor of Eq. (4). In the second-order perturbation theory used in dealing with indirect transitions, it is shown that the oscillator strength for this process [given by the coefficients $C_i^{\pm}$ of Eq. (2), C of Eq. (3), and A^2 of Eq. (4)] is proportional to a term of the form

$$\left(\sum_j \frac{p_j}{E_j}\right)^2;$$

p_j is a matrix element and E_j is an energy denominator corresponding to a virtual two-step process involving a particular intermediate state, specified by j.[69] The pressure dependence of this term is dominated by the pressure dependence of the energy denominators. If we assume, for lack of better information, that all of the p_j's are equal, it follows that $A=\text{const}\cdot\sum_j E_j^{-1}$. Substituting this into the expression for β, we find that

$$\beta=\frac{\sum_j(1/E_j^2)(\partial E_j/\partial P)}{\sum_j 1/E_j}. \tag{7}$$

[69] We have assumed that phonon energies are negligible relative to the energy separations of electron states ($k\theta_i \ll E_j$ for all i, j). Otherwise E_j^i would depend on a phonon energy (specified by i), as well as on the energy of the intermediate electronic state (specified by j). The expression for $C_i^{\pm}$ would then just contain E_j^i in place of E_j, but the situation for C and A^2 would be more complicated.

In Fig. 12 there are four intermediate states available for the indirect transition labeled by E_G: ${}^1\Gamma_1{}^c$, ${}^3\Gamma_{15}{}^c$, ${}^1X_3{}^c$, and ${}^2X_5{}^v$. The corresponding energy denominators are E_0-E_G, $E_0'-E_G$, $E_G+\Delta E_2$, and E_2-E_G, respectively. Using (7) and the information given in Table V (and ignoring all other intermediate states but the ones lying within the energy range of Fig. 12), we obtain $\beta=1.0\times10^{-5}$ bar^{-1}. The excellent agreement with the experimental value of 1.15×10^{-5} bar^{-1} is most likely fortuitous in view of the drastic assumptions made; nevertheless, it does show that the measured β is consistent with the proposed pressure-dependent band structure of Fig. 12 and Table V.

8. SUMMARY

The effect of pressure on several optical properties of GaP has been used to construct a tentative electronic energy-band structure for this material over a region of energy within about 4 eV of the valence band maximum at $k=0$. The major experimental results are summarized in Table V; the deduced band structure is shown in Fig. 12.

The data of Table V are consistent with the idea of correlation between pressure coefficients and types of electronic transitions[4-6]: The coefficients of E_G and E_0' are close to those for the corresponding transitions in Si[2,26]; that of E_0 is close to the corresponding coefficient in Ge[10] and GaAs.[11] The result for E_G confirms the location of the lowest conduction band minima as lying along [100] directions in k space.

Evidence for the direct gap E_0 comes from absorption measurements at lower energies, as well as from the weak reflectivity peak at about 2.78 eV, which has not been previously reported. Its temperature coefficient is about -4.6×10^{-4} eV/°K, compared to about -5.2×10^{-4} eV/°K for the indirect gap.

The small pressure shift of the 0.3-eV absorption band observed in n-type material indicates that vertical transitions between conduction bands is the mechanism responsible, as previously proposed by one of the authors.

All of the narrow edge emission lines we observed from a green-emitting diode shifted with pressure at the rate of the indirect gap.

ACKNOWLEDGMENTS

We are indebted to several laboratories for generously supplying us with the GaP material used in this study. Most of the absorption edge measurements were performed on samples cut from a large polycrystalline ingot provided by J. W. Allen of S.E.R.L., who also provided us with two red-emitting diodes. M. Gershenzon of Bell Laboratories sent us the two green-emitting diodes studied at 80°K. W. G. Spitzer provided us with the n-type material which exhibited the infrared absorption band. Other material was received from the Monsanto Chemical Company, Battelle Memorial Institute, and RCA Research Laboratory.

We are grateful to Dr. Allen, Dr. Gershenzon, and Dr. Spitzer for sending us preprints of their own interesting work, and to Dr. M. Cardona of RCA for valuable discussions. We have also benefited from discussions with P. Grant and V. Prakash of this laboratory.

The optical samples used for absorption and reflectivity measurements were prepared by David MacLeod. The optical high-pressure vessel was constructed largely by the efforts of James Inglis. The help of Albert Manning in the construction of apparatus is also acknowledged. We thank B. Kosicki for assisting with some of the diode experiments.

Thermal Disorder in a Dislocation Core and its Effect on Damping*

P. D. SOUTHGATE AND K. S. MENDELSON
Physics Division, IIT Research Institute, Chicago, Illinois

(Received 27 January 1964)

It is postulated that, at elevated temperatures, the core of a dislocation consists of a thermally disordered quasiliquid region, whose size increases with temperature. Calculations based on the effect of the disordering in relieving elastic stresses indicate that a flat strip core should be favored. A moving dislocation of this form will experience two distinct damping forces. One is thermodynamic, caused by the heat of disordering, and is analogous to the thermoelastic damping produced by the dislocation stress field; while the other is viscous, caused by the shear between the two sides of the strip. The calculated magnitudes of both of these damping forces in covalent and metallic crystals are comparable with those required to explain internal friction observations, although a positive demonstration of the validity of the mechanisms cannot be made on the basis of present data.

INTRODUCTION

A DISLOCATION moving through a crystal experiences a damping force, the magnitude of which depends on the dislocation velocity. Measurements of this damping force must be made indirectly and interpretation of the experiments is often open to doubt. It is generally supposed, however, that for small velocities, corresponding to values of the applied shear stress that are small compared to the shear modulus, the damping force is proportional to the velocity. This is the region which will be of interest in this paper.

Theoretically it is found that the nature of the damping force depends very strongly on the type of model assumed for the dislocation. This dependence is particularly sensitive to the structure of the dislocation core, where the Hooke's law approximation breaks down. The simplest model considers the core to be of very small radius and to move as an approximately straight cylinder. If the remainder of the crystal is treated as a continuum exhibiting linear elastic behavior, the only forces are those acting through the long-range stress field of the dislocation. Thermoelastic damping was treated by Eshelby[1] using this model in conjunction with a classical macroscopic thermodynamic method of calculation. If, in addition, nonlinear elastic effects occur near the core, interaction with thermal vibrations will occur. The periodic nature of the crystal can be taken into account by considering the dislocation core to be affected by a periodic Peierls stress field. Leibfried[2] and Nabarro[3] considered such a model, assuming that acoustic waves were scattered by a straight dislocation moving through the lattice without change of form.

A further improvement in the model is made by considering that the dislocation core does not move in the Peierls field as a straight segment, but rather proceeds by the formation and lateral motion of kinks.[4] The main sources of damping are then the energy losses experienced in thermal activation of kinks and the damping of the individual kinks. At low temperatures the damping is caused by the diffusion of built-in kinks (kinks necessitated by the geometry of the dislocation[5]); as the temperature is raised a little the thermal activation of kinks becomes important.[6–10] It appears logical to use discrete kink models at these moderately low temperatures. As the temperature becomes higher, however, the kink density becomes large and kink interactions become frequent. Eventually so much interaction occurs that one can no longer identify individual kinks. In this situation it is better to treat the entire region of the dislocation occupied by kinks as a disordered region of the crystal, and to consider this region as the dislocation core.

Such a model of the dislocation is discussed in this paper. It is assumed that the disorder in the dislocation core is very similar to that found in the liquid state, while the crystal outside the core is treated as a solid isotropic elastic continuum. There are then two separate sources of energy loss which originate at the core of the moving dislocation; one thermodynamic, due to the heat of disordering of the material passing through the dislocation core, and the other viscous, due to the shear rate of the disordered material. In the next section we calculate the size of the disordered region. Following sections then contain calculations of the magnitudes of the two types of damping, and a discussion of the applicability of the theory to experiment.

EQUILIBRIUM SIZE OF DISORDERED CORE

An immediate indication that disordering must occur in the core of a dislocation near the melting point is

obtained by considering the lowering of the melting point of the material as a consequence of hydrostatic pressure produced by the stress field of an edge dislocation. In a purely elastic and isotropic material, the pressure within an off-axis cylinder of diameter r will exceed $Gb/2\pi r(1-\nu)$, where G is the shear modulus, b the Burgers vector, and ν Poisson's ratio. The sign depends on whether the cylinder lies above or below the glide plane. If one now applies the Clapeyron equation for melting of bulk material, the melting point will be depressed in the positive pressure region for a material that contracts on melting, or in the tension region if the material expands. For example, in silicon, a material which has geometrically well-defined dislocations at low temperatures, a region of diameter of the order 10 Å will have its melting point suppressed more than 10% (170°C). In this paper we will refer to the region which becomes melted or disordered as the "core." In reality the core will not retain a cylindrical shape, since the material there will not be able to support shear stresses, and hence redistribution of the general stress pattern will occur, favoring a different core shape.

The exact method of calculating the core size would be to consider the free energy of the whole dislocation and then minimize this. Such a calculation would be very elaborate, involving a continuously decreasing disorder at increasing distances from the center. A more limited model is considered here, in which the core is taken to be a single phase, uniformly disordered, immediately surrounded by ideally elastic material. The core size may now be derived in a manner analogous to that employed for the standard Clapeyron equation.

Consider the core to have fixed, but arbitrary, shape and variable size. Denote the core size by a parameter ρ, having dimensions of length. The independent thermodynamic variables are then ρ and the temperature T. Initially it is supposed that the core is acted upon by an arbitrary stress field, whose net effect will be represented by a parameter p, conjugate to ρ, which may be thought as of analogous to a pressure which produces melting point depression. Take a boundary immediately surrounding the core, of dimension ρ_0, and let the internal energy of the total material within the boundary be $U(\rho,T)$. Then the heat entering through the boundary, in any general change, will be

$$dQ=dU+dW=(\partial U/\partial T)dT+(\partial U/\partial\rho)d\rho+pd\rho. \quad (1)$$

If these changes take place reversibly, the entropy change dQ/T will be a perfect differential. Hence,

$$(\partial U/\partial\rho)+p=T(\partial p/\partial T). \quad (2)$$

A change $d\rho$ involves the disordering of a volume $f(\rho)d\rho$ of material, with latent heat of solidification L. In an isothermal change, this heat all passes through the boundary. A change of temperature will require transfer of specific heat also; so, in general,

$$dQ=cdT+Lf(\rho)d\rho. \quad (3)$$

Comparing (1) and (3) and noting that $c=\partial U/\partial T$, yields

$$f(\rho)L=(\partial U/\partial\rho)+p \\ =T(\partial p/\partial T) \text{ from (3)}. \quad (4)$$

In fact the material transforming is in a state of strain in the ordered phase, and in addition the total interface area may be changed during transformation. The effective latent heat is hence that for unstrained material, L_0, less the strain energy and surface energy contributions $L_s(\rho)$.

At this point we restrict consideration to equilibrium conditions only, with the fixed dislocation stress field as the source of p. Now ρ and p are functions of T only, and the partial differential in (4) may be replaced by a total. Integrating, and inserting the sum in place of L, gives

$$p/(L_0-L_s)f(\rho)=\ln T+\text{const}. \quad (5)$$

If now the elastic strain energy outside the boundary is $U_0(\rho,T)$, the parameter p is given by

$$p=\partial U_0/\partial\rho,$$

since all changes of elastic energy appear as work done on the core.

The constant in (5) may be evaluated by considering the dislocation at the melting point. Here the core remains melted in the absence of any peripheral forces, and hence the elastic system should be in a state of static equilibrium. The stress-field energy will continuously reduce as the core size increases, while the surface energy of the solid-liquid interface will increase. The latter is also of the nature of an elastic energy, and so the equilibrium core size ρ_m at T_m may be obtained by minimizing the total stress-field plus surface energy.

Two possible configurations of the disordered core, representing extreme cases, have been considered. They are the flat strip, lying in the glide plane (or some minimum energy plane such as the most closely packed, for a screw dislocation), and the cylinder. It is shown in the Appendix that the rate of change of elastic energy outside a fixed contour close to the core, as the core size changes, is finite for the strip, and zero for the cylindrical configuration. It is probable that the strip represents the most efficient configuration for the relief of stress energy by the core disordering mechanism, and it will be assumed from now on that the core takes this form.

Let q be the thickness and 2ρ the width of the strip, and suppose that only ρ varies with temperature. This constraint will affect the final answer only slightly, and is introduced as a simplifying approximation. The total elastic and surface energy (see Appendix) is

$$(G\beta b^2/4\pi)\ln(kR/\rho)+4\rho s,$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

where s is the energy per unit area of liquid-solid interface, and the constant β varies from $1/(1-\nu)$ for an edge dislocation to unity for a screw. Minimizing this gives

$$\rho_m = Gb^2\beta/16\pi s.$$

Noting that the shape function $f(\rho)$ will be $2q$, and substituting in Eq. (5) yields

$$\rho = \frac{Gb^2\beta}{8\pi([L_0-L_s]q\ln(T_m/T)+2s)} \tag{6}$$

for the equilibrium core size in the flat strip configuration.

The approximate stress distribution discussed in the Appendix gives a shear strain in the solidifying material at the strip edges of $b\beta/2\pi q$, and hence the strain energy modification to L is

$$Gb^2\beta^2/8\pi^2\rho^2.$$

This turns out usually to be only a small fraction of L_0, and so it may be introduced into (6) as a second-order correction. The magnitude of the surface energy correction is not certain, but it is assumed that this also is fairly small.

DAMPING FORCE

We now calculate the magnitudes of the thermodynamic and viscous damping forces mentioned in the Introduction, again assuming that in most respects the situation may be treated as macroscopic. Both sources of damping are additional to any which may act on the dislocation stress field.

The thermodynamic damping is derived from the rate of entropy gain due to the temperature difference between the leading and trailing edges of the core. If the core were sufficiently wide, the temperature difference would be proportional to the normal thermal resistivity as well as the rate of latent heat release. However, the width is usually comparable with the mean free path of the thermal phonons, and in this situation the heat-transfer mechanism becomes one of phonon radiation rather than diffusion. The phonons may be considered to travel with an effective group velocity v_s, rather less than that of lower frequency acoustic waves. If the rate of heat generation per unit length of dislocation at the solidifying edge is Qq, the excess heat density near the source will be Q/v_s. The temperature difference between leading and trailing edges is therefore

$$\delta T = 2Q/av_sc_v,$$

where c_v is the specific heat per unit volume, and a is an effective radius, of the order of one atom distance, of the material which may be considered to have its temperature changed.

The entropy gain rate, treating the system macroscopically, is

$$\frac{dS}{dt} = Q\left(\frac{1}{T_1}-\frac{1}{T_2}\right) = \frac{Q\delta T}{T^2},$$

if δT is small. If the configuration of the dislocation core remains constant as it moves, the rate of change of internal energy of the system will be

$$dU/dt = T(dS/dt) = Q\delta T/T, \tag{7}$$

which may be represented by a damping force coefficient B_t:

$$dU/dt = B_tV^2, \tag{8}$$

where V is the dislocation velocity. The heat-generation rate will be

$$Q = (L_0-L_s)qV, \tag{9}$$

where L_0-L_s is the effective latent heat of solidfication. Thus, from (7), (8), and (9), the damping coefficient becomes

$$B_t = 2(L_0-L_s)^2q^2/aTv_sc_v. \tag{10}$$

Viscous damping may be calculated very simply for a strip-shaped core by assuming that the shear flow pattern is laminar. The relative displacement of the two faces as the core passes by is b; since it takes time $2\rho/V$ to pass, the shear rate is

$$\dot{\theta} = (b/q)(V/2\rho).$$

The total power dissipation is $2\rho q\eta\dot{\theta}^2 = B_vV^2$, giving

$$B_v = \eta b^2/2\rho q. \tag{11}$$

In the case of a core which has a shape closer to the cylindrical, the flow pattern might become more complex. There will be a tendency for the core to "roll" as the dislocation progresses, lessening the frictional force. However, estimates of the flow pattern have been made for a cylinder, allowing the formation of four main eddies, which show that the viscous damping differs from Eq. (11) by a factor of the order of unity. It is supposed that this effect will be unimportant in the case of a nearly flat strip.

APPLICATION OF MODEL

The theory developed in the previous sections should apply to dislocations in crystals which have a low-impurity content so that interactions between impurities and dislocations are not significant, and in which dislocation motion is over such short distances that they do not actually intersect other dislocations in the course of their motion. Internal friction measurements, or microscopic studies of the motion of identifiable dislocations, are two ways in which such a situation may be studied. Unfortunately there is a scarcity of experimental data, the tendency having been to con-

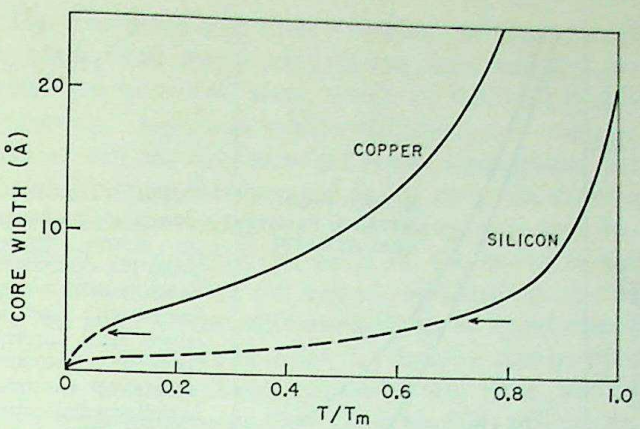

FIG. 1. Widths of disordered cores computed for copper and silicon. Arrows denote Burgers vector of dislocation, below which size the width loses its significance.

centrate on the behavior of dislocations at lower temperatures where appreciable dislocation broadening is not expected. We will take the case of two materials, for which there is some published information: silicon and copper. These form fairly typical covalent and metallic crystals. Ionic crystals are expected to behave in a similar manner to metallic, since the parameters involved have similar values.

The most significant factor in the theory is the heat of disorder. As a first approximation, this could be equated to the heat of fusion of the material and in copper we will assume this is the value. In silicon, melting involves not only disordering but also a change from essentially covalent to essentially metallic bonding,[11] which change presumably is exothermic. If we assume that in the core the disorder is sufficiently localized so that the covalent bonding is retained, and that one bond per atom is broken on the average, requiring about 1.5 eV, a heat of disorder is derived which is approximately twice that of melting; this will be used.

The second factor involved is the surface energy of the interface, and the value of this is very uncertain. No direct measurements exist, and such values as are quoted are derived from observations of supercooling of solidifying melts, using nucleation theory.[12] It is not clear whether the surface energy of significance under these conditions is the same as that at the dislocation core. We shall therefore guess a value for the surface energy of one-tenth the disorder energy, per atom. The core width will be sensitive to error in this approximation only near the melting point.

TABLE I. Values used in computing core widths.

	Silicon	Copper
Latent heat L (ergs cm^{-3})	1.2×10^{11}	1.6×10^{10}
Shear modulus G (dyne cm^{-2})	8×10^{11}	7.5×10^{11}
Burgers vector b (Å)	4.0	2.55
Strip width q (Å)	6.0	4.0
Melting point (°K)	1685	1356

Figure 1 shows the variation of core width to be expected for silicon and copper as a function of temperature. The dislocations considered are simple 60° dislocations in the (111) glide plane in both cases; Table I lists the values of parameters used. An isotropic average shear modulus is taken. It can be seen that as the temperature reduces to the Bordoni peak region in copper, below 110°K, and the region below 1200°K in silicon, the dislocation becomes less than one Burgers vector wide and it may be expected that the Peierls force should attain its full value. Above these temperatures, a smearing-out effect will occur. In both materials, dislocation behavior below these temperatures has been explained in terms of kink mechanisms, which require a large Peierls force; hence, the disordered-core theory is consistent with the kink hypothesis.

The thermodynamic component of damping may be computed from Eq. (10), the assumption being made that the effective phonon velocity is of the order 10^5 cm/sec. In silicon, B_t is then 2.5 dyn-sec-cm^{-2} at 1000°K and in copper 10^{-2} dyn-sec-cm^{-2}. These values are considerably larger than those obtained from the other models in which the Peierls force is not important, such as the thermoelastic theory of Eshelby ($B\sim10^{-5}$) or the interaction of thermal vibrations via nonlinear behavior near the core ($B\sim10^{-4}$), and hence will always dominate these other mechanisms.

Viscous damping is more difficult to evaluate, since a considerable extrapolation of viscosity data to the supercooled case is required. We assume that the viscosity is a thermally activated process, with the coefficient of viscosity $\eta\sim10^{-4}\exp(H/kT)$. In copper, the activation energy is assumed similar to that in other metals,[13] about 0.1 eV. In silicon, a higher activation energy is taken, corresponding to a bond-breaking process; the value of 1.4 eV gives a good match to the experimental observations. The viscous damping exceeds the thermodynamic damping below 0.1 T_m in copper and 0.85 T_m in silicon. It appears, therefore, that in copper (and, presumably many other metals also) the viscous mechanism is never important, since below 0.1 T_m the kink description of dislocation motion becomes valid. In silicon, on the other hand, it is anticipated that it forms a good description between 0.7 T_m and 0.85 T_m.

At the present time, comparison with experiment cannot do more than indicate support for the theory as applied to silicon. A major difficulty is the extraction of a damping coefficient from the measurements of

internal friction, since the free length of dislocation is an important, and frequently unknown, factor. The Koehler-Granato-Lucke[14,15] stretched-string model of dislocation damping gives for the logarithmic decrement δ of a crystal, at low oscillation amplitudes,

$$\delta=\frac{\alpha 8Eb^2NL^2}{\pi^3 C}\frac{\omega\tau}{1+\omega^2\tau^2},$$

with relaxation time

$$\tau=L^2B/\pi^2C,$$

where E is Young's modulus, N the dislocation density, L the free length of the dislocation, C its line tension, and α an orientation factor of the order 0.25. Now if $\omega\tau\gg1$, both L and C vanish from the expression, and B can be computed readily from δ and N. For silicon, where the disordered-core theory predicts B always greater than unity, the inequality will hold for measurements at 10 kc/sec as long as $L>4\times10^{-4}$ cm, which will be the case in pure material with dislocation densities of less than 10^7 cm^{-2}. Figure 2 gives a curve for B derived from measurements of δ on a silicon crystal bar oscillating at 8 kc/sec and containing a dislocation density of approximately 10^6 cm^{-2}. The form of the curve is very similar to that obtained by summing B_t and B_v from the theory; the factor of 2 or so difference in magnitude is not significant as it could easily arise from a nonuniform orientation distribution of a portion of the dislocation.

In the case of copper, the situation is more complex as the damping coefficient is expected to be lower, and hence the dislocation length will become important. For most measurements reported, it is probable that $\omega\tau<1$. The internal friction will then be proportional to the damping coefficient, which itself varies inversely as the temperature. Such behavior is not observed, increases with temperature always being reported above about 200°K, sometimes gradual,[16] sometimes rapid.[17] Two additional effects, which would influence the temperature dependence of the logarithmic decrement, might be mentioned here. The first is the possible release of dislocation pinning points as the temperature increases. This could cause an increase of decrement with temperature, either by increasing the free dislocation lengths, or by allowing some less limited motion at the pinning points. Secondly, dislocations in the (111) plane of face-centered cubic metals split into two half-dislocations. Changes with temperature in the spacing of these half-dislocations, particularly the possibility of their recombining at higher temperatures,

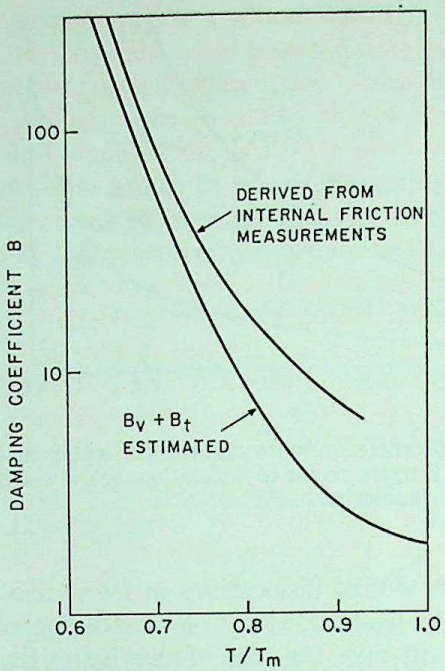

FIG. 2. Dislocation damping coefficient in silicon derived from the disordered-core model, compared with that derived from internal friction measurements by assuming a uniform dislocation distribution and free length greater than 10^{-3} cm.

could affect the temperature dependence of the logarithmic decrement. It is not clear what sort of effect this might be, although it is not expected to modify the behavior drastically. It is evident that further theoretical and experimental investigation is required.

DISCUSSION

A thermally disordered dislocation is a complicated system whose behavior can only be specified accurately in terms of the motions of a large number of atoms. The situation lies midway between a macroscopic and microscopic system; too small for the averaging processes implicit in the treatment of macroscopic systems to be used with complete rigor, and yet so large that analysis in terms of microscopic variables such as local phonon modes, or the statistics of some disorder parameter such as the kink density, would become immensely complex. The model which has been presented here uses the macroscopic approximation, modified at the points where it obviously breaks down, such as in the thermal conductivity. However, the validity of this approximamation is purely intuitive, since the treatment is, strictly speaking, inconsistent; neither can it be said at present to be supported by any good fit to experimental data. In its defense, it may be argued that the dislocation is at least of macroscopic length, so that although thermal fluctuations, for instance, may exceed the systematic difference due to dislocation motion over a very short length of line, over the total length they will be averaged out.

One prediction of the theory is that even in an isotropic material, a screw dislocation will lose its radial symmetry at high temperatures. In a real crystal, the anisotropy will give preferred glide planes, and presumably the strip core would form in one of these planes.

The disordered-core theory modifies to some extent the concepts of interaction between impurities and the dislocation in several ways, which we will now briefly enumerate. Impurities which condense onto the dislocation will not only form a Cottrell atmosphere, but will also become incorporated in the core, the ratio of the equilibrium concentration in the core to that immediately surrounding it being of the order of the segregation coefficient for normal solidification. A core containing impurities will have a higher thermodynamic potential, and hence in order to minimize this by dilution, a further increase of core width will occur. Motion of the dislocation away from the impurities will require the dissipation of a pinning energy, but this will be less than for the small-core dislocation normally considered. In addition, an oscillation of the dislocation with amplitude less than the dislocation width will not involve the same pinning energy, and the impurities will act as "soft" pinning points in that case. If a dislocation moves sufficiently slowly for impurities to follow, there will be a significant frictional force, the relaxation time of the process being of the order of the time for an impurity to diffuse across the core. All these points require further exposition, and it is intended to do this in a later paper.

A further effect of the disordered core will be seen in the "pipe diffusion" of defects. Diffusion coefficients for this process are high[18,19] and special structures, such as that of a hollow core, have been postulated to explain their magnitude. Queisser *et al.*[18] derive an activation energy for dislocation diffusion of phosphorous in silicon which is about 1.5 eV less than that of bulk diffusion. This difference was interpreted in terms of excess concentration of vacancies and impurities near the dislocation due to the formation of Cottrell atmospheres. However, the disordered-strip model shows that in the 1050 to 1200°C region where the measurements were made, there is appreciable broadening, which significantly lowers the Cottrell binding energy. Excess vacancy concentrations outside the core will therefore not be so large, and this mechanism of enhanced diffusion becomes less important. The alternative explanation is that the lower activation energy is associ- with the disordered-core material itself, which presumably would have an energy closer to that of the liquid state. Such a theory is being developed, taking into account possible changes of core size with impurity concentration in the core and the ratio of this to the concentration in the surrounding solid.

SUMMARY

The model presented here attempts to deal with the very complex problem of dislocation configuration and damping force by applying macroscopic thermodynamics to a microscopic situation. Although not strictly correct, the model has the advantage of involving a relatively simple conceptual picture of the dislocation at high temperatures, that of the thermally disordered core. The disordered material is considered to be quasi-liquid, so that appeal may be made to the concepts of latent heat of disorder, and of viscosity, in the calculations. "Melting" of the core relieves the stresses in the vicinity. It seems to be a reasonable assumption that a flat strip configuration does this most efficiently, in both edge and screw dislocations, although this has not been proven. A cylindrical disordered-core coaxial with the dislocation does not relieve stresses. The core width increases considerably as the melting point is approached, and will be greater than several atomic spacings over a significant temperature range in many crystals. Near the melting temperature, the surface energy of the order-disorder interface is a controlling factor in the size, and uncertainty in the value of the surface energy is reflected in an uncertainty in the width here.

Two separate contributions to the dislocation damping coefficient are derived: thermodynamic and viscous. The thermodynamic damping originates in the heat required to produce disorder in the forward edge of the moving dislocation and the entropy changes in transferring this heat from the solidifying trailing edge. It varies inversely as the temperature, but disappears when the dislocation narrows to only one or two atoms wide. Viscous damping decreases with temperature due to both the increase of dislocation width and decrease in viscosity of the disordered core. Both mechanisms appear to give damping coefficients of a significantly large order of magnitude; although good estimates of the viscosity of the disordered core are difficult to make.

Application of the theory to silicon shows that the damping will be large and will predominate near the melting point, while at lower temperatures, it is reasonable to suppose that viscous damping becomes important. The magnitudes are consistent with those derived from experiment. In the case of copper, the thermodynamic damping is expected to dominate the viscous over a wide temperature range, but the form of the temperature dependence deviates considerably from the experimentally observed variation. When the temperature becomes so low that the core is only two or three atoms wide, the disorder is better described as an assembly of kinks, and the more complex theories of kink generation and diffusion may then be used in place of the viscosity approximation.

A disordered core is expected to modify dislocation interactions with impurities, and to lead to a higher equilibrium concentration of impurities in the core, "soft" pinning effects, additional dislocation drag mechanisms, and enhanced impurity diffusion along the dislocation.

APPENDIX: DEPENDENCE OF STRESS-FIELD ENERGY ON CORE SIZE

1. Cylindrical Core

The dislocation core is considered to be a cylinder of radius ρ. We wish to calculate the stress-field energy per unit length, U_0, in the region outside a larger cylinder of radius ρ_0, and to obtain

$$\lim_{\rho_0 \to \rho} (\partial U_0/\partial \rho).$$

Consider a straight dislocation lying along the z axis and let σ^{ij} and e_{ij} be components of the stress and strain produced by this dislocation. Then

$$U_0 = \frac{1}{2}\int \sigma^{ij} e_{ij} dS, \tag{A1}$$

where the upper and lower indices denote contravariant and covariant components,[20] and the usual summation convention has been used. The integration is taken over the region of the xy plane between circles of radius ρ_0 and R (large). For an isotropic medium the stress and strain components are related by [21]

$$e_{ij} = \frac{1}{2G}\left[\sigma_{ij} - \frac{\nu}{\nu+1} g_{ij} g^{mn} \sigma_{mn}\right], \tag{A2}$$

where the g_{ij} are the components of the metric tensor.

The physical stress components[20] for a screw dislocation are given in Eq. (2.16) of Cottrell.[22] They are independent of ρ; hence U_0 will also be independent, and

$$\lim_{\rho_0 \to \rho} (\partial U_0/\partial \rho) = 0.$$

For an edge dislocation one cannot take the stress components directly from Eq. (2.10) of Cottrell. It is necessary to correct the components so that the stresses across the surface of the core vanish. Following the method outlined by Cottrell one obtains the corrected covariant stress components:

$$\begin{aligned}
\sigma_{rr} &= -\frac{Gb\sin\theta}{2\pi(1-\nu)r}\left[1 - \frac{\rho^2}{r^2}\right], \\
\sigma_{\theta\theta} &= -\frac{Gbr\sin\theta}{2\pi(1-\nu)}\left[1 + \frac{\rho^2}{r^2}\right], \\
\sigma_{\theta r} &= \sigma_{r\theta} = \frac{Gb\cos\theta}{2\pi(1-\nu)}\left[1 - \frac{\rho^2}{r^2}\right], \\
\sigma_{zz} &= \nu(\sigma_{rr} + (r^2)^{-1}\sigma_{\theta\theta}).
\end{aligned} \tag{A3}$$

Now, using the relation $\sigma^{ij} = g^{ik} g^{jl} \sigma_{kl}$ to obtain the contravariant stress components, and neglecting terms in $1/R^2$ and $1/R^4$, we derive

$$U_0 = \frac{Gb^2}{4(1-\nu)}\left[\ln\frac{R}{\rho_0} - \frac{\rho^2}{2(1-\nu)\rho_0^2} + \frac{\rho^4}{4(1-\nu)\rho_0^4}\right], \tag{A4}$$

and again

$$\lim_{\rho_0 \to \rho} (\partial U_0/\partial \rho) = 0.$$

We might note that $\lim_{\rho_0 \to \rho} U_0$ does not agree with the expression given by Cottrell [the right side of Eq. (2.22b) of Ref. 22]. Cottrell calculates the energy by considering a half-plane cut made in the unstressed material and determining the work done in displacing the two sides of the cut by the Burgers vector. However, this procedure ignores the work done in changing the shape of the core during the displacement, and it is apparent that this work is of the same order as the correction terms.

2. Flat Strip Core

Let the dislocation core be a strip of variable width 2ρ in the glide plane and fixed thickness q. Take a fixed boundary outside the core, width $2\rho_0$, and thickness q; U_0 is the elastic energy outside this boundary. We are interested in the case $q \ll \rho$ and hence, for simplicity, will calculate U_0 in the limit $q \to 0$. Suppose U' is the energy outside the strip of width 2ρ. As $q \to 0$, the volume between the two strips becomes vanishingly small and hence $U' \to U_0$. Since the limits involved in calculating the partial derivatives are independent of q, they will also become equal as $q \to 0$.

A convenient way of deriving U_0 is the use of the analogy between the magnetostatic field energy of a current and the elastic field energy of a dislocation.[23] The analogy is effected in this case by substituting the elastic modulus $G\beta$ for the permeability μ_0, and the Burgers vector b for the current I. We regard the strip as having a uniform distribution of Burgers vector between $-\rho$ and $+\rho$, and hence take a uniform current distribution for the analogous case. The magnetostatic energy is related to the inductance L by

$$U_m = \tfrac{1}{2} L I^2,$$

while L is readily obtained from the formulas of Oberhettinger and Magnus[24] for the characteristic impedance of a transmission line consisting of a flat strip surrounded by a large outer conductor. If the outer conductor is sufficiently large, a good approximation is

$$L = (\mu_0/2\pi)\ln(kR/\rho),$$

[20] See, for example, G. E. Hay, *Vector and Tensor Analysis* (Dover Publications Inc., New York, 1953), Chap VI.

[21] This can be obtained by generalizing Eq. (12.3) of Ref. 24, which is given in Cartesian coordinates. The m in this equation is the reciprocal of Poisson's ratio ($m = 1/\nu$).

where k is of the order of 2.5 and depends on the geometry of the outer conductor, and mks units are used. Therefore

$$U_0=(G\beta b^2/4\pi)\ln(kR/\rho)$$

and

$$\partial U_0/\partial\rho=-(G\beta b^2/4\pi\rho).$$

The same expression is obtained by an approximation in which the material within a circle of radius ρ is taken to be uniformly stressed, in tension above and in compression below the strip, while outside the circle it is stressed just as if the strip were of infinitesimal width. This relatively simple stress distribution appears to be a good approximation to the exact situation.

PHYSICAL REVIEW VOLUME 134, NUMBER 6A 15 JUNE 1964

Surface Effect in Secondary and Photoelectric Emission

I. ADAWI
Battelle Memorial Institute, Columbus, Ohio

(Received 10 January 1964; revised manuscript received 28 February 1964)

The secondary emission yield of metals by the surface effect δ is expressed in terms of the surface photoelectric yield $y(\omega)$ for a radiation of frequency ω and angle of incidence of $\cos^{-1}\frac{1}{2}(5^{\frac{1}{2}}-1)$ which is about 52°. It is shown that $\delta\sim(2\pi\alpha E_p)^{-1}\int_{\omega_1}^{\omega_2} y(\omega)d\omega/\omega$, where E_p is the primary energy in atomic units, $\alpha=1/137$, ω_1 is the threshold frequency, and ω_2 depends on the energy of the primary and may be replaced by ∞. For a square-well potential model for a metal, $\delta\sim10^{-3}/E_p$ with a relative error of order $(E_F/E_p)\ln(E_p/E_F)$, where E_F is the Fermi energy.

1. INTRODUCTION

THE purpose of this paper is to establish a general and simple relation between the surface effect in secondary electron emission[1] (SSE) from metals and the surface photoelectric effect[2,3] (SPE), and to use this relation to show clearly why the SSE is so small that it can be neglected in explaining the experimental facts. Such a relation is of interest for its own sake, and in addition a new examination of the problem is desirable since most of the published papers on the SSE, are incorrect.[4,5]

We shall use for convenience Hartree's atomic units in which $\hbar$, the electron mass m, the Bohr radius a_B, and the electron charge e are unity, and the speed of light c is 137. As was done in discussing the surface photoelectric effect in I, we treat the conduction electrons as independent noninteracting particles. The motion of a single electron in the y and z directions is free and can be described by the plane-wave $L^{-1}\exp i(k_y y+k_z z)$ obeying cyclic boundary conditions and normalized to unity in a square area of side L. The x motion is bound by a general surface potential $V(x)$ which is the same for all electrons and varies only in the direction x which is normal to the metal surface. This motion is described by the wave function $L^{-1/2}\phi_0(x)$ normalized to unity. The length L is the thickness of the metal plate which extends from $x=-L$ to $x=0$. The function $\phi_0(x)$ satisfies the wave equation,

$$H_1\phi_0=E_0\phi_0, \tag{1.1}$$

where

$$H_1(x)=-\tfrac{1}{2}\partial^2/\partial x^2+V(x). \tag{1.2}$$

Inside the metal, $V(x)$ is a constant equal to $-V_0$, and we can write $\phi_0(x)=2^{1/2}\sin(k_x x+\gamma)$ where γ is a phase factor depending on $V(x)$, and $\frac{1}{2}k_x^2=E_0+V_0$. The potential $V(x)$ rises to zero in the surface barrier regions near $x=0$ and $x=-L$ in a distance much less than L, and $\phi_0(x)$ behaves as $\exp(-px)$ for large x, where $-\frac{1}{2}p^2=E_0$. We ignore thermal effects and assume that all energy states below the Fermi energy E_F are occupied, and all energy states above the Fermi energy are empty. The conduction electrons in this model assume k values which fill "a Fermi hemisphere" given by $k^2=k_F^2$ and $k_z>0$, where k_F is the Fermi momentum,

[3] I. Adawi, Phys. Rev. **134**, A788 (1964). This paper will be denoted by I.

[4] A. Viatskin, Zh. Eksperim. i Teor. Fiz. **9**, 826 (1939) treated a semi-infinite square-well potential model. The basic formulation is correct but the final integrations and conclusions are obscure and incorrect.

[5] W. Brauer and W. Klose, Ann. Physik **19**, 116 (1956). This paper has been assumed correct in the two review articles cited in Ref. 1, but it contains unfortunately basic errors. They treat a finite square well of width $2a$ in the limit that $a\to\infty$. The correct final state which should be used in the transition matrix element is the function v^* used here. Using the notation and Eq. (4.5) of I we have that the incoming wave v is given by $v=\frac{1}{2}(\phi^s/\Lambda_s^*+\phi^a/\Lambda_a^*)$. When the correct limiting procedure is applied as $a\to\infty$, the results of the finite and the semi-infinite square well become identical as has been discussed in general in I. With this in mind, and for a primary electron incident normal to the metal surface, none of the four delta functions obtained by Brauer and Klose and on which essentially all their discussion is based should arise; and the effect is precisely determined by terms similar to those they ignored. The yield by the surface effect in secondary emission as in photoelectric emission is independent of the dimensions of the model analyzed, and there is no need to introduce an *ad hoc* depth d_s for calculating the effect.

i.e., $E_F=\frac{1}{2}k_F^2$. The number of electrons per unit volume in the interval d^3k is given by $4d^3k/(8\pi^3)$, where the factor 4 is contributed by the usual factor 2 for spin and an additional factor 2 to take account of the distribution of the bound states of the x motion in the continuum limit[3] (large $V_0^{1/2}L$).

We consider a primary electron of momentum $\mathbf{K}$ and energy $E_p=\frac{1}{2}K^2$ incident *normal* to the metal surface, namely, $\mathbf{K}=(-K,0,0)$. The mutual Coulomb repulsion between the primary electron and the conduction electrons bound by the surface potential offers a *direct* mechanism for a secondary electron emission from the bombarded metal surface. It is with this process that we are here concerned. We do not concern ourselves with those electrons which are left excited after colliding with the primary, and which diffuse in the metal, and appear later as secondaries. We hardly need to emphasize that the effect we are discussing exists only by virtue of the binding of the conduction electrons to the surface potential, since it is well known that no secondaries can be *directly* emitted from a metal surface bombarded with *normally* incident primaries if the electron gas is completely free.[6]

In Sec. 2 we discuss the scattering problem of the system consisting of a primary electron and a conduction electron, hereafter referred to as secondary. We shall consider only fast primaries (nonrelativistic) whose energy is much greater than the Fermi energy. Indeed, the situations of most practical interest[1] are those where the primary energy E_p is of order 10 (272 eV) and E_p/E_F of order 100. We are then justified in treating the Coulomb field of the two electrons as a perturbation and neglecting the effect of the surface potential on the primary wave functions. We shall, however, treat exactly the effect of the surface potential on the motion of the secondary in the final state which leads to the use of the well-known "incoming wave"[3,7] in the transition matrix element. The two electrons will be treated as distinguishable particles described by a product wave function, since we shall see that the main contributions to the SSE come from small-angle scattering for which exchange effects are not important.

In Sec. 3 we use the small-angle scattering approximation and derive the main result of the paper which expresses the secondary emission yield by the surface effect as an integral over the surface photoelectric yield. In Sec. 4 we illustrate this result by treating two examples. In the first example we use experimental measurements on the SPE. In the second example we apply our formulas to the previously treated[4,5] square-well potential model for the metal, and obtain the yield by the SSE which turns out to be in agreement with Baroody's unpublished result.[8]

2. FORMULATION

The unperturbed Hamiltonian of the system H_0 consists of three commuting parts: H_1 defined in (1.2), H_2 the kinetic energy of the secondary for the y and z motions, and H_3 the kinetic energy of the primary. Thus,

$$H_0=H_1+H_2+H_3, \tag{2.1}$$

$$H_2=-\tfrac{1}{2}(\partial^2/\partial y^2+\partial^2/\partial z^2), \tag{2.2}$$

$$H_3=-\tfrac{1}{2}\nabla_{\mathbf{R}}^2, \tag{2.3}$$

where $\mathbf{r}=(x,y,z)$ is the position of the secondary and $\mathbf{R}$ is the position of the primary. The perturbation potential H' is given by the Coulomb field,

$$H'=1/|\mathbf{R}-\mathbf{r}|. \tag{2.4}$$

We consider as in Sec. 1 a metal plate defined by $-L<x<0$, and discuss the secondary emission from a square region of area L^2 of the surface $x\approx 0$ which is bombarded by a uniform primary beam moving in the $-x$ direction. The interaction volume is L^3 and we normalize the primary wave function to unity in this volume. Thus the initial primary state is $L^{-3/2}\exp(i\mathbf{K}\cdot\mathbf{R})$ with $\mathbf{K}=(-K,0,0)$. The initial state of the secondary has been defined, and we take for the initial state of the system the wave function ψ_0 defined by

$$\begin{aligned} &H_0\psi_0=\mathcal{E}\psi_0,\\ &\psi_0=L^{-3}\exp i(\mathbf{K}\cdot\mathbf{R}+\mathbf{k}_\perp\cdot\mathbf{r})\phi_0(x),\\ &\mathcal{E}=E_0+\tfrac{1}{2}(k_\perp^2+K^2), \end{aligned} \tag{2.5}$$

where for any vector $\mathbf{s}$, $\mathbf{s}_\perp\equiv(0,s_y,s_z)$.

The solution ψ^+ of the perturbed problem for outgoing waves satisfies the scattering integral equation,[9,10]

$$\psi^+=\psi_0+[1/(\mathcal{E}-H_0+i\epsilon)]H'\psi^+. \tag{2.6}$$

If we write

$$\psi^+=\psi_0+\psi_s, \tag{2.7}$$

where ψ_s is the scattered wave, we obtain to first order in H' that

$$\psi_s=[1/(\mathcal{E}-H_0+i\epsilon)]H'\psi_0. \tag{2.8}$$

We expand H' in terms of the eigenfunctions of the primary and write the usual Fourier series,

$$H'=1/|\mathbf{R}-\mathbf{r}|=\textstyle\sum_\kappa(4\pi/\kappa^2)L^{-3}\exp[i\boldsymbol{\kappa}\cdot(\mathbf{r}-\mathbf{R})], \tag{2.9}$$

in which the components of $\boldsymbol{\kappa}$ are given by $(2\pi/L)$ times an integer which is also the case for k_y and k_z.

If in (2.8) we substitute for H' and ψ_0 the expressions given by (2.9) and (2.5) and observe that the relation

$$\begin{aligned} (\mathcal{E}-H_0+i\epsilon)^{-1}&\exp i(\mathbf{K}'\cdot\mathbf{R}+\mathbf{k}_\perp'\cdot\mathbf{r})\\ &=[\exp i(\mathbf{K}'\cdot\mathbf{R}+\mathbf{k}_\perp'\cdot\mathbf{r})]\\ &\quad\times[\mathcal{E}-H_1-\tfrac{1}{2}(K'^2+k_\perp^2)]^{-1}, \end{aligned} \tag{2.10}$$

holds for a general $\mathbf{K}'$ and $\mathbf{k}'$, we obtain

$$\psi_s=\sum_\kappa \exp\{i[(\mathbf{K}-\boldsymbol{\kappa})\cdot\mathbf{R}+(\mathbf{k}_\perp+\boldsymbol{\kappa}_\perp)\cdot\mathbf{r}]\} \times(4\pi/\kappa^2)L^{-6}\phi(\boldsymbol{\kappa},x), \quad (2.11)$$

$$\phi(\boldsymbol{\kappa},x)=\int G^+(E';x,x')e^{i\kappa_x x'}\phi_0(x')dx', \quad (2.12)$$

$$G^+(E')\equiv(E'-H_1+i\epsilon)^{-1}, \quad (2.13)$$

$$E'\equiv\tfrac{1}{2}q^2\equiv E_0+\omega, \quad (2.14)$$

$$\omega=-\kappa_x K-\tfrac{1}{2}\kappa_x^2-\kappa_\perp^2-\mathbf{k}_\perp\cdot\boldsymbol{\kappa}_\perp, \quad (2.15)$$

which reduces the problem to a one-dimensional problem, since the Green's function $G^+(E')$ contains only the Hamiltonian of the x motion.

To obtain the secondary current we examine the asymptotic behavior of ψ_s for positive large x. For large x and finite x' we have as in I that,

$$G^+(E';x,x')\sim(iq)^{-1}e^{iqx}v(x'), \quad (2.16)$$

where $v(x)$ is the "incoming wave" defined as the *incident wave* $\exp(-iqx)$ *plus the reflected and transmitted waves due to the potential* $V(x)$. From (2.16) and (2.12)

$$\phi(\boldsymbol{\kappa},x)\sim(iq)^{-1}Me^{iqx}, \quad (2.17)$$

$$M\equiv\int v(x)e^{i\kappa_x x}\phi_0(x)dx\equiv\langle v^*|\exp(i\kappa_x x)|\phi_0\rangle. \quad (2.18)$$

From the cylindrical symmetry of the problem, the total secondary particle current is in the x direction, and we need to calculate, therefore, the current element dI_x contributed by ψ_s and threading the area L^2. Using (2.17) in (2.11) and the usual formula,

$$dI_x(x)=\frac{1}{2i}\int\left[\psi_s^*\frac{\partial\psi_s}{\partial x}-\psi_s\frac{\partial\psi_s^*}{\partial x}\right]d^3Rdydz, \quad (2.19)$$

we obtain

$$dI_x=\sum_\kappa 16\pi^2\kappa^{-4}|M|^2q^{-1}L^{-7}. \quad (2.20)$$

Notice that in (2.19) the y and z integrations give L^2, the $\mathbf{R}$ integration gives L^3, and the orthogonality of the primary final states eliminates any interference terms between different values of $\boldsymbol{\kappa}$. The total current I_x is obtained by summing (2.20) over the conduction electrons in the volume L^3, and if we replace the summations by integrations we obtain

$$I_x=L^{-1}\int(d^3k/2\pi^3)\int(2/\pi)d^3\kappa(\kappa^{-4}|M|^2q^{-1}), \quad (2.21)$$

where the $\mathbf{k}$ integration is extended over the Fermi hemisphere and the $\boldsymbol{\kappa}$ integration is restricted by the condition that q is real.

If the normally incident primary is to lose energy to the secondary, κ_x *must be negative*. Furthermore, ω of (2.15) must exceed the metal work function ω_1 before any secondaries can be emitted *directly* by the present mechanism. This implies that some screening of the Coulomb field is automatically included in the model and we see from (2.15) that, to a good approximation, all $\kappa<\omega_1/K$ do not contribute.[11]

The SSE yield δ, which is the number of secondaries emitted per incident primary, is obtained by dividing I_x by the primary current K/L, namely,

$$\delta=(2/\pi K)\int(d^3k/2\pi^3)\int d^3\kappa(\kappa^{-4}q^{-1}|M|^2). \quad (2.22)$$

To show clearly that δ is independent of L as $L\to\infty$, we must investigate the nature of M in this limit. It was shown in I that in discussing electron emission from the surface $x=0$, a finite plate model with two surface barriers, one at $x=0$ and the other at $x=-L$, reduces in the limit $L\to\infty$ to a semi-infinite model with one barrier at $x=0$. The limiting "incoming wave" $v(x)$, which must be used in (2.18), is a solution of the wave equation for this limiting potential for $x>-L$, and is zero for $x<-L$. Thus inside the metal $v(x)\propto\exp(-ik_x'x)$ where a cutoff is implied to render $v(x)$ zero as $x\to\infty$, and where $k_x'^2=q^2+2V_0=k_x^2+2\omega$. The integrand in (2.18) for $x<0$ is of the form

$$\exp i(-k_x'\pm k_x+\kappa_x)x$$

for which the phase cannot vanish, since $k_x'>k_x$ and $\kappa_x<0$, and hence the integral cannot display a delta-function-type singularity which, if it were present, would bring a length[12] L in $|M|^2$. Obviously, the integration in (2.18) over x between $x=0$ and $x=\infty$ is convergent since $\phi_0(x)$ is a damped wave for large x. We conclude that except for thin films, to which still the present formulation can easily be adapted, $|M|^2$, and δ are independent of L, and we can set formally $L=1$ in the preceding equations.

For completeness, we give now the results of the time proportional transitions method in discussing the scattering problem. A detailed derivation can be found in Gell-Mann and Goldberger,[10] or obtained by other means. The transition from the initial state ψ_0 of (2.5) to the plane-wave final state ψ_f of energy $\mathcal{E}'$, where $\psi_f=\exp i(\mathbf{K}'\cdot\mathbf{R}+\mathbf{k}'\cdot\mathbf{r})$, $\mathbf{K}'=\mathbf{K}-\boldsymbol{\kappa}$ and $\mathbf{k}'=(q,k_y',k_z')$, is determined by the transition matrix element T_{f0}

---

[11] For a uniform electron gas screening sets in for momenta $<\omega_p/K$ where ω_p is the plasma frequency, see, e.g., H. A. Kramers, Physica 13, 401 (1947), J. Lindhard, Kgl. Danske Viedenskab. Selskab, Mat. Fys. Medd. 28, 8 (1954). In the surface problem under consideration, the electron density, plasma frequency, and dielectric constant are variable in the region of interest, and it is not deemed worthwhile to discuss screening beyond what naturally occurs in the problem.

[12] Notice that as $L\to\infty$, $2\pi\delta(k)=\int_{-1/2L}^{1/2L}dx\exp(ikx)$, and $2\pi|\delta(k)|^2$ is interpreted as $L\delta(k)$. If M had a delta function behavior the sum over k_x would have to be restricted to a length d_s and not L, where d_s is a characteristic escape depth for the secondary, but then we would be really discussing a volume effect!

which is given by

$$T_{f0}=\langle\psi_f|H'+V|\psi^+\rangle. \tag{2.23}$$

After some algebra (2.23) gives to first order in H' the result,

$$T_{f0}=\langle\psi_f^-|H'|\psi_0\rangle, \tag{2.24}$$

where $\psi_f^-=v^*(x)\exp i(\mathbf{K}'\cdot\mathbf{R}+\mathbf{k}_\perp'\cdot\mathbf{r})$, the only difference between (2.24) and the simple version of the Born approximation is the replacement of $\exp(iqx)$ by $v^*(x)$. The $\mathbf{R}$ integration in (2.24) gives $4\pi\kappa^{-2}$, and the y and z integrations give Kronecker deltas, since momentum is conserved for these directions, and we have

$$T_{f0}=4\pi\kappa^{-2}M\delta_{k_y',k_y+\kappa_y}\delta_{k_z',k_z+\kappa_z}. \tag{2.25}$$

By summing the transition rate, $2\pi|T_{f0}|^2\delta(\mathcal{E}'-\mathcal{E})$, over k_y' and k_z' holding $\boldsymbol{\kappa}$ fixed, and integrating over q we obtain $16\pi^2\kappa^{-4}|M|^2q^{-1}$, which when summed over $\boldsymbol{\kappa}$ and $\mathbf{k}$ gives exactly Eq. (2.21) for the total current (with $L=1$).

3. RESULT

The yield δ of (2.22) is controlled mainly by the Coulomb scattering which is proportional to κ^{-4}, and by the matrix element M which is the Fourier transform of $v\phi_0$, where v and ϕ_0 are eigenfunctions of H_1 whose energy difference is ω. The problem is basically the same as the ionization of atoms by fast electrons for which the physical principles are well established.[13] We shall here use the energy k_F^2 as a characteristic energy to obtain order of magnitude estimates, in much the same way as the binding energy is used in atomic collisions. For $\kappa_x=0$, $M=0$, and for small κ_x we write $\exp(i\kappa_x x)\sim1+i\kappa_x x$, and we have the well-known dipole approximation,

$$M\approx i\kappa_x\langle v^*|x|\phi_0\rangle. \tag{3.1}$$

From the commutation relations, $[x,H_1]=\partial/\partial x\equiv D$, and $[D,H_1]=\partial V/\partial x$, we can rewrite[3] (3.1) as

$$\begin{aligned} M&\approx -i\kappa_x\omega^{-1}M_1,\\ M_1&\equiv\langle v^*|D|\phi_0\rangle\equiv-\omega^{-1}\langle v^*|V'|\phi_0\rangle. \end{aligned} \tag{3.2}$$

For $\kappa_x\gg k_F$ the binding effect of the potential $V(x)$ should become negligible, and the conduction electrons can be treated as free electrons. Since we know that in such a situation no secondaries can be emitted,[6] we conclude that M must decrease very rapidly as κ_x becomes large. This coupled with the fact that the Coulomb field strongly favors small momenta transfer, leads to the conclusion that the major contributions to the yield come from those values of κ for which $\kappa_x\ll k_F$ and $\omega\sim k_F^2$. The dipole approximation (3.1) applies and there is no need to consider large values of κ_x.

The expression (2.15) for ω will now be simplied. To estimate various terms, we recall that for a fractional energy loss Δ by the primary and for a scattering angle Θ we have $K'\approx(1-\frac{1}{2}\Delta)K$, $-\kappa_x=\frac{1}{2}(\Delta+\Theta^2)K$, and $\kappa_\perp\approx\Theta K$. The term $\frac{1}{2}\kappa_x^2$ can certainly be neglected. The term $\mathbf{k}_\perp\cdot\boldsymbol{\kappa}_\perp$ is zero on the average, and it is small compared to $-\kappa_x K$ for $\Theta^2\ll\Delta\sim k_F^2/K^2$ or $\Theta<k_F/K$. For $\Theta\gg k_F/K$, $\kappa_\perp^2\gg\boldsymbol{\kappa}_\perp\cdot\mathbf{k}_\perp$. We can, therefore, neglect the term $\boldsymbol{\kappa}_\perp\cdot\mathbf{k}_\perp$ without committing a serious error. Equation (2.15) now takes the approximate form

$$\omega\approx-\kappa_x K-\kappa_\perp^2, \tag{3.3}$$

whose accuracy will be later discussed.

By using (3.2) and (3.3) in (2.22) we can hold $\boldsymbol{\kappa}$ fixed and integrate over $\mathbf{k}$, and we can write

$$\delta=(\pi^2\alpha K)^{-1}\int d^3\kappa\,\kappa_x^2\omega^{-1}y(\omega), \tag{3.4}$$

where, by definition,

$$y(\omega)=2\pi\alpha\omega^{-1}\int(d^3k/2\pi^3)q^{-1}|M_1|^2, \tag{3.5}$$

and $\alpha=1/137$. To identify $y(\omega)$ we shall use the results of I on the first-order SPE. For a monochromatic radiation beam of angular frequency ω and polarization ($\mathbf{E}$ vector) in the plane of incidence, we find by summing Eq. (2.15a) of I over $\mathbf{k}$ that the photoelectric current density I_1 is given by

$$I_1=137ny(\omega)\sin^2\theta, \tag{3.6}$$

where n is the number of photons/unit volume in the incident beam, and θ is the angle of incidence. By dividing I_1 by $nc\cos\theta$ which is the normal component of the photon current density, we obtain the SPE yield $Y(\omega,\theta)$, namely,

$$Y(\omega,\theta)=y(\omega)(\sin^2\theta/\cos\theta). \tag{3.7}$$

Thus, $y(\omega)$ is the SPE yield for $\theta=\cos^{-1}\frac{1}{2}[(5)^{1/2}-1]=51°50'$.

The azimuthal integration in (3.4) gives 2π. The remaining double integral is written using the new variables, $\omega=-\kappa_x K-\kappa_\perp^2$ as in (3.3) and $u=\kappa_\perp^2$, and we have

$$\delta=(2\pi\alpha E_p)^{-1}\int_{\omega_1}^{\omega_2}(d\omega/\omega)y(\omega)F(\omega), \tag{3.8}$$

where

$$F(\omega)=2E_p\int_0^{u_0}du\left(1+E_p\frac{\partial}{\partial E_p}\right)[(u+\omega)^2+2E_pu]^{-1}. \tag{3.9}$$

Here, $\omega_2=\kappa_{x0}K$, where κ_{x0} is a maximum value of $-\kappa_x$ consistent with the approximation $-\kappa_x\ll k_F$, and u_0

$=\omega_2-\omega$. Performing the integration in (3.9), we obtain

$$F(\omega)=\frac{\omega E_p^{1/2}}{(E_p+2\omega)^{3/2}}\ln\frac{u-u_1}{u-u_2}-\frac{2E_p[(E_p+\omega)u+\omega^2]}{(E_p+2\omega)[u^2+2(E_p+\omega)u+\omega^2]}\Bigg|_0^{u_0},$$

where

$$u_{1,2}\equiv-(E_p+\omega)\pm(E_p^2+2E_p\omega)^{1/2}. \quad (3.10)$$

For $\omega^2/E_p\ll u_0\ll E_p$, Eq. (3.10) gives

$$F(\omega)\approx 1+(\omega/E_p)\ln(1+2u_0E_p\omega^{-2}). \quad (3.11)$$

It is evident that $F(\omega)$ is a slowly varying function of ω and u_0 and hence the SPE yield in (3.8) controls the SSE yield. It is well known that[2,3] $y(\omega)$ reaches a peak for $\omega\sim k_F^2$ and drops rapidly with increasing frequency. If we take $\kappa_{z0}\sim k_F/4$ we see that $\omega_2\gg k_F^2$ for $K/k_F\gg 4$ and ω_2 may be replaced by ∞ in (3.8). This shows that the important values of ω are of order k_F^2 and that the emitted secondaries are of low energy. If $u_0\ll\omega^2/E_p$, (3.10) shows that $F(\omega)$ is small, but then $y(\omega)$ is small since $\omega_2\gg k_F^2$ and these values of ω are not decisive in determining δ. We set $u_0=\omega_2$ in (3.11) and neglect the one in the logarithmic term, and substitute the result in (3.8) to obtain

$$\delta\approx(2\pi\alpha E_p)^{-1}\int_{\omega_1}^{\infty}(d\omega/\omega)y(\omega)\times[1+(\omega/E_p)\ln(2\omega_2E_p\omega^{-2})]. \quad (3.12)$$

To simplify (3.12) we treat the logarithmic term as a constant in which we set $\omega_2=\beta_1k_FK$ and $\omega=\omega_{\max}$, where β_1 is a small fraction and $\omega_{\max}$ is the angular frequency for which the SPE yield $y(\omega)$ is maximum. We can write $\omega_{\max}=\beta_2k_F^2$ where β_2 is of order unity, and denote β_1/β_2^2 by a new parameter β. We obtain the result,

$$\delta\approx(2\pi\alpha E_p)^{-1}\int_{\omega_1}^{\infty}(d\omega/\omega)y(\omega)\times[1+(\omega/E_p)\ln\beta(E_p/E_F)^{3/2}]. \quad (3.13)$$

The leading term in (3.13) would have been obtained if we neglected the term κ_1^2 in (3.3). The logarithmic term gives a correction term of order $\frac{3}{2}(E_F/E_p)\times\ln(E_p/E_F)$ which is about 25% for $E_p/E_F\sim 20$.

Let us now return to the approximations made:

(*a*) $\cdot\mathbf{k}_1\cdot\boldsymbol{\kappa}_1$ *term:* This is the most bothersome term in the calculation and was neglected in (3.3). We can estimate the error by including this term in (3.9) and averaging the denominator over $\mathbf{k}$ to obtain $(u+\omega)^2+2u(E_p+E_F/5)$ for the new denominator. The integration can be carried out and we obtain the correction term, $(E_F/5E_p)\ln\beta(E_p/E_F)^{3/2}$, to be added inside the bracket of (3.13). Since this correction is smaller than the second term retained in (3.13), we can ignore it.

(*b*) *Large* κ_x: If in (3.10) we set $u_0=E_p-\omega$ which would allow for the primary to lose all its energy we obtain (for $\omega\ll E_p$) that

$$F(\omega, E_p-\omega)\approx(4/3)+(\omega/E_p)\ln(4E_p^2/3\omega^2). \quad (3.14)$$

Comparing (3.14) and (3.11) we see how little the large momenta transfers contribute to the effect. Since the dipole approximation of (3.2) is expected to overestimate M for large κ_x, Eq. (3.14) cannot be trusted and will be discarded.

(*c*) $-\frac{1}{2}\kappa_x^2$ *term:* This term can easily be included in (3.3). The resulting integral is similar to (3.9) and can be evaluated exactly. We find that $F(\omega)$ of (3.11) remains the same (except that 1 is replaced by $\frac{1}{2}$ inside the logarithm) and (3.13) is not altered. Equation (3.14), however, now takes the form,

$$F(\omega, E_p-\omega)\approx(5/3)+(\omega/E_p)\ln(8E_p^2/3\omega^2), \quad (3.15)$$

to which the previous remarks apply.

Thus our approximations are good, and we conclude that the simple formula,

$$\delta\sim(2\pi\alpha E_p)^{-1}\int_{\omega_1}^{\infty}(d\omega/\omega)y(\omega), \quad (3.16)$$

is quite satisfactory, and that (3.13) contains the major corrections to the SSE yield δ.

4. EXAMPLES

A. Experimental

To obtain an estimate of (3.16), let us use the experimental yield curves $Y(\omega,\theta)$ for Na and K which are reproduced in Weissler's review article.[14] From the relation (3.7) we obtain $y(\omega)$. By a *crude* numerical integration we find that the yield integrals, $\int y(\omega)d\omega/\omega$ are $\sim 6.7\times10^{-4}$ and 4×10^{-5} for Na and K, respectively, which lead to the values $\delta\sim 1.5\times10^{-2}/E_p$ and $0.9\times10^{-3}/E_p$, respectively. This shows clearly that the effect is entirely negligible, since the observed values[1] of δ are of order unity for $E_p\sim 10$.

B. Theoretical

A theoretical calculation of δ is possible for a square-well potential model. Let $V(x)=-V_0$ for $x<0$, and $V(x)=0$, for $x>0$. The wave functions v and ϕ_0 can be

[14] G. L. Weissler, *Handbuch der Physik*, edited by S. Flügge (Springer-Verlag, Berlin, 1956), Vol. 21, p. 351. For Na we use the measurements of Maurer at $\theta=60°$, and for K the measurements of Suhrmann and Theissing at $\theta=65°$. The yield curve for K has to be cut off, since a true SPE must asymptotically drop rapidly with frequency. For square well potential, for example, $y(\omega)\propto\omega^{-7/2}$ as $\omega\to\infty$ as can be deduced from Eqs. (4.4) and (4.5).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

written down easily as in I, namely,

$$v(x)=\left(\frac{2q}{q+k_x'}e^{-ik_x'x},\ e^{-iqx}+\frac{q-k_x'}{q+k_x'}e^{iqx}\right),$$
$$\phi_0(x)=2^{-1/2}\left(\frac{k_x-ip}{k_x+ip}e^{-ikxx}+e^{ikxx},\ \frac{2k_x}{k_x+ip}e^{-px}\right) \quad (4.1)$$
$$\text{for } x<0 \quad \text{and} \quad x>0,$$

where the propagation constants have been previously defined. By using (4.1) in (2.18) we obtain after some lengthy algebra:

$$|M|^2=32\kappa_x^2q^2k_x^2(k_x'-q)(k_x'+q)^{-1}/R,$$
$$R\equiv(2\omega-2\kappa_xk_x'+\kappa_x^2)^2[4\omega^2+\kappa_x^2(\kappa_x^2+4p^2-4\omega)]. \quad (4.2)$$

We see that if $\frac{1}{2}\kappa_x^2\ll\omega$, $R\approx16\omega^4$ and

$$|M|^2\approx2\kappa_x^2q^2k_x^2(k_x'-q)(k_x'+q)^{-1}\omega^{-4}, \quad (4.3)$$

which is precisely the dipole approximation of (3.2) with which we could have started. The advantage of giving the exact $|M|^2$ is to show how good are the approximations of Sec. 3. It is evident from (4.2) that for a finite ω and large κ_x, $|M|^2\propto\kappa_x^{-6}$ which justifies the neglect of large values of κ_x.

It follows from Eqs. (4.3), (3.2), and (3.5) above, or from Eqs. (3.9) and (3.10) of I, that

$$y(\omega)=(16\alpha/\pi)(\omega/E_F)^{-3}J_1(\omega), \quad (4.4)$$

$$J_1(\omega)=\frac{1}{2\eta}\int_{\epsilon+\Omega-\eta>0}^{\epsilon=1}(1-\epsilon)(\epsilon+\Omega-\eta)^{1/2}\times\epsilon^{1/2}[(\epsilon+\Omega)^{1/2}-(\epsilon+\Omega-\eta)^{1/2}]^2d\epsilon, \quad (4.5)$$

where $\Omega=\omega/E_F$, $\epsilon=(V_0+E_0)/E_F$, and $\eta=V_0/E_F$.

If we substitute (4.4) and (4.5) in (3.13), define the parameter λ by

$$\lambda=(E_F/E_p)\ln\beta(E_p/E_F)^{3/2}, \quad (4.6)$$

and introduce the integration variables ϵ and ζ where $\zeta=\epsilon+\Omega-\eta$, we have

$$\delta=\frac{4}{\pi^2E_p\eta}\int_0^\infty d\zeta[(\zeta+\eta)^{1/2}-\zeta^{1/2}]^2\times\zeta^{1/2}\int_0^1(1-\epsilon)\epsilon^{1/2}S(\lambda,\zeta,\epsilon)d\epsilon, \quad (4.7)$$

where

$$S(\lambda,\zeta,\epsilon)=(\eta+\zeta-\epsilon)^{-4}+\lambda(\eta+\zeta-\epsilon)^{-3}. \quad (4.8)$$

Expanding S in a power series of ϵ and integrating term by term we obtain

$$\delta=\frac{16}{\pi^2E_p}\eta^{-5/2}\left\{\frac{1}{15}\eta C_{-1}\lambda+\sum_{n=0}^{\infty}\binom{-4}{n}(-\eta)^{-n}\frac{1}{(2n+5)}\times\left[\frac{1}{2n+3}+\frac{3\lambda}{(n+1)(2n+7)}\right]C_n\right\}, \quad (4.9)$$

where

$$C_n=\int_0^\infty\zeta^{1/2}[(\zeta+1)^{1/2}-\zeta^{1/2}]^2(\zeta+1)^{-(4+n)}d\zeta$$
$$=(-1)^{n+1}\binom{1/2}{n+2}\frac{2n+9}{2n+6}\pi-\frac{8}{(2n+5)(2n+3)}, \quad (4.10)$$

$C_{-1}=7\pi/8-8/3=0.0822$, $C_0=(3\pi/16)-8/15=0.0557$,

$C_1=(11\pi/128)-8/35=0.0414$.

The leading term in (4.9) is $\delta\sim0.06(\pi^2E_p\eta^{5/2})^{-1}$ which is of order $10^{-3}/E_p$ since η is about 2. The relative error committed by neglecting terms in λ is of order $[\eta(C_{-1}/C_0)+9/7]\lambda\sim4\lambda$, which could amount to 25% for $E_p/E_F\sim100$ (if we take $\beta=1$).

This agrees with Baroody[8] who obtained the first two terms of (4.9) with $\lambda=0$, by using the same method as did Viatskin, but making an independent evaluation of the final integral. It also agrees surprisingly well with the estimate obtained above from the measurements on the surface photoelectric effect of potassium.

Note added in proof. Equation (3.16) predicts that the energy loss of the primary (essentially ω) by SSE is nearly peaked at the energy value for which $y(\omega)/\omega$ is maximum, and this is usually of order 5–10 eV. It would be interesting to investigate if such an energy loss can be detected in experiments on the characteristic energy losses of electrons in thin foils. Since the relative intensity of the scattered primaries by this effect is of order $10^{-2}-10^{-3}/E_p$, primary energies E_p of order 10 (i.e., 272 eV) are preferable, if experiments with these energies are now feasible.

ACKNOWLEDGMENTS

I wish to thank Dr. E. M. Baroody for many fruitful discussions, and for showing me his unpublished work, Dr. A. C. Beer for suggestions on the manuscript, and Battelle Memorial Institute for financial support.

PHYSICAL REVIEW VOLUME 134, NUMBER 6A 15 JUNE 1964

Scattering of Spin Waves by Magnetic Defects*

JOSEPH CALLAWAY AND ROBERT BOYD
Department of Physics, University of California, Riverside, California
(Received 27 January 1964)

A previous calculation of the scattering amplitude for the scattering of spin waves by magnetic defects in a simple cubic lattice is simplified and extended to body-centered and face-centered cubic lattices. Expressions are given for the mean free path, and the thermal resistivity due to defect scattering is calculated by a method which takes some account of spin-wave interactions.

I. SCATTERING THEORY

IN a previous study[1] (which will be referred to as I), the general theory of the scattering of spin waves by magnetic defects was discussed, and results were obtained for the cross section and mean free path in simple cubic lattices. In the present note, the cumbersome procedures of that calculation are both simplified and generalized, and the results are extended to include body-centered cubic and face-centered cubic lattices. This is of particular interest since several of the recently discovered ferromagnetic insulators are face-centered cubic. The thermal resistivity produced by defect scattering is calculated by a method which includes some of the effects of spin-wave–spin-wave interactions.

The theory of the scattering of spin waves by magnetic defects is an application of the general theory of the scattering of excitations by imperfections in solids. An account of this theory is being published elsewhere.[2] Therefore, the present discussion will contain only as much of the theory as is required to make the application of those results to a spin-wave system intelligible.

We consider a spin system described by a simple Heisenberg exchange Hamiltonian with nearest-neighbor interaction only:

$$H=\sum_{i,\Delta} J(\mathbf{R}_i, \mathbf{R}_i+\boldsymbol{\Delta})\mathbf{S}(\mathbf{R}_i)\cdot\mathbf{S}(\mathbf{R}_i+\boldsymbol{\Delta}). \quad (1)$$

Neither external fields nor dipole-dipole interactions are included. The system is said to contain a magnetic defect if at some site $\mathbf{R}_0$ (which we choose as the origin), there is an atom whose spin S' is coupled to its neighbors by an exchange integral J'. For the remainder of the atoms, these quantities are S and J, respectively. The quantity $\boldsymbol{\Delta}$ is a vector connecting a lattice site with one of its nearest neighbors.

The excited states of the system which contain a single spin deviation can be described by a set of functions $\phi(\mathbf{R})$ such that $|\phi(\mathbf{R})|^2$ gives the probability of finding the spin deviation on site $\mathbf{R}$. It was shown in Ref. 3 that $\phi(\mathbf{R})$ satisfies the equation

$$E\phi(\mathbf{R}_l)=2\sum_\Delta J(\mathbf{R}_l,\mathbf{R}_l+\boldsymbol{\Delta})[S(\mathbf{R}_l+\boldsymbol{\Delta})\phi(\mathbf{R}_l) -\{S(\mathbf{R}_l)S(\mathbf{R}_l+\boldsymbol{\Delta})\}^{1/2}\phi(\mathbf{R}_l+\boldsymbol{\Delta})]. \quad (2)$$

In this equation $S(\mathbf{R}_l)$ is the "magnitude" of the spin on the site $\mathbf{R}_l$ in that the eigenvalue of $S^2(\mathbf{R}_l)$ in the ground state is $S(\mathbf{R}_l)[S(\mathbf{R}_l)+1]$. Equation (2) can be written as a Schrödinger equation in the form

$$\sum_l (m|E-H_0|l)\phi(\mathbf{R}_l)=\sum_l (m|V|l)\phi(\mathbf{R}_l), \quad (3)$$

in which

$$(m|E-H_0|l)=(E-2JSz)\delta_{l,m}+2JS\delta_{l-m,\Delta} \quad (4)$$

and

$$(m|V|l)=\delta_{lm}[2Sz(J'-J)\delta_{l,0}+2(J'S'-JS)\delta_{l,\Delta}] -2[J'(S'S)^{1/2}-JS]\delta_{l-m,\Delta}(\delta_{l,0}+\delta_{m,0}). \quad (5)$$

Each atom is assumed to have z nearest neighbors. The subscript $l-m$ refers to $\mathbf{R}_l-\mathbf{R}_m$.

The solutions of this equation for energies, E, within the continuous spectrum of H_0 have been shown to have the following asymptotic form:

$$\phi(\mathbf{R}_l)=\frac{\Omega^{1/2}}{(2\pi)^{3/2}}\left[e^{i\mathbf{k}\cdot\mathbf{R}_l}+f\frac{e^{ikR_l}}{R_l}\right], \quad (6)$$

provided the energy is low enough so that the energy wave vector relation (energy band) for spin waves is spherical:

$$E=\gamma k^2, \quad (7)$$

$$\gamma=2JSa^2, \quad (8)$$

in which a is the cubic lattice constant. The quantity f may be interpreted as the scattering amplitude for spin waves. It may be expressed as a sum of scattering amplitudes for partial waves transforming according to one of the irreducible representations of the crystal point group:

$$f=\sum_\beta f_\beta, \quad (9)$$

in which β denotes an irreducible representation. The partial-wave scattering amplitudes are

$$f_\beta=-\frac{2\pi^2}{\gamma D_\beta}\sum_{pnm} V_{\beta,pn}P_{\beta,nm}\sum_\nu C_{\beta,\nu}^{(0)*}(k',R_p) \times C_{\beta,\nu}^{(0)}(k_0,R_m). \quad (10)$$

In this equation, the functions $C^{(0)}(k,R)$ are symmetrized linear combinations of plane waves $(\Omega/8\pi^3)^{1/2}\times\exp(i\mathbf{k}\cdot\mathbf{R})$ transforming according to the νth row of the βth irreducible representation. These functions are characterized by wave vectors $\mathbf{k}_0$ and $\mathbf{k}'$, in which $\mathbf{k}_0$ is the wave vector of the incident wave and $\mathbf{k}'$ is a vector of magnitude k_0 parallel to $\mathbf{R}_l$ [see Eq. (6)]. We can write

$$C_{\beta,\nu}^{(0)}(k,R_m)=\frac{\Omega^{1/2}}{(2\pi)^{3/2}}\sum_m{}' U(\beta_\nu,\mathbf{R}_m)e^{i\mathbf{k}\cdot\mathbf{R}_m}, \quad (11)$$

in which the quantities $U(\beta_\nu,R_m)$ are the matrix elements of a unitary transformation. The prime on the summation in Eq. (11) indicates that the vectors R_m which are included are those which can be found from any one of them by rotation with all the operators of the point group. (Only distinct vectors are considered.)

The quantities $V_{\beta,pn}$ are given by

$$V_{\beta,pn}=\sum_{p,n}{}' U(\beta_\nu,\mathbf{R}_p)(p|V|n)U^\dagger(\mathbf{R}_n,\beta_\nu), \quad (12)$$

in which $U^\dagger$ is the adjoint of the matrix U. $V_{\beta,pn}$ is independent of the row of the representation ν. The remaining quantities are found as follows. We consider the Green's function, $\mathcal{G}(\mathbf{R}_l-\mathbf{R}_n)$, which satisfies

$$\sum_l(m|E-H_0|l)\mathcal{G}(\mathbf{R}_l-\mathbf{R}_n)=\delta_{mn}, \quad (13)$$

and define

$$\Gamma_{\beta,ln}=\sum_{ln}{}' U(\beta_\nu,\mathbf{R}_l)\mathcal{G}(\mathbf{R}_l-\mathbf{R}_n)U^\dagger(\mathbf{R}_n,\beta_\nu). \quad (14)$$

Then, considering only those values of the indices l, m, such that $V_{\beta,lm}$ is not zero, we construct the matrix

$$Q_{\beta,lm}=\delta_{lm}-\sum_n\Gamma_{\beta,ln}V_{\beta,nm}. \quad (15)$$

The summation in (10) and (15) includes one term for each different symmetrized combination of plane waves. The quantities P_β and D_β occurring in Eq. (9) may now be defined by writing the matrix inverse to Q as

$$[Q^{-1}]_{\beta,lm}=D_\beta^{-1}P_{\beta,lm}, \quad (16)$$

with

$$D_\beta=\det(Q_\beta)=\det[I-\Gamma_\beta V_\beta]. \quad (17)$$

The quantity D_β determines the locations of possible scattering resonances or localized modes. Let E' (in general, a complex number) be a solution of

$$D_\beta(E')=0. \quad (18)$$

Put $E'=E_R-i\Gamma/2$. Then, if $\Gamma>0$, E_R is the energy of a scattering resonance, and Γ is the width of the resonance. If $\Gamma=0$ (which occurs only outside the continuum of eigenstates of H_0), we have a localized mode.

In the case of spin waves, the perturbation V extends only to nearest neighbors of the defect. The irreducible representations which occur in the sum over β in Eq. (7) have been determined for cubic lattices[2,3]: They are Γ_1, Γ_{15}, and Γ_{12} for a simple cubic lattice; Γ_1, Γ_{15}, $\Gamma_{25'}$, and $\Gamma_{2'}$ for a body-centered cubic lattice, and Γ_1, Γ_{15}, $\Gamma_{25'}$, Γ_{12}, and Γ_{25} for face-centered cubic.[4] The k dependence of the partial-wave scattering amplitude f_β at low energies can be studied by expanding the symmetrized combinations of plane waves $C_{\beta,\nu}^{(0)}(k,R)$ in powers of k. One finds that

$$C_{\beta,\nu}^{(0)}(k,R)\propto(kR)^lK_{\beta,\nu,l}(\theta,\phi), \quad (19)$$

in which $K_{\beta,\nu,l}$ is a Kubic harmonic belonging to the νth row of the βth irreducible representation, and is a linear combination of spherical harmonics of order l.[5] For Γ_1, $l=0$; for Γ_{15}, $l=1$; for Γ_{12} and $\Gamma_{25'}$, $l=2$, and for $\Gamma_{2'}$ and Γ_{25}, $l=3$. We conclude that (since $|\mathbf{k}_0|=|\mathbf{k}'|$)

$$f_\beta\propto k^{2l}, \quad (20)$$

unless there are cancellations among the elements V, P which raise the power of k in (20). We do not expand D_β since this contains the possible resonances.

For spin waves we find that the p-wave amplitude (Γ_{15}) is proportional to k^2, but cancellations do occur for the s-wave amplitude (Γ_1), which then turns out also to be proportional to k^2. Other (d,f) partial waves give terms proportional to k^4 and k^6. Hence, the total amplitude is proportional to k^2 for small k.

We will now determine the scattering amplitude to this order for simple cubic, body-centered cubic, and face-centered cubic lattices. The p-wave portion i simplest because only one term appears in the summation over p, m, and n in Eq. (8). From this fact x follows, with the use of Eq. (16), that the only satrim element of P is unity. Hence Eq. (10) has the for it

$$f_p=(-2\pi^2/\gamma D_p)V_{p,11}\sum_\nu C_{p,\nu}^{(0)*}(k',R_1)\times C_{p,\nu}^{(0)}(k_0,R_1). \quad (21)$$

The rows of the triply degenerate Γ_{15} representation contain functions transforming as x, y, or z. In each of the three lattices we have in the small k limit

$$C_{p_x}=[\Omega^{1/2}/(2\pi)^{3/2}]\sqrt{2}ik_xa, \quad (22)$$

etc., and

$$V_{p,11}=-2JS[1-(J'S'/JS)]. \quad (23)$$

Then

$$f_p=(\Omega/2\pi D_pa^2)[1-(J'S'/JS)]k^2a^2\cos\theta, \quad (24)$$

in which θ is the angle between k and k'.

It is now necessary to express the determinant D_p in terms of the Green's functions. If (ξ,η,ζ) are the rectangular components of $(\mathbf{R}_l-\mathbf{R}_n)/a$, we have for

the three lattices:

Simple cubic,

$$D_p=1-\tfrac{1}{2}[1-(J'S'/JS)][\mathcal{G}(0)-\mathcal{G}(2,0,0)]; \quad (25)$$

body-centered cubic,

$$D_p=1-\tfrac{1}{2}[1-(J'S'/JS)] \times[\mathcal{G}(0)+\mathcal{G}(1,0,0)-\mathcal{G}(1,1,0)-\mathcal{G}(1,1,1)]; \quad (26)$$

face-centered cubic;

$$D_p=1-\tfrac{1}{2}[1-(J'S'/JS)][\mathcal{G}(0)+2\mathcal{G}(\tfrac{1}{2},\tfrac{1}{2},0) -2\mathcal{G}(1,\tfrac{1}{2},\tfrac{1}{2})-\mathcal{G}(1,1,0)]. \quad (27)$$

We infer from these results that for the same value of the lattice constant a, the scattering amplitude depends on the lattice structure partly through the cell volume Ω which has the value a^3, $a^3/2$, and $a^3/4$ in the simple body-centered, and face-centered cubic lattices, respectively. In addition, more complicated dependence on structure is contained in the determinants, D_p.

We now turn to a consideration of the s-wave amplitude. This calculation is quite tedious and will not be given in detail. For each lattice, the relevant quantities V, P are 2×2 matrices. The symmetrized linear combinations of plane waves are given by

$$C_s^{(0)}(k,0)=\Omega^{1/2}(2\pi)^{-3/2}, \quad (28a)$$

$$C_s(k,R_1)=(\Omega/z)^{1/2}(2\pi)^{-3/2}\textstyle\sum_\Delta \exp(i\mathbf{k}\cdot\boldsymbol{\Delta}). \quad (28b)$$

Equation (28b) can be expressed in terms of the spin-wave energy $E(k)$, since

$$E(k)=2JS[z-\textstyle\sum_\Delta \exp(i\mathbf{k}\cdot\boldsymbol{\Delta})].$$

Hence,

$$C_s^{(0)}(k,R_1)=(\Omega/z)^{1/2}(2\pi)^{-3/2}(z-E/2JS). \quad (29)$$

Equation (29) enables us to eliminate the functions $C_s^{(0)}$ from the s-wave amplitude. In addition, it is possible to express all the combinations of Green's functions which enter into D_s and P_s in terms of $\mathcal{G}(0)$, with the aid of certain identities which were derived in Ref. 3. Since $\mathcal{G}(0)$ can be expressed in terms of the density of states $G(E)$,

$$\mathcal{G}(0)=\frac{\Omega}{(2\pi)^3}\int\frac{d^3q}{E-E(q)}=P\int\frac{G(E')dE'}{E-E'}-i\pi G(E) \equiv -g_0/4JS, \quad (30)$$

this means that the s-wave amplitude can be determined from the $G(E)$ without explicit reference to $E(k)$. The relevant identities are

$$z^{-1}\textstyle\sum_i \mathcal{G}(\boldsymbol{\Delta}_i)=[1-(E/2JSz)]\mathcal{G}(0)+(1/2JSz) \equiv -g_1/4JS, \quad (31)$$

$$\textstyle\sum_j \mathcal{G}(\boldsymbol{\Delta}_i-\boldsymbol{\Delta}_j)=[1-(E/2JSz)]\sum_i \mathcal{G}(\boldsymbol{\Delta}_i) =-g_2/4JS. \quad (32)$$

In these equations, $\boldsymbol{\Delta}_i$ and $\boldsymbol{\Delta}_j$ indicate sites which are nearest neighbors of the defect site (the origin). Only the particular combinations of Green's functions appearing in (30), (31), and (32) are involved in the s-wave amplitude.

In addition, we have

$$V_s=-4JS\begin{pmatrix}\epsilon & \eta\sqrt{z}\\ \eta\sqrt{z} & \rho\end{pmatrix}, \quad (33)$$

$$P_s=\begin{pmatrix}1-g_2\rho-z\eta g_1 & z^{1/2}(g_0\eta+g_1\rho)\\ z^{1/2}(g_1\epsilon+g_2\eta) & 1-g_0\epsilon-z\eta g_1\end{pmatrix}, \quad (34)$$

in which

$$\epsilon=\tfrac{1}{2}z(1-J'/J), \quad (35a)$$

$$\eta=\tfrac{1}{2}[(J'/J)(S'/S)^{1/2}-1], \quad (35b)$$

$$\rho=\tfrac{1}{2}(1-J'S'/JS). \quad (35c)$$

After a rather tedious calculation, we obtain for the s-wave portion of the scattering amplitude to lowest order in k

$$f_s=\frac{-\Omega}{2\pi D_s a^2}\frac{E}{4JS}\left(\frac{J'}{J}\right)\left(1-\frac{S'}{S}\right) =\frac{-\Omega}{4\pi D_s a^2}\left(\frac{J'}{J}\right)\left(1-\frac{S'}{S}\right)k^2a^2, \quad (36)$$

in which

$$D_s=1+\frac{z}{2}(g_1-g_0)\left(1-\frac{J'}{J}\right)+\frac{Eg_1}{4JS}\left(1-\frac{J'S'}{JS}\right). \quad (37)$$

It will be observed that f_s goes to zero as k^2 at low energies. This is the result of cancellation among some of the terms and of the Green's function identities (32). The expression (37) for D_s is exact. We do not expand D_s (or D_p) since they contain the possible low-energy resonances.

The total amplitude to order k^2 is the sum of (36) and (24):

$$f=f_s+f_p=\frac{-\Omega}{4\pi a^2}\left[\frac{1}{D_s}\left(\frac{J'}{J}\right)\left(1-\frac{S'}{S}\right) -\frac{2}{D_p}\left(1-\frac{J'S'}{JS}\right)\cos d\right]k^2a^2. \quad (38)$$

It will be observed that the amplitude in this order depends on the lattice structure in an obvious manner through the cell volume. There is, however, an equally important structure dependence incorporated in the function D_s and D_p. The higher order (in k) terms in the amplitude also exhibit a significant dependence on the lattice structure since different representations appear. In general, it does not appear to be possible to express the scattering amplitude solely in terms of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

पुस्तकालय 111678

angle between the incoming and outgoing wave vectors when higher order terms are included.

When the scattering amplitude is considered only to lowest order in $\hbar$, so that it depends only on the angle θ a simple calculation of the mean free path l_D, for scattering of a spin wave by a defect is possible. This has been shown to be determined by the momentum transfer cross section σ_n which is given by

$$\sigma_n=\int |f(\theta)|^2(1-\cos\theta)d\Omega. \tag{39}$$

Then[6]

$$l_D^{-1}=N_D\sigma_n, \tag{40}$$

where N_D is the concentration of defects. We obtain

$$\sigma_n=\frac{\Omega^2k^4}{4\pi}\left\{\frac{1}{|D_s|^2}\left(\frac{J'}{J}\right)^2\left(1-\frac{S'}{S}\right)^2 +\frac{4}{3}\left(1-\frac{J'S'}{JS}\right)\left[\frac{1}{|D_p|^2}\left(1-\frac{J'S'}{JS}\right) +\frac{1}{2}\left(\frac{J'}{J}\right)\left(1-\frac{S'}{S}\right)\left(\frac{1}{D_s^*D_p}+\frac{1}{D_sD_p^*}\right)\right]\right\}. \tag{41}$$

If we suppose that the denominators D_s and D_p can be set equal to unity, thereby neglecting the possibility of resonant scattering, we obtain

$$\sigma_n=\frac{\Omega^2k^4}{4\pi}\left[\left(\frac{J'}{J}\right)^2\left(1-\frac{S'}{S}\right)^2 +\frac{4}{3}\left(1-\frac{J'S'}{JS}\right)\left(1+\frac{J'}{J}-\frac{2J'S'}{JS}\right)\right]. \tag{42}$$

II. THERMAL CONDUCTIVITY

In this section we consider the thermal conductivity of a system of spin waves in interaction with each other and containing N_D magnetic defects per unit volume. We hope to consider spin-wave–phonon interactions in subsequent work. Unless explicitly stated, the system will be assumed to be of infinite extent.

We propose here to calculate the thermal conductivity of spin waves by the same techniques which have proved to be reasonably successful in application to lattice thermal conductivity.[7] We will consider each scattering process to be described by a relaxation time, but explicit account will be taken of the conservation of crystal momentum by normal spin-wave–spin-wave scattering processes.

The distinction between normal and umklapp processes in spin-wave interactions is just as vital as it is in the case of phonon-phonon interactions. Since normal processes conserve the total pseudomomentum of the spin-wave system, they cannot, if acting alone, produce a thermal resistance. This statement is essentially independent of the details of the dispersion relation for the magnons. It is true that the interactions between magnons do not conserve the heat flow at the microscopic level (as is the case for phonons if a linear dispersion law is assumed). A statistical argument shows, however, that a thermal resistance will not appear. An explicit demonstration is given in the Appendix.

Nevertheless, it is not permissible to neglect normal processes in studying the thermal conductivity. Their contribution may be pictured qualitatively as that of converting some of the low-frequency magnons into high-frequency magnons which may easily be scattered by defects. We will show that in the limit of strong normal processes, the thermal conductivity becomes limited by the defect scattering in a fashion similar to that obtained by Ziman[8] for lattice thermal conductivity.

The importance of distinguishing normal and umklapp processes has been stressed here because it has been ignored in other calculations of the spin-wave thermal conductivity.[9] We contend that such work may have yielded an erroneous thermal resistance.

We begin by considering the Boltzmann equation in the form

$$\left(\frac{\partial N}{\partial t}\right)_c-\mathbf{V}_\mathbf{k}\cdot\nabla T\frac{dN}{dT}=0, \tag{43}$$

in which ∇T is the temperature gradient, N is the distribution function, and $\mathbf{V}_\mathbf{k}$ is the group velocity of the spin waves

$$\mathbf{V}_\mathbf{k}=\hbar^{-1}\nabla_\mathbf{k}E(\mathbf{k}). \tag{44}$$

The first assumption of the present approach is that the collision term $(\partial N/\partial t)_c$ may be approximated as follows:

$$\left(\frac{\partial N}{\partial t}\right)_c=\frac{N(\boldsymbol{\lambda})-N}{\tau_n}+\frac{N_0-N}{\tau_u}, \tag{45}$$

in which $N(\boldsymbol{\lambda})$ is a displaced Bose distribution

$$N(\boldsymbol{\lambda})=\{\exp[(E-\boldsymbol{\lambda}\cdot\mathbf{k})/KT]-1\}^{-1}. \tag{46}$$

N_0 is the usual Bose function; τ_n is the relaxation time for a single mode via normal processes, and τ_u is the relaxation time for all those processes which do not conserve the crystal momentum.[10] We assume that $\boldsymbol{\lambda}$ is small so that $N(\boldsymbol{\lambda})$ may be expanded, and only first-

[9] A. Quattropani, Phys. Kondens. Materie **1**, 125 (1963).

[10] R. E. Nettleton, Phys. Rev. **132**, 2032 (1963), has partially justified this approximation for lattice thermal conductivity. In applying Nettleton's discussion to the present calculation, one should note that in spite of appearances, an explicit expression for the normal process relaxation time, τ_N, is not required to obtain our essential results, Eqs. (60) and (67). The quantities which are required are τ_D and τ_c.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

order terms in $\mathfrak{z}$ are retained. Put

$$\mathfrak{z}=-S\nabla T/T, \quad (s \text{ is a constant}) \tag{47a}$$

$$N-N_0=n_1=-\nu\mathbf{V}_k\cdot\nabla T\left(\frac{E}{KT}\right)^2\frac{e^{E/KT}}{(e^{E/KT}-1)^2}, \tag{47b}$$

$$\tau_c^{-1}=\tau_u^{-1}+\tau_n^{-1}. \tag{47c}$$

(These equations are definitions of s, ν, and τ_c.) We also require the group velocity. We continue to use a quadratic dispersion law

$$E=\gamma k^2+\epsilon, \tag{48}$$

so that

$$\mathbf{V}_k=2(\gamma/\hbar)\mathbf{k}. \tag{49}$$

The constant term ϵ in (48) does not play an important role in the mechanics of the thermal conductivity calculation and has been ignored in computing scattering amplitudes, but it is important in preventing the quantity $E-\mathfrak{z}\cdot\mathbf{k}$ in (46) from becoming negative for low energies. It is therefore important to realize that a nonzero value of ϵ is always obtained, since the material is magnetized. One has, approximately,[11]

$$\epsilon=g\beta[(4\pi/3)M+H_{\text{ext}}], \tag{50}$$

where M is the magnetization and H_{ext} is a possible external field.

Equations (45)–(49) are substituted in the Boltzmann equation, which then gives a relation between ν and s. This is

$$\nu=\tau_c[1+\hbar s/(2\gamma\tau_N E)]. \tag{51}$$

The thermal conductivity of the system is

$$\begin{aligned}\kappa&=[1/(2\pi)^3]\int \mathbf{V}_k^2\nu(k)\cos^2\theta C_{sw}(k)d^3k,\\ &=(2\gamma^2/3\pi^2\hbar)\int k^4\nu(k)C_{sw}(k)dk,\\ &=(2\gamma^2/3\pi^2\hbar^2)\int k^4\tau_c[1+S\hbar/(2\gamma\tau_n E)]C_{sw}(k)dk.\end{aligned} \tag{52}$$

We have assumed cubic symmetry and also employed (49). $C_{sw}(k)$ is the contribution to the specific heat from a mode of wave vector k. Evidently another relation between ν and s is required. This is obtained from the requirement that the normal processes do not change the total wave vector of the system:

$$\int\left(\frac{\partial N}{\partial t}\right)_N\mathbf{k}d^3k=\int\frac{N(\mathfrak{z})-N}{\tau_N}\mathbf{k}d^3k=0. \tag{53}$$

This condition leads to the relation

$$\int\frac{\mathbf{k}}{\tau_N}(\mathbf{k}\cdot\nabla T)\left[s-\frac{2\gamma\nu E}{\hbar}\right]\frac{e^{E/KT}}{(e^{E/KT}-1)^2}d^3k=0. \tag{54}$$

Only the component of $\mathbf{k}$ parallel to the temperature gradient survives on integration over solid angles. We substitute (51) and solve for s

$$s=\frac{2\gamma}{\hbar}\int\frac{\tau_c}{\tau_N}\frac{Ek^4e^{E/KT}}{(e^{E/KT}-1)^2}dk\Bigg/\left[\int\frac{1}{\tau_N}\left(1-\frac{\tau_c}{\tau_N}\right)\frac{k^4e^{E/KT}}{(e^{E/KT}-1)^2}dk\right]. \tag{55}$$

We combine (55) and (53), substitute for the spin-wave specific heat

$$C_{sw}=K\left(\frac{E}{KT}\right)^2\frac{e^{E/KT}}{(e^{E/KT}-1)^2},$$

introduce the change of variables

$$x=\gamma k^2/KT, \quad \delta=\epsilon/KT, \tag{56}$$

replace the relaxation time by mean free paths,

$$l_c=V_k\tau_c,$$

etc., and obtain our final expression for the thermal conductivity:

$$\kappa=\frac{K(KT)^2}{6\pi^2\gamma\hbar}\left\{\int_0^{x_m}x(x+\delta)^2l_c\frac{e^{x+\delta}}{(e^{x+\delta}-1)^2}dx+\left[\int_0^{x_m}x^{3/2}\frac{l_c}{l_N}\frac{(x+\delta)e^{x+\delta}}{(e^{x+\delta}-1)^2}dx\right]^2\Bigg/\left[\int_0^{x_m}\frac{l_c}{l_nl_u}\frac{x^2e^{x+\delta}}{(e^{x+\delta}-1)^2}dx\right]\right\}. \tag{57}$$

The upper limit x_m for these integrals is determined by an argument analogous to that establishing the Debye temperature for a crystal lattice and is given by $x_m=(\gamma/KT)(6\pi^2/\Omega)^{2/3}$. We will consider here only temperatures low enough so that the upper limit can be made infinite.

The dependence of the thermal conductivity on an external magnetic field can be obtained from (57). A magnetic field decreases the thermal conductivity by reducing the probability of excitation of spin waves. It is evident from (57) that in the limit of large δ (low temperatures or strong fields), the thermal conductivity must decrease as $\delta^ne^{-\delta}$; here the exponent n will depend on the scattering mechanism. Further discussion of the field dependence of the conductivity will be reserved for subsequent work.

[11] T. Holstein and Primakoff, Phys. Rev. 58, 1098 (1940); S. H. Charap and E. Boyd (to be published). This dispersion relation is only approximate since in the presence of dipole-dipole couplings, the spin-wave energies are anisotropic.

There is a great similarity between Eq. (57) and the corresponding expressions which are obtained in the theory of lattice thermal conductivity. In particular, we observe that if the relaxation time for processes which do not conserve the wave vector becomes very long, the thermal conductivity of the spin-wave system increases without limit. If only normal processes were present, there would be no thermal resistance.

It follows that in the limit in which the mean free path for normal processes is very short compared to that for processes which do not conserve the wave vector, the thermal conductivity will depend sensitively on the latter processes. This is the Ziman limit. To obtain the thermal resistance in this limit, we drop the first term of (57) and neglect the contribution of l_u to l_c. Then

$$W=\frac{1}{\kappa}=\frac{6\pi^2\gamma\hbar}{K(KT)^2}\int\frac{x^2}{l_u}\frac{e^{x+\delta}}{(e^{x+\delta}-1)^2}dx\Big/\left[\int x^{3/2}\frac{(x+\delta)e^{x+\delta}}{(e^{x+\delta}-1)^2}dx\right]^2. \quad (58)$$

One interesting consequence of (58) is that the thermal resistance in the Ziman limit is the sum of additive contributions from each possible type of "U" process. In particular we consider defect scattering, for which the mean free path is given by Eqs. (40) and (41). We will not consider here the effects of possible scattering resonances which could increase the thermal resistance substantially. We abbreviate the mean free path due to defect scattering as

$$l_D^{-1}=N_DAk^4, \quad (59a)$$

in which

$$A=\frac{\Omega^2}{4\pi^2}\left[\left(\frac{J'}{J}\right)^2\left(1-\frac{S'}{S}\right)^2+\frac{4}{3}\left(1+\frac{J'}{J}-2\frac{J'S'}{JS}\right)\right]. \quad (59b)$$

We can evaluate the thermal resistance due to defects approximately by neglecting δ in (58). We get

$$W_D=\frac{6\pi^2\hbar N_DA}{K\gamma}\int_0^\infty\frac{x^4e^x}{(e^x-1)^2}dx\Big/\left[\int_0^\infty\frac{x^{5/2}e^x}{(e^x-1)^2}dx\right]^2$$
$$=\frac{6\pi^2N_DA\hbar}{K\gamma}\frac{\Gamma(5)\zeta(4)}{[\Gamma(7/2)\zeta(5/2)]^2}=38.6\frac{N_DA\hbar}{JSKa^2}. \quad (60)$$

In the last step of (60), we have substituted Eq. (8).

The thermal resistance due to the defects is independent of temperature. This expression is valid in the limit in which defect scattering is weak compared to normal magnon-magnon scattering. Our treatment has included the effects of magnon-magnon scattering on the distribution function, and thereby has taken account of these interactions implicitly. Our formula, Eq. (60), does not depend explicitly on the details of the magnon-magnon interaction. It does differ somewhat from the expression for the defect resistivity if these interactions are neglected. The situation in which defect scattering is weak compared to boundary scattering and normal processes are ignored was examined in I. In that case a thermal resistance W_D' due to defects was obtained which is independent of temperature, and differs from (60) only in respect to the numerical constant. That result is[12]

$$W_D'=20\pi^2\frac{N_DA\hbar}{K\gamma}\frac{\zeta(5)}{[\zeta(3)]^2}=70.8\frac{N_DA\hbar}{JSKa^2}. \quad (61)$$

It will be noted that the thermal resistance due to defects given in (61) is larger by a factor of almost 2 than that of Eq. (60). This situation should be contrasted with that which obtains in the theory of lattice thermal conductivity where the contribution to the thermal resistance from defects is, in the Ziman limit, larger by a factor of 25 than when umklapp scattering dominates.

Next, we will discuss the thermal conductivity in the opposite limit in which the defect scattering is strong compared to magnon-magnon scattering. This requires a more detailed knowledge of the combined mean free path l_c, including normal processes. The interaction of two spin waves can produce bound states,[13] and probably scattering resonances. A complete theory of the scattering of two spin waves has not yet been given, but for an introduction, we can make use of a calculation reported by Dyson.[14] Dyson showed that, to the extent that resonances and such may be neglected, the mean free path for a spin wave of wave vector k due to spin-wave–spin-wave interactions, may be written as

$$l=BT^{5/2}k^2. \quad (62)$$

This expression is valid at low temperatures. The quantity B is a rather complicated function of J and S, and is given by

$$B=\frac{3\zeta(3/2)a}{z\omega S^2}\left(\frac{3K}{2\pi JSz\mu}\right)^{5/2}, \quad (63)$$

in which

$$\omega=(1, 3\times2^{-5/3}, 2^{-1/3}),$$
$$\mu=(1, 3\times2^{-4/3}, 2^{1/3}), \quad (64)$$

for the simple cubic, body-centered cubic, and face-centered cubic lattices, respectively.

With the use of (62) and (59), we have a combined mean free path including defect scattering and magnon-magnon scattering

$$l_c^{-1}=BT^{5/2}k^2+N_DAk^4. \quad (65)$$

[12] A factor of $(K\zeta(3))^{-1}$ was omitted in the statement of this equation in Ref. 1.

In the limit $l_c \ll 1$ which corresponds to defect scattering strong compared to magnon-magnon scattering, we can drop all but the first term of (57). This follows since if we consider both l_c and l_u to be proportional to some small constant α, the first term of (57) is proportional to α, whereas the second term is proportional to α^2. We then substitute (65) into (57), let $\delta \to 0$, and obtain

$$\kappa = \frac{K\gamma}{6\pi^2\hbar N_D A}\int_0^{x_m} \frac{x^2}{x+y}\frac{e^x}{(e^x-1)^2}dx, \qquad (66)$$

in which $y = B\gamma T^{3/2}/N_D A K$.

We consider this integral at temperatures low enough so that the upper limit may be made infinite. Even so, the integral needs to be approximated if we are to avoid numerical computation. We follow the procedure used under somewhat similar circumstances in I, in which we replace $x^2e^x/(e^x-1)^2$ by 1 for $x<1$, and neglect y for $x>1$. This is valid only when $y \ll 1$, but if this condition is not satisfied, it is not legitimate to neglect the second term in (57). Hence

$$\kappa = \frac{K\gamma}{6\pi^2\hbar N_D A}\left[\int_0^1 \frac{dx}{x+y} + \int_1^\infty \frac{xe^x}{(e^x-1)^2}dx\right]$$

$$= \frac{K\gamma}{6\pi^2\hbar N_D A}\left[\ln\left(1+\frac{1}{y}\right) + \sum_{n=1}^{\infty} e^{-n}\left(1+\frac{1}{n}\right)\right]$$

$$= \frac{KJSa^2}{3\pi^2 N_D A\hbar}\left[\ln\left(1+\frac{N_D A K}{B\gamma T^{3/2}}\right) + 1.0407\right]. \qquad (67)$$

Evidently, in this limit, the temperature dependence of the thermal conductivity is weak.

APPENDIX

In this appendix, we give an explicit demonstration that for magnons whose energy is related to the wave vector by Eq. (48), normal scattering processes (N. P.) cannot, by themselves, produce a thermal resistance. We recall that a normal process is one in which the total wave vector of the excitations involved is conserved. It is to be distinguished from an umklapp process, for instance, in which the wave vector changes by a reciprocal lattice vector.

It is fairly easy to see intuitively that if only N. P. operate, the crystal relaxes to equilibrium subject to the condition that the total crystal wave vector be nonzero and constant $\sum_k \mathbf{k}n_\mathbf{k} = \mathbf{K}$ (in which $n_\mathbf{k}$ is the number of particles in a state of wave vector $\mathbf{k}$). There must be a flow of heat in the direction of $\mathbf{K}$.

The simplest mathematical justification of this intuition can be found by returning to the derivation of the Fermi-Dirac (F. D.) and Bose-Einstein (B. E.) distribution functions for an ideal gas using the microcanonical ensemble. A system of weakly interacting excitations is considered.

To obtain the distribution function n_k we maximize the entropy, σ, subject to the constraints imposed by conservation laws.[15] We do this by multiplying those quantities $g_j(n_\mathbf{k})$ which must be conserved by Lagrange undetermined multipliers λ_j. Then we add their variation with respect to $n_\mathbf{k}$ to the variation of σ and set the whole equal to zero. Thus,

$$\frac{\delta\sigma}{\delta n_\mathbf{k}} + \sum \lambda_j \frac{\delta g_j}{\delta n_\mathbf{k}} = 0. \qquad (A1)$$

Let the upper/lower signs represent B. E./F. D. statistics, respectively. We have

$$\delta\sigma/\delta n_\mathbf{k} = \ln(n_\mathbf{k}^{-1} \pm 1). \qquad (A2)$$

Let us choose the following conserved quantities:

$$\sum_\mathbf{k} n_\mathbf{k} = N; \quad \sum_\mathbf{k} E_\mathbf{k} n_\mathbf{k} = E; \quad \sum_\mathbf{k} \mathbf{k} n_\mathbf{k} = \mathbf{K}. \qquad (A3)$$

We vary these quantities, multiply by Lagrange multipliers, and substitute together with (2) in (1) to obtain

$$n_\mathbf{k} = \left[\exp\left(\frac{E_\mathbf{k} - \mu - \boldsymbol{\lambda}\cdot\mathbf{k}}{KT}\right) \mp 1\right]^{-1}, \qquad (A4)$$

where the multipliers of N, E, and $\mathbf{K}$ have been written in the conventional manner. (If the number of particles is not conserved, we should set $\mu = 0$, and this must be done for magnons and phonons.)

Clearly, since $E_\mathbf{k} = E_{-\mathbf{k}}$, modes with $\mathbf{k}$ parallel to $\boldsymbol{\lambda}$ contain more particles than modes with $\mathbf{k}$ antiparallel, so we expect a net heat current Q in the direction of $\boldsymbol{\lambda}$.

To demonstrate this we consider the expression for the heat current

$$\mathbf{Q} = \sum_k E_\mathbf{k} V_\mathbf{k} n_\mathbf{k}. \qquad (A5)$$

We will evaluate this approximately on the basis of the dispersion relation[16]

$$E_k = \gamma k^n + \epsilon. \qquad (A6)$$

In this equation the relevant values of the exponent n are 1 and 2. If $n=1$, we have a situation approximately describing low-energy phonons (also $\epsilon = 0$ in this case). The case $n=2$ characterizes spin waves, but now $\epsilon \neq 0$; a nonzero value of E is provided by the magnetization (M) plus any external field (H_{ext}), as was described in the main text [see Eq. (50)]. With the use of (6), we obtain for Q

$$\mathbf{Q} = \frac{n\gamma}{(2\pi)^3\hbar}\int \frac{(\gamma k^n + \epsilon)\mathbf{k}k^{n-2}}{\{\exp\{[\gamma k^n + \epsilon - \boldsymbol{\lambda}\cdot\mathbf{k}]/KT\} - 1\}}d^3k. \qquad (A7)$$

---

[15] K. Huang, *Statistical Mechanics* (John Wiley & Sons, Inc., New York, 1963), p. 192.

[16] The importance of including ϵ is that if it is not present, the argument of the exponential in (A4) will become negative for small k when $n=2$.

The total wave vector K is

$$\mathbf{K}=\frac{1}{(2\pi)^3}\int\frac{\mathbf{k}}{\{\exp\{[\gamma k^n+\epsilon-\boldsymbol{\lambda}\cdot\mathbf{k}]/KT\}-1\}}d^3k. \quad \text{(A8)}$$

Neither of these integrals is zero. If $n=1$, $(\epsilon=0)$ it is easy to see that

$$\mathbf{Q}=(\gamma/\hbar)\mathbf{K}. \quad \text{(A9)}$$

For $n=2$, $(\epsilon\neq 0)$ the situation is somewhat more complex. The substitution $\mathbf{q}=\mathbf{k}-\boldsymbol{\lambda}/2\gamma$ enables the integrals to be transformed to a form in which the portions which vanish on integration over angle can be readily separated. The results are

$$\mathbf{Q}=\frac{\boldsymbol{\lambda}}{4\pi^2\hbar}\left(\frac{KT}{\gamma}\right)^{3/2}\left[\frac{5KT}{3}I(x_0,\tfrac{3}{2})+\left(\epsilon+\frac{\lambda^2}{4\gamma}\right)I(x_0,\tfrac{1}{2})\right], \quad \text{(A10a)}$$

$$\mathbf{K}=\frac{\boldsymbol{\lambda}}{8\pi^2\gamma}\left(\frac{KT}{\gamma}\right)^{3/2}I(x_0,1/2), \quad \text{(A10b)}$$

in which

$$I(x_0,\nu)=\Gamma(\nu+1)\sum_{n=1}^{\infty}\frac{e^{-nx_0}}{n^{\nu+1}} \quad \text{(A11)}$$

and $KTx_0=\epsilon-\lambda^2/4$.

Equation (A10b) may be used to eliminate $\boldsymbol{\lambda}$ from the expression for $\mathbf{Q}$. In the limit in which ϵ and λ are both small, we obtain a simple result

$$\mathbf{Q}=C(KT/\hbar)\gamma\mathbf{K}, \quad \text{(A12)}$$

in which C is a numerical constant.

We have shown that in the absence of processes which do not conserve the total wave vector, there is a constant nonzero heat current in the presence of nonzero total crystal wave vector. A state with a nonvanishing $\mathbf{K}$, once established, could not be changed by collisions. Since no thermal gradient was assumed, this means that in the absence of umklapp processes the ideal no thermal resistivity. There is no conflict with the result of the analogous classical problem of the thermal conductivity of gas in a cylinder, since in that case a state of nonzero momentum is not established.
